Coulomb has furnished the most accurate and varied observations on the measure of human labour. A man will climb a stair, from 70 to 100 feet high, at the rate of 45 feet in a minute. Reckoning his weight at 155 lbs., the animal exertion for one minute is 6975, and would amount to 4,185,000 if continued for ten hours. But such exercise is too violent to be often repeated in the course of a day. A person may clamber up a rock 500 feet high, by a ladder-stair, in 20 minutes, and, consequently, at the rate of 25 feet each minute; his efforts are thus already impaired, and the performance reaches only 3875 in a minute. But, under the incumbrance of a load, the quantity of action is still more remarkably diminished. A porter, weighing 140 lbs., was found willing to climb a stair 40 feet high 266 times in a day; but he could carry up only 66 loads of firewood, each of them 163 lbs. weight. In the former case, his daily performance was very nearly 1,500,000; while, in the latter, it amounted only to 808,000. The quantity of permanent effect was hence only about 700,000, or scarcely half the labour exerted in mere climbing.

In the driving of piles, a load of 42 lbs., called the *ram*, is drawn up $3\frac{1}{2}$ feet high 20 times in a m

nute; but the work has been considered so fatiguing as to endure only three hours a day. This gives about 530,000 for the daily performance. Nearly the same result is obtained, by computing the quantity of water which, by means of a double bucket, a man drew up from a well. He lifted 36 lbs. 120 times in a day, from a depth of 120 feet, the total effect being 518,400. A skilful labourer working in a field with a large hoe, creates an effect equal to 728,000. When the agency of a winch is employed in turning a machine, the performance is still greater, amounting to 845,000. In all these instances, a certain weight is heaved up, but a much smaller effort is sufficient to transport a load horizontally.

A man could, in the space of a day, scarcely reach an altitude of two miles by climbing a stair; though he will easily walk over 30 miles on a smooth and level road. But he would, in the same time, carry 130 lbs. only to the fourth part of that distance, or 7½ miles. Assuming his own weight to be 140 lbs., the quantity of horizontal action would amount to 42,768,000, or 28 times the vertical performance; but the share of it in conveying the load is 20,961,780, or about 30 times what was spent in its elevation. The greatest advantage is obtained by reducing the burden to 102 lbs., the length of journey being augmented in a higher ratio. These results are apparently below the average of English labour, which is not only more vigorous, but in many cases quite overstrained. Moderate exertion of strength, joined to regularity and perseverance, would be more conducive to robust health and the comfortable duration of human life.

A porter in London is accustomed to carry a burden of 200 lbs. at the rate of three miles an hour. In the same metropolis, a couple of Irish chairmen continue, at the pace of four miles an hour, under a load of 300 lbs. These exertions are greatly inferior, however, to the labour performed by porters in Turkey, the Levant, and generally on the shores of the Mediterranean.

At Constantinople, an Albanian porter will carry 800 or 900 lbs. on his back, stooping forward, and assisting his steps by a sort of staff. At Marseilles, four porters commonly carry the immense load of nearly two tons, by means of soft hods passing over their heads, and resting on their shoulders, with the ends of poles, from which the goods are suspended. According to some experiments of the late Mr. Buchanan, the exertions of a man in working a pump, in turning a winch, in ringing a bell, and in rowing a boat, are as the numbers 100, 167, 227, and 248. But those efforts appear to have been continued for no great length of time.

The Greek seamen, in the Dardanelles, are esteemed more skilful and vigorous in the act of rowing, than those of any other nation. The Chinese, applying both their hands and their feet, are said to surpass all people in giving impulsion to boats by sculling. The several races of men differ materially in strength, but still greater diversity results from the constitution and habits of the individual. The European and his American descendants are, on the whole, more powerful than the other inhabitants of the globe; and man, reared in civilized society, is a more robust and vigorous animal than the savage. In the temperate climates, likewise, men are capable of much harder labour than under the influence of a burning sun. Coulomb remarks, that the French soldiers, employed on the fortifications of the Isle of Martinique, became soon exhausted, and were unable to perform half the work executed by them at home. The most violent and toilsome exertion of human labour is performed in Peru, by the carriers, or *cargueros,* who traverse the loftiest mountains, and clamber along the sides of the most tremendous precipices, with travellers seated on chairs strapped to their backs. In this manner, they convey loads of 12, 14, or even 18 stone; and possess such strength and action, as to be able to pursue their painful task eight or nine hours, for several successive days. These men are a vagabond race, consisting mostly of mulattoes, with a mixture of whites, who prefer a life of hardship and vicissitude to that of constant though moderate labour. When a man stands, he pulls with the greatest effect; but his power of traction is much enfeebled by the labour of travelling.

If v denote the number of miles which a person walks in an hour, the force which he exerts in dragging forward a load will be expressed nearly by $\frac{1}{5}(12-2v)^2$. Thus, when at rest, he pulls with a force of about 29 lbs. avoirdupois; but if he walks at the rate of two miles an hour, his power of traction is reduced to 14 lbs.; and if he quickens his pace to four miles an hour, he can draw only 3 lbs. There is, consequently, a certain velocity which procures the greatest effect, or when the product of the traction by the velocity becomes a maximum. This takes place when he proceeds at the rate of two miles an hour. The utmost exertion which a man, walking, might continue to make, in drawing up a weight by means of a pulley, would amount, therefore, in a minute, only to 2430; but if he applied his entire strength, without moving from the spot, he could produce an effect of 3675.

The labour of a horse in a day is commonly reckoned equal to that of five men; but then he works only eight hours, while a man easily continues his exertions for ten hours. Horses, likewise, display much greater force in carrying than in pulling; and yet an active walker will beat them on a long journey. Their power of traction seldom exceeds 144 pounds, but they are capable of carrying more than six times as much weight. The pack-horses in the West Riding of Yorkshire were accustomed to transport loads of 420 lbs. over a hilly country. But, in many parts of England, the mill-horses will carry the enormous burden of 910 lbs. to a short distance. With regard, however, to the ordinary power of draught, the formula $(12-v)^2$, where v denotes the velocity in miles an hour, will, perhaps, be found sufficiently near the truth. Thus a horse, beginning his pull with the force of 144 lbs., would draw 100 lbs. at a walk of two miles an hour, but only 64 lbs. when advancing at double that rate, and not more than 36 lbs. if he quickened his pace to six miles an hour. His greatest performance would hence be made with the velocity of four miles an hour. The accumulated effort in a minute will then amount to 22,528. The measure generally adopted for computing the power of steam-engines is much higher, the labour of a horse being reckoned sufficient to raise, every minute, to the elevation of one foot, the weight of 32,000 lbs. But this estimate is not only greatly exaggerated, but should be viewed as merely an arbitrary and conventional standard.

Wheel carriages enable horses, on level roads, to draw, at an average, loads about 15 times greater

than the power exerted. The carriers between Glasgow and Edinburgh transport, in a single-horse cart, weighing about 7 cwt., a load of a ton, and travel at the rate of 22 miles a day. At Paris, one horse, in a small cart, conveys along the streets half a cord of wood, weighing two tons; but three horses, yoked in a line, are able to drag 105 cwt. 5¼ lbs., or that of a heavy cart loaded with building stones. The Normandy carriers travel from 14 to 22 miles a day, with two-wheeled carts, weighing each 11 cwt., and loaded with 79 cwt., or nearly 4 tons of goods, drawn by a team of four horses. The French draught horses, thus harnessed to light carriages, are more efficient, perhaps, than the finer breeds of this country. They perform very nearly as much work as those in the single-horse carts used at Glasgow, and far greater than those fine yet heavy animals which drag the towering waggons in this country. The London draught horses, in the mere act of ascending from the wharfs, display a powerful effort, but they afterwards make little exertion, their force being mostly expended in transporting their own ponderous mass along.

Oxen, on account of their steady pull, are in many countries preferred for draught. They were formerly employed universally in the various labours of husbandry. The tenderness of their hoofs, unless shod, however, makes them unfit for pulling on paved roads, and they can work only with advantage in soft grounds. But they want all the pliancy and animation which are the favourite qualities of the horse. The patient drudgery of the ass renders him a serviceable companion of the poor. Much inferior in strength to the horse, he is maintained at far less cost. In America, an ass will carry about two hundred weight of coals or limestone twenty miles a day. But, in the warmer climates, he becomes a larger and finer animal, and trots or ambles briskly under a load of 150 pounds. The mule is still more powerful and hardy, being fitted equally for burden and draught.

In the hotter parts of Asia and Africa, the ponderous strength of the elephant has been long turned to the purposes of war. He is reckoned more powerful than six horses, but his consumption of food is proportionally great. The elephant carries a load of three or four thousand pounds; his ordinary pace is equal to that of a slow trot; he travels easily over forty or fifty miles in a day, and has been known to perform in that time a journey of one hundred and ten miles. His sagacity directs him to apply his strength according to the exigency of the occasion.

The camel is a most useful beast of burden in the arid pains of Arabia. The stronger ones carry a load of ten or twelve hundred weight, and the weaker ones transport six or seven hundred; they walk at the rate of two miles and a half in an hour, and march about thirty miles every day. The camel travels often eight or nine days without any fresh supply of water. When a caravan encamps in the evening, he is perhaps turned loose, for the space of an hour, to browze on the coarsest herbage, which serves him to ruminate during the rest of the night. In this manner, without making any other halt, he will perform a dreary and monotonous journey of two thousand miles.

Within the arctic circle, the rein-deer is a domesticated animal, not less valuable. He not only feeds and clothes the poor Laplander, but transports his master, with great swiftness, in a covered sledge, over the snowy and frozen tracts. The rein-deer subsists on the scanty vegetation of moss or lichens, and is docile, but not powerful. Two of them are required to draw a light sledge: so harnessed, they will run fifty or sixty miles on a stretch, and sometimes perform a journey of a hundred and twelve miles in the course of a day. But such exertions soon wear them out. A sort of dwarf camel was the only animal of burden possessed by the ancient Peruvians.

The lama is, indeed, peculiarly fitted for the lofty regions of the Andes. The strongest of them carry only from 150 to 200 pounds, but perform about fifteen miles a day over the roughest mountains. They generally continue this labour during five days, and are then allowed to halt two or three days before they renew their task. The paco is a similar animal, employed likewise in transporting heavy goods in that singular country; it is very stubborn, however, and carries only from fifty to seventy pounds. Even the exertions of goats have, in some parts of Europe, been turned to useful labour. They are made to tread in a wheel which draws water, or raises ore from the mine. Though a very light animal, the goat exerts much force, as he climbs at a high angle. Supposing this soaring creature, though only the fourth part of the weight of a man, to march as fast along an ascent of 40°, as he does over one of 18°, the sine of the former being double that of the latter,—it must perform half as much work.

Forceps, in *surgery*, &c.; a pair of scissors for cutting off, or dividing, the fleshy, membranous parts of the body, as occasion requires.

Fore; the distinguishing character of all that part of a ship's frame and machinery which lies near the stem.

Forecastle; a short deck placed in the fore part of a ship, above the upper deck; it is usually terminated, both before and behind, in vessels of war, by a breast-work, the foremost part forming the top of the beak head, and the hind part reaching to the after-part of the fore chains. — *Forecastle Men;* sailors stationed on the forecastle, who are generally experienced seamen.

Foreshortening, in *drawing* and *painting;* the art of representing figures of all sorts as they appear to the eye, in oblique positions. This art, which, in many instances, is very difficult, was known to the Greeks; and Pliny speaks particularly as to its being sucessfully practised by Parrhasius and Pausias. Among the moderns, Correggio must be allowed the palm for excellence in foreshortening. In painting ceilings, it is particularly important. In a celebrated picture of the body of Christ lying horizontally, the figure is so much foreshortened that the toes appear almost to touch the chin.

Forge; a small furnace, as that used by smiths, &c., or simply, a pair of bellows, the muzzle of which is directed upon a smooth area, on which coals are placed. This term is also used when speaking of a large furnace, in which iron ore, taken out of the mine, is melted down; or it is more properly applied to another kind of furnace, wherein the iron ore, melted down, and separated in a former furnace, and then cast into sows and pigs, is heated and fused over again, and beaten afterwards with large hammers, and thus rendered more soft, pure, ductile, and fit for use. The forge furnace consists of a hearth,

upon which a fire may be made, and urged by the action of a large pair of double bellows, the nozzle of which is inserted through a wall or parapet constructed for that purpose. Black-lead pots, or small furnaces of every desired form, may be placed, as occasions require, upon the hearth; and, the tube of the bellows being inserted into a hole in the bottom of the furnace, it becomes easy to raise the heat to almost any degree required.

Forestalling is the buying or bargaining for any corn, cattle, or other merchandise, by the way, before it comes to any market or fair to be sold, or as it comes from beyond the seas, or otherwise, towards any port or creek, to sell the same again at a higher price. At the common law, all endeavours to enhance the price of merchandise, and all practices which have a tendency thereto, whether by spreading false rumours, or by purchasing things in a market before the accustomed hour, or by buying and selling again the same thing in the same market, or by such devices, are criminal, and punishable by fine and imprisonment.

Forlorn Hope, in the *military art*, signifies men detached from several regiments, or otherwise appointed, to make the first attack in the day of battle, or, at a siege, to storm the counterscrap, mount the breach, or the like. They are so called from the great danger they are unavoidably exposed to.

Form, Printer's; an assemblage of letters, words, and lines, disposed into pages by the compositor, and from which the printed sheets are taken.

Formic Acid; thus named from having been discovered first in the expressed liquor of ants; at present it is procured from the application of a gentle heat to a mixture of tartaric acid, water, and the protoxide of manganese. The tartaric acid is converted into water, carbonic acid, and formic acid. This acid has a very sour taste, and continues liquid at very low temperatures. Its specific gravity is 1.1068 at 68° Fahr. M. C. G. Gmelin has prepared formic acid from cane sugar, sugar of milk, starch, wood, the root of the *althæa*, mucic acid, &c., by distilling those bodies with dilute sulphuric acid and peroxide of manganese; but the formic acid thus obtained is always impure. He has, however, obtained it in a high state of purity, by distilling alcohol with sulphuric acid and oxide of manganese. But, to prevent the formation of ether, dilute alcohol must always be employed; common spirits of wine is the most convenient. Concentrated alcohol produces not only sulphuric ether, but also formic ether. The fibrin of the blood furnishes a very impure formic acid. According to Berzelius, the formiate of lead consists of 4.696 acid and 14 oxide of lead; and the ultimate constituents of the dry acid are hydrogen 2.84, carbon 32.40, oxygen 64.76.

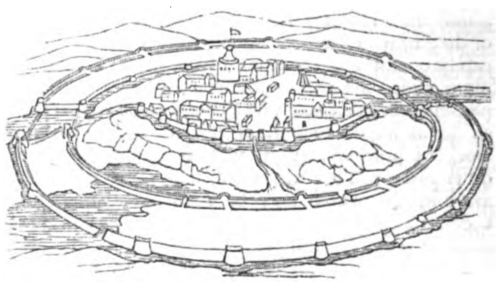
Fort; a small fortified place, surrounded with a ditch, rampart, and parapet, for the purpose of defending a pass, river, road, harbour, &c. Forts are made of different forms and extent, according to the exigencies of the case.

Forte. See Piano.

Fortification, as a science, had no place in the military history of ancient times. The details furnished in Scripture prove incontestibly, that even the circumvallations used by the Jewish people were inadequate to the purposes of security and duration. In fact, the events that shone conspicuous in those times were, with very few exceptions, pitched battles in the open plain, or ambuscades. Nor do we find in the more recent histories of Rome, of Greece, or of Asia, much to support the opinion of the ancients having a knowledge of fortification. The few places that made any resistance appear to have been principally maintained by the personal prowess of their defenders. Their walls were, indeed, sometimes of great extent, as we see in the instance of Troy; which, existing in eighteenth century, would probably capitulate at the first summons.

It was not to be expected, where the powers of demolition were insignificant, the means of resistance would be extended beyond the quantum absolutely necessary. The catapulta, the battering-ram, the tower, and such devices, were opposed by heavy masses of stone, or of other adequate materials, on which the besieged mounted to repel the assault. The various contrivances by which those machines received additional vigour, and the necessity that arose for opposing to their progress more resistance than could be accumulated immediately in their front (of the tower in particular), first give rise to the introduction of projections from the even line of the wall, whereby the besiegers could be annoyed laterally, as well as immediately front to front.

Still the engineer confined himself to small projections, generally semicircular, which, for the most part, appear to have been added to the old walls, impending like our modern balcony windows. In the sequel, these towers were built the same as the other parts of the circumvallation, and, like the modern bastion, rested on the firm ground. It however seems doubtful, whether the former mode was not the best, considering every circumstance attendant upon the ancient mode of assault, and the nature of their weapons.



The above view will serve to furnish the reader with some notion of the earliest state of methodical fortification. The great object seems to have been, by double and sometimes triple lines of walls to increase the means of resistance, by protracting the advance of the enemy.

The invention of gunpowder does not appear to have led to any important change for several years; nor indeed until heavy artillery formed a part of the assailants' means, as may be proved by an examination of the castles and towns still remaining. Such were the solidity and hardness of many ancient buildings, that the stone shots, originally used, produced a very slight effect; nor was it until iron balls were brought into use, that the powers of cannon were in any measure ascertained.

That point being gained, the whole system of defence was necessarily made to conform to the destructive engines which were now added to the common

practice of assault. The sword, buckler, lance, dart, javelin, sling, bow and arrow, lost their wonted estimation, and, dwindling into insignificance on the great scale, were reserved for individual contest, or for the lesser purposes of desultory warfare. The great object was to construct such stupendous bulwarks as might not only oppose the newly devised missiles, but, at the same time, support similar means of destroying the besieging army. Hence arose the formation of ramparts, and gradually, the necessity for deep ditches, and various outworks; by which considerable delay and difficulty might be created.

The fortifications of the fifteenth century, although to a certain extent new modelled, and made conformable to the necessity imposed by the invention and use of cannon, nevertheless did not display any ingenuity in regard to mutual defence. That great principle was little understood, and the minutiæ of the science remained, for a long time, miserably defective. Men of genius, at length, in part remedied the errors of the old school, and opened the way for that exactness of proportion, and for that systematic arrangement, which characterizes the works of modern times. The impregnable fortresses to be seen in various parts of Europe, cannot fail to transmit the names of their several engineers to posterity.

The immense armies now constantly brought into the field, and the heavy trains of artillery by which they are, in almost all cases, accompained, occasion not only an adequate preparation for resistance, but the necessity for establishing lines of communication, of depôts, &c., all of which must be on the best construction, for defence, containing safe lodgment for a sufficient garrison, together with ample and secure magazines for provisions and stores. Hence the province of the engineer becomes peculiarly important; it comprises various branches of information, and requires that readiness of computation, of discernment, and of appropriate resourse, which rarely combine in the same individual. The merely planning in the closet, and the laying down on the proper scite such defences as may perhaps be void of fault, so far as relates to mutual support, and to the great work of procrastination, will avail nothing, if the other essentials are neglected; and even when they are not, the whole may be rendered abortive, and become contemptible, merely from a want of judgment in point of locality.

Fortification is generally considered under two heads; *natural* and *artificial*. The former relates entirely to those situations which, being either completely inaccessible, or nearly so, require but few additions, and demand only such guards as may prevent surprise. For want of that precaution, some posts have been taken, which no army, however numerous and well provided, could have forced to a capitulation. Perhaps, of all the instances that could be adduced in regard to so fortunate a position as should defy every thing short of continued bombardment, the fortress of Ootradroog, situated in the dominions of the late Tippoo Saib, sultan of Mysore, may be justly considered as the most worthy of being cited. It stands on a plain, no hill or eminence of any importance being within several miles. It is, in fact, insulated, and consists of a solid rock, rising, on an average, about eight hundred feet above the adjacent level; its sides are nearly perpendicular throughout its whole circumference, which measures nearly a mile. The ascent to it is by stone steps, intermixed with occasional breaks for temporary ladders, the whole of which could be destroyed by the fall of a few large stones, always kept on the parapet for that purpose. Indeed, the interior is lined with such, they being admirably suited to the defence of so peculiar a station. There is no want of cannon on the works, which are ample, and were formed under the direction of a French engineer; they have plenty of water; ample stores were kept in immense excavations; and the most secure lodgment for a numerous garrison. Yet, as soon as the fall of Bangalore was ascertained, this important and almost impregnable fortress, to which, perhaps, there exists not a counterpart, surrendered to two battalions of Bengal sepoys.

It would be impossible to afford any instructions regarding those works which may be conjoined to natural defences, so as to render the whole complete: such must depend entirely on local circumstances, of which the skilful engineer will not fail to take advantage.

The term *artificial fortification* applies to every kind of defence, whether regular or irregular, pure or mixed; and has been divided by the most celebrated engineers into two distinct kinds, viz. *offensive* and *defensive*. The former relates principally to the various works used in attacks and sieges; the latter appertains to the more general purpose of securing towns, forming depôts, commanding important situations, defiles, &c., protecting harbours, and, in general, tending more to self-preservation, and to control, than to the annoyance of others, or to the extension of dominion.

This important science is again sub-divided into the *permanent* and the *temporary*: the former being with the view to endure the test of ages, while the latter is confined principally to operations in the field; and such works are, for the most part abandoned so soon as the occasion for their construction may have subsided.

Defensive fortification consists of three systems, each of which has its particular uses:

1. That which is usually adopted in the construction of works having four or five sides, or citadels, various small, or detached posts, horn-works, crown-works, &c., where the exterior of the defences, that is, between the salient angles of the two bastions, does not exceed 350 yards.

2. The next, which is of general use, and forms a very considerable portion of all regular fortifications, whose exterior sides of defence may be from 350 to about 400 yards.

3. The great, which is principally used where the exterior of the defences measures more than 380, and as far as 500 yards, or perhaps rather more; it is obvious, that very extensive fronts, even in a hexagon, or figure of six sides, would inclose an immense area; consequently would require a moderate army to man the defences. Hence we generally find this system composing only part of the works; such as are on the borders of a lake, or along the bank of a river; while the other sides are composed of the second, or mean system.

Such are the leading features and application of the three systems, as settled by the celebrated Vauban, and adopted by the most distinguished professors of our own time. Occasional deviations have, however, been made in several instances, with the approbation of military men; but, for the most part, such have

been with the view of conforming to local necessity, and of effecting a saving, either of materials, where they are scarce, or to disbursement, where that was an object.

We now come to the description of the several defences, as regulated by Vauban, and others of acknowledged military skill.

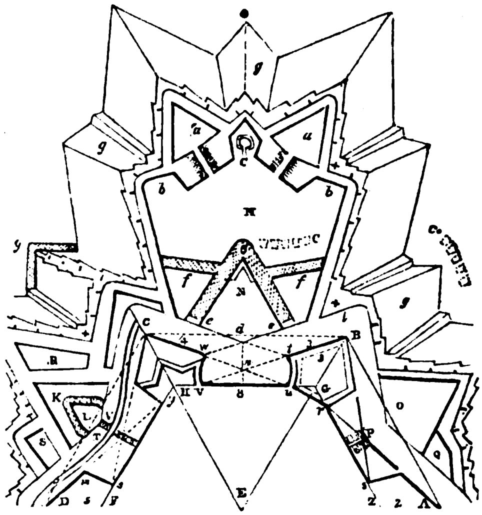
Fortifications may be considered as regular, when the inclosed area is of such a form as can be inscribed in some regular figure; such as a triangle, a rectangle, a circle, or an ellipsis; observing that such figure should, to a certain extent, suit itself to the town, &c., it is intended to protect.

It is usual to divide the perimeter, or whole outline of the figure, when it is either of the two latter forms, into as many faces, or portions, as may admit of suitable defences in either of the three systems already detailed. The number of faces must be regulated as well by the form, as by the extent of the figure. Small circles may be divided into five or six faces; moderately extensive ovals may have six also, while the more extensive circles and ovals will require an additional face or more, in order to reduce the exterior lines of defence within due bounds; so that every part of each face may be within musket-shot of those parts whereby it is flanked, or defended. Whenever this fundamental principle is disregarded, the plan will be proportionably weaker, according to the undue prolongation of the faces, and the consequent deficiency of mutual support.

The several fronts of a fortification may be all dissimilar, both in their proportions and in their extent; as also in the number and construction of their several outworks; yet the whole cannot be termed irregular. Thus the two ends of a long oval may be constructed on the second, or *mean* system; while each of the two long sides may be upon the third, or *great* system. One end may have a horn-work; the other a crown-work; the lateral faces being strengthened with ravelins, lunettes, tenailles, or other works. All these are evidently members of a perfect whole, and, when duly combined, according to the rules of art, form a complete and regular defence, founded on approved systems. Bergen-op-zoom affords one of the most striking instances on record of a purely artificial fortification; and as we have adduced one instance of a natural fortification in which but little of art was needed, this will form a valuable contrast. The fortification to which we have alluded is in reality a great earth work. It is almost level with the surrounding country, and resembles the engraving in the next column; but its masonry is protected by masses of earth, which deadens and destroys the effect of the balls.

When the number of faces has been adjusted and laid down, it is proper to decide whether the works are to be planned outwards, or inwards, from the line laid down. In the former case much space is gained by keeping all clear within that line, which, by this means, becomes the interior side: in the latter instance the line becomes the exterior side, all the works being raised within it, which considerably diminishes the area within them.

It is to be remembered, that in laying down the plan of a fortification, the several lines, describing the outer part of each rampart, exhibit the situation of a semicircular projection of masonry, called the cordon, which is, with few exceptions, made at the top of their respective facings of stone, brick, &c., called revetments. The line thus following the direction of the cordon, as it proceeds along the works, is called the principal.



A reference to the above engraving will illustrate the foregoing description. The half of a hexagon, or polygon of six equal sides, is selected, as being the most appropriate to this occasion. The line A D is the diameter of the circle; which circle having been divided into six equal parts, each equal to the radius, or semidiameter, A E, or E D, gives the faces formed by the passage of the rays B E and C E, through the points of equal division, B and C. Let us suppose the fortification to proceed inwards: in such case the lines A B, B C, C D, will be termed exterior sides, and all the principal will be formed within them; whereas, had it been intended to cover more ground, and to keep the whole of the area contained within the lines A B, B C, C D, and D C, clear, the principal would have been projected outwards, and the lines A B, B C, C D, would then have been termed the interior side. The former mode is in use when the exterior of the defences is first marked out, and has its separate mode of formation; and the latter is adopted where the interior of the works is established by any pre-existing circumstances, such as fortifying an old town, &c.; and proceeds on a suitable plan of projection. The two modes correspond perfectly, giving the same angles and proportions; the former on a diminished, the latter on an extended scale.

The interior lines, F G, G H, H I, form parallel faces with those on the exterior lines A B, B C, C D. If it were required to fortify outwards, they would be the bases of their several defences respectively, and the measurements would be taken from them, in lieu of from the exterior line. We shall proceed according to the latter mode, it being the most common and the most familiar.

To fortify inwards from an exterior line.—Let the exterior line B C be 180 toises (each toise being one fathom, or six feet); bisect it in *d*, and draw the perpendicular *d* 8, equal to one-sixth of the exterior line B C, namely, thirty toises. Now from B draw the line B *v*, passing through the point *n*; and from C draw the line C *u*, intersecting B *v* in *n*. Set off

fifty toises from the points B and C, on their respective lines, which are called the lines of defence, giving B *t* and C *w* for the faces of the two bastions. With the opening *t w*, measure *t v*, and *w u*, on the lines of defence, to determine their proper lengths, so as to give *u v* for the length and position of the curtain; next draw the lines *t v*, and *w u*, either curved or straight, for the flanks of the bastions. If they are to be curved, which are generally preferred, the points *t* and *w* will be the centres of equal circles, whereof the two flanks will be equal segments.

Proceed in the same manner with the other two fronts, A B and C D; you will thus complete two bastions, 3 and 4, and the halves of two more, 2 and 5. Next measure off fifteen toises, and draw something less than quadrants, or quarters of circles, from the points B and C; the centres of those quadrants being exactly opposite thereto, place your scale so that you may draw lines from the ends of the quadrants towards the shoulders of the bastions, but draw no farther than suffices to touch upon the perpendicular of thirty toises; thus your scale would give the direction *l w*, but your line would stop a little below *d*. This being done in both directions, and throughout the three faces, will give the width of the ditch, and the interior lines, or re-entering angles of the ravelins O, N, K. The body of the ravelin is formed by measuring ten toises on the face of each bastion, setting off from the shoulders *t w* towards the salient or projecting angles (there called flanked angles) B and C. An opening of the compasses equal to *u w* (or to *t v*), with the ten toises included, will give the distance of the salient angle, *o*, of the ravelin N, from the centre, 8, of the curtain *u v*. The sides, or faces, of the ravelin are determined by lines drawn from the salient angle to those points, on the faces of the bastions 3 and 4, already set off at ten toises each from their respective shoulders, *t* and *w*.

It should have been stated that all angles projecting outward from the body of the place, are called salient angles: for instance, *s*, B, *t*, of bastion 3, and *e*, *o*, *e*, of the ravelin N; while such angles as point inwards, towards the body of the place, are designated re-entering angles; such as *t*, *u*, *w*, on the lines of defence of the centre face. When an angle re-enters at such a position in the outworks that its apex, or point, cannot be seen, and consequently cannot be defended from the body of the place, it is called a dead angle. Such cannot easily take place where the smallest attention is paid to the most ordinary rules, but, wherever found, should be exploded from the defences, either by cutting off a large part of the pinch, or narrowest part, and substituting a curtain, or by new-modelling the defences in that part. It may be proper to observe, in this place, that works intended for mutual defence should never exceed an angle of 120°, nor be less than 60°. The medium, or 90°, which forms a right angle, generally considered, is indisputably the best for the above purposes. Where batteries stand at such an opening that their direct fire (that is, immediately to their own front) is parallel with the front of the part they flank, it is called a razant, or grazing fire; but when the angle is less than 90°, so that the direct fire would strike upon the face of the work to be defended, it is termed fishant: both have their uses, but the latter is rarely adopted, except from necessity, because a direct fire, at right angles, may be made to plonge, by giving the cannon an inclination more parallel with the side of the embrasure, which, being angular, allows a deviation of many degrees from the direct fire.

When two lines form a very acute angle with each other, they no longer are defences; for, in case the enemy should carry either of them, he would be able to work its battery against the other line; and though the fire would be plonging, and that too at a great disadvantage, yet, as many shots would light within the embrasures, the parapet would speedily be destroyed. The revetment, or masonry, in the front of the line so plonged, would not be much hurt, as it would turn off the shots.

Before we proceed farther, it is expedient that the reader should examine the line of the principal work, following along A, *o*, S, *r*, *s*, B, *t*, *u*, *v*, *w*, C, *b*, *y*, *s*, *m*, D, in all which he will perceive that every part is made to flank some other. The ravelins O, N, K, will be found to give great security to their several curtains, S, *r*, *u*, *v*, and *y s*; while at the same time they would enfilade whatever approaches might be made towards the salient angles of the bastions. In examining these circumstances, all the other outworks must be exempted from consideration: our view must be confined to the manner in which the gates in the curtains are protected; the flanks of the bastions concealed from every part but the line of their direct fire; and the spaces opposite the salient angles subjected to a heavy cross fire. The ravelins themselves stand at too wide an angle to absolutely flank each other, but they are capable of scouring the glacis reciprocally, and would, as before remarked, subject the besieger to a dangerous enfilade, or flanking fire, were he to proceed without due attention to their obnoxious positions. In works of more sides, where the angles of the bastions are necessarily more obtuse, the ravelins are thrown more towards a right angle with each other, and afford mutual support, even in cases of assault.

The communications with the ravelins are effected by the aid of bridges, when wet ditches are in question, as may be seen in the third face, *y s*, where the bridge V is carried over from the curtain to the counterscarp, or outer face of the ditch, so as to afford access to the ravelin K, in which is the intrenched redoubt L. The double lines, T, represent a channel of about fourteen feet broad, and about six or seven feet deep, made in all ditches that are at any time filled with water. These channels are called cunettes, or cuvettes; they are usually lined with masonry, and kept full, so as to prevent surprise: when the water is allowed to fill the whole ditch, which should generally be to the depth of nine or ten feet, or at all events so as not to be fordable, the cunette proves a formidable obstacle.

The bridges have barriers at their outer ends, and towards their inner ends generally a drawbridge, besides one that lifts immediately under the gateway, to which it gives additional strength. The very small compass allowed for the exhibiting of such figures as are indispensably necessary towards the right understanding of the subject, absolutely precludes the possibility of showing the dimensions of the ramparts, &c., and of necessity occasions the omission of many particulars in our engraving. In the common mode of building ramparts, with a revetment of masonry, the berm should be at least ten or twelve feet; and, where only turf facing is used, or that the soil with

which the rampart is filled, between the outer and inner faces of masonry, is of a loose nature, the berm should then be full twenty feet broad. The bulk of the rampart should, however, be considered; also whether it be much exposed or not; for on these points much will depend as to the probable quantity of battered rubbish to be sustained. There used to be a work, called the fausse-bray, carried all round the principal and the edge of the berm; its intention was to defend the ditch, and its fire was indeed highly destructive; but the facility with which it could be enfiladed (for it was necessarily low) evinced its inutility in general: the immense number of splinters falling from the rampart, immediately above, was another formidable objection. The fausse-braye is, therefore, out of repute; though in some fortifications a substantial parapet supplies its place, generally of masonry, more for the purpose of stopping the rubbish of a battered rampart than for that of sheltering troops. Perhaps the strong hedge adopted in many instances may be preferable: to say the least, it is far cheaper, and almost as useful.

The first drawbridge generally connects with the body of the bridge passing over the ditch, and is drawn up by persons standing on the brink; while that drawbridge, which rises close up against the gate, is so contrived as to bury itself, for at least its own thickness, into the masonry; while its edges are secured from the grazing of shots, ranging against the wall, and the possibility of wrenching the timber out of its place is sufficiently obviated. The gates usually close in the ordinary way; and over them a *portcullis* is sometimes suspended horizontally, its hinges being close behind the gates when shut. This immense machine resembles a very large harrow, and lets down, much like the ports of a ship, until it hangs vertically, close at the back of the gates, and, being secured with long iron stays, beams of wood, passing like window-bars into the wall, and other devices, it proves adequate to the repulsion of even a common sized petard. Some places have a succession of such gates and portcullises, one behind the other, which, added to the casemates being lined with defenders, renders it almost impossible to force these passages. When matters are driven to extremity, owing to the ravelin being possessed by the enemy, and by the defences on the curtain and flanks being raised, the gateways are filled up with rubbish, either loose or in bags, &c., so that they are no longer passable.

The unguarded point opposite the angle B, of bastion 3, is left purposely to show how easily a besieging army would effect a breach at that angle, provided no additional outworks were supplied; for, as yet, we are to consider the fortress to consist only of the principal and the ravelins. A suitable train of battering cannon brought to act upon the point B, while other batteries were employed to silence the faces of the adjacent ravelins O and N, would, in a very few days, effect a breach, and give the besiegers a command of the ditch, by establishing themselves in a lodgment on the crest of the glacis *g*, at the salient point Q; whence they would batter the flanks *o* S, and *w v*. Then, as nothing could oppose their passage over the ditch, which if wet would be passed by sap (that is to say, by filling up with fascines, &c.), the angle B would be carried by storm; for the matter would obviously rest on the numbers and on the personal prowess of the contending forces. The issue of such affairs have been so various, that it would be presumption to say the besiegers must succeed; but if the breach be practicable, and the internal state of the bastion as seen at No. 3, even though there should be an intrenchment of the gorge, from *r* to *u*, the chances would be in their favour after the breach was gained. This mode of defence is perhaps the best in hollow bastions (that is, in such as are not solid, but have deep areas within them level with the streets of the town, &c., called the terre-pleine); but in a solid bastion some defences should be internally constructed while the breach is making: of this some idea may be formed by the flanked angle in bastion 4, where a rampart and ditch are made, to force those who may ascend the breach to quit the bastion. The gorge may also be fortified as in bastion 3, whereby much time may be gained; a matter often of the utmost importance, either from expectation of succours, or to favour the evacuation of the fortress altogether.

In bastions No. 3 and 4, the flanks *t u*, and *w v*, are not only curved, but they are double, presenting of course two tiers of cannon, of which the upper stand on the bastion, while the lower are just below the level of the berm, whereof they constitute a part, and cannot be discovered beyond the crest of the glacis. These latter, therefore, cannot be battered from the approaches in the early stages of a siege; they lay, as it were perdue, in reserve for the defence of the ditch. There are two little semicircular projections at *t* and *w*, called orillons; these serve not only to cover the flanks *t u* and *w v* from enfilade, but each mounts a gun which cannot be perceived until half way over the bridge, and which serves to defend the gate when assaulted, as well as to take the assailants in flank and partly in reverse (i. e. from behind) as they advance to the attack. They are especially useful when a tenaille, as seen at P, is constructed in the dry ditch before the curtain S *r*; for when those who were placed in the tenailles which command the interior of the ravelin O, and of the redoubt Q, may be attacked in flank, and be obliged to retreat into the principal along the caponnaire P Δ, these guns pour in grape along the interior of the tenaille, when it is in the hands of the enemy, and enfilade so as to cause its abandonment.

The caponnaire is a passage made between two parapets, each having a long talus, or slope, outwards, as expressed by the small lines diverging from the path. It is commanded by (that is to say, open to the fire of) the flanks *o* S, and *s r*, and the centre of the curtain S *r*.

Having established, by this exposition, the absolute necessity for adding exteriorly to the defence of the principal, we shall now proceed to give a general insight into the various modes of constructing the other outworks; all being so designated which do not come within the principal, or body of the place. The reader should understand that every outwork, as it is placed more distant from the principal, must have a less elevation from the terre-pleine, or level of the area, on which the walls of the principal are founded. Thus we find, that a line drawn from the foot of the glacis *g*, at ⊕, opposite to the flanked angle of the bastion C, in the horn-work M, carried through the centre all the way up to *e*, which is the centre of the polygon, should graze the crests or inner summits of all the parapets standing in that line: this is called the defilement of the ramparts. By such a construction, it must be obvious that every work

added is a screen to, but is commanded by, that within it: thus, the bastion C, in the crown-work M, is a screen to the ravelin N, and that again to the curtain *u v*; while the intrenchments *f f* correspond in height with the flanks of the horn-work, so as to be under the command of the ravelin though they command all that portion of M which is in their front; and would continue to do so until the besiegers should construct batteries in the gorges of the bastions *b*, C *b*, or elsewhere, and render *f f* untenable.

The angle C, of bastion 4, is covered by the counterguard 7, which not only has that effect, but protects the adjacent tenaillon R, and can plonge upon the adjoining flank of the crown-work M. As a still farther covering to the bastion 4, a fleche, 9, is added, parallel to the counterguard, at the foot of its glacis, serving to render the attack more tedious and difficult, by compelling the besiegers to commence their approaches at a greater distance, where they are more generally subject to the fire of the bastions, &c., of the crown-work. The fleche, or arrow-head, should properly extend equally each way, having both faces alike, but that is not of any moment, and might have a second glacis; it is connected with the counterguard, or with the crown-work, or with the tenaillon, by means of a sortie, or winding passage cut through the glacis, or by a caponnier, as in the figure, intercepted with traverses, which will be duly explained when treating of the covert-way.

The ravelin K is defended within by the redoubt L, surrounded by a dry ditch. This redoubt should not be too high, because it would else serve to shelter the enemy in case they should succeed in silencing the faces of C *b*, and *m* D, of the corresponding bastions 4 and 5. The small work S is a lunette, which must be carried, or silenced, before the ravelin can be breached in that part; and, indeed, before any lodgment can be made opposite to the flanked angle D, of the bastion 5. The lunette must be lower than the ravelin, from which it properly derives its defilement, as will be hereafter explained.

The tenaillon is a very important conjunctive to the ravelin K; it, in fact, doubles its force on that side, and prolongs the battery of its other face; it flanks the counterguard, and its direct fire is a great protection to the demi-bastion *b*, on that side of the horn-work, as well as to the whole face of its ravelin *a*; it commands the fleche; and, being itself commanded by the ravelin K, and by the face C, and the counterguard, cannot be occupied by an enemy while any of these three works remain in force.

With respect to the construction of the counterguard, lunette, and tenaillon, they are not upon any exact scale in proportion to the principal, as the ravelin is; but, though not perfectly arbitrary, their formations depend on some general rules, which should invariably be had in view. The counterguard is always placed on the counterscarp, its front immediately behind the glacis, and its rear generally being a continuation of the revetment of the counterscarp, so that the passage lies along its terre-pleine, or battery. This kind of work may be of any extent; that is, it may proceed from ravelin to ravelin without interruption; or it may break off where it enters a lunette, a tenaillon, or a redoubt; or it may be only formed of two parallels equal in length with the faces of the bastion. On account of the number of men required for the defence of extensive outworks, counterguards are advantageously made hollow, having casemates covered with bomb-proofs, their parapets being solid masonry: their entrances, at each end, are secured by barriers and drawbridges; and their walls may, in places, be pierced with loop-holes, through which musketry may be discharged against assailants.

Casemates are likewise made on each side of posterns, or arched passages through the faces of ravelins; there are always drawbridges and barriers in such situations, as also at the cuts through the lunettes, &c., which lead through the covert-way to the esplanade, and are called sorties. The necessity for casemates must, generally, depend on the quantity and distance of outworks from the body of the place: it should be a rule never to place an outwork so that it could be cut off, without receiving aid from some sufficiently strong and contiguous part. Were this neglected, the enemy would not fail to surround such ill-judged detachments, and to a certainty carry them off during the night. Admitting this principle, the fleche 9 would be subject to the foregoing evil, if there were not a strong body of troops stationed in the counterguard, or the flank of the crown-work, from which detachments could be sent without delay.

Lunettes are generally constructed by producing their faces at about one-half the length of the ravelin, which they flank at right angles; their own flanks are drawn perpendicular to the face of the bastions which command them, generally falling about the middle of such face. Sometimes the lunette is separated, by a narrow fosse, from the body of the ravelin; in other instances, its face joins that of the ravelin, the fosse being arched over, and a battery placed on the arch, by which the ditch of the ravelin is scoured. The face of the lunette gives a direct fire towards the glacis, before the salient angle of the bastion 5.

Tenaillons are sometimes made on each side of a ravelin; and even beyond them a small detached ravelin, or a bonnet, is sometimes added. The rule for constructing a tenaillon is, to prolong the other face of the ravelin, thereby to make its front, and to determine the length of that front by a flank drawn perpendicular to the centre of the face of that bastion before which the tenaillon stands; as is seen in the tenaillon R, standing in front of the bastion 4, and covering the face of the ravelin K.

Redoubts standing in ravelins, being intended as a resort for the troops driven from the defences of its faces, and requiring great strength of defenders, should invariably be casemated throughout, in the most substantial manner; they may not only mount batteries on their ramparts, which should command those of the ravelins wherein they are placed, but they may be pierced below with abundance of loop-holes, and with embrasures for cannon, provided the ditch be of sufficient depth and width to prevent assault, and that the interior of the ravelin be, as it ought, perfectly level, and contain nothing to conceal the enemy: in each redoubt there should be a small expense magazine, and in every outwork one or more wells should be made, if practicable, of sufficient capacity to supply plenty of water.

Redoubts made to flank other works can have no fixed rule; they are generally placed to most advantage, and their fronts are always disposed towards those parts of the exterior which stand in need of

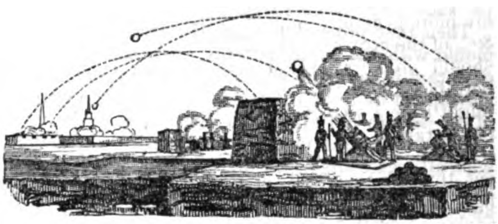
such support. In some places, as at Q, they are made more to cover a weak point, than with any immediate view to protracting the assault; the want of a redoubt, or some other work, on the other side of the bastion O, serves to prove the utility of that at Q; it being evident, that could an enemy's battery be placed anywhere about C *o*, that is, in a position to batter the bastion 3, the greater part of the defences of the principal would be subjected to mischief; and that, as the approaches should advance upon the glacis, the ravelins N and O would be in a measure cut off from all connection with the curtains S *r*, and *u v*. We suppose the crown-work M not to exist.

We now come to speak of the crown-work; it is a part of immense importance, and should be rendered as strong and efficient as possible. This kind of fortification is built on various accounts, viz., to occupy ground which, being left at the disposal of an enemy, might prove of considerable injury to the body of the place; to inclose buildings that could not be included within the principal; to defend a promontory, or a projection, covering a harbour; to prolong a line of works, and other causes which the locality may suggest. When, however, a piece of ground, which stands higher than could be commanded from the works of the principal, is to be occupied, a crown-work would be improper: in such case, a citadel is advantageously made on the superior ground; observing that, in lieu of a ravelin being at N, there would be a complete defensive face, appertaining to the citadel commanding the works of the fortress, which, instead of presenting defences along the centre B C, should rather lay open to the batteries of the citadel. These latter should command the whole interior of the polygon, and be well casemated throughout, for the safe lodgment of all the garrison, and for the safe keeping of provisions and stores, for six months at least. The instances on record of citadels holding out for a long time, should render their use more common, especially where the ground favours their command of all the other works.

Although we have, in tracing the defilement of the ramparts, from the point ⊕, to the centre of the polygon E, laid it down as a general rule, that the ascent of the works should assimilate to that line; yet, in such very spacious defences as crown-works sometimes are (for their area is occasionally equal to a third of that within the interior line of the polygon), some exceptions will take place; especially when the ravelins opposite to the faces of the crown-work are defended by still farther advanced outworks: then the angle of defilement would be so acute, from the terre-pleine, or horizon, as to cause scarce any difference between the heights of the ravelins, and of the bastions of the crown-work: a matter of obvious impropriety. Hence it is often necessary to give the ramparts of a crown-work rather more height than the line of defilement might allow; raising the ravelin and its intrenchments, and making cavaliers, as instanced in the bastion C, of the crown-work, on the solid bastions 3 and 4, so as to command the whole of the crown-work completely. A moineau, or flat bastion, of similar height with the cavaliers, may be made in the centre of the curtain *u v*, for the same purpose.

Cavaliers are of singular use on many other occasions, to which their form should be accommodated: that in the bastion *c* of the crown-work, is, from its shape, termed a horse-shoe; the flatness of its front is applicable to the situation it there holds, because it opposes a direct fire towards the point ⊕; but its circular tendency gives its front a bias towards the inner parts of the faces of the ravelins, while its flanks present a direct fire into the ravelins themselves, and give an oblique fire into the opposite ditches, whereby an assault of breaches in the salient angles of the demi-bastions *b b*, would become very hazardous.

We have already observed, that many outworks might be shown in addition to those given to the faces of the crown-work, such as lunettes, tenailles, tenaillons, fleches, advanced lunettes, redoubts, bonnets, &c.; but we apprehend the reader will, from the previous details, and the engraving to which they refer, be able to acquire a good general knowledge on the subject.



In the above engraving we give a view of the most destructive species of missile which has yet been brought to bear on regular fortifications. The mortar-battery, which is seen in operation, is usually placed near the rocket corps, and, when their labours are undisturbed, the most scientific fortifications are speedily demolished. An instance of this occurred at Antwerp, when the weight of the shells, and the destructive character of a newly-discovered rocket fire, in a few days accomplished what it would have taken months to effect by the ordinary means of offence.

Fossil. See Organic Remains.

Fothering; a peculiar method of stopping a leak in the bottom of a ship, while she is afloat, either at sea or at anchor, which is performed by fastening a sail at the four corners, letting it down under the ship's bottom, and then putting a quantity of chopped rope-yarn, oakum, wool, cotton, &c., between it and the ship's side.

Foundation, in *architecture*, is that part of a building which is under ground, and which Palladio makes as deep as one fourth part of the height of the whole building, unless there be cellars, when it may be somewhat lower.

Founder; an artist who casts metals in various forms, for different uses, as guns, bells, statues, &c.

Founder, in *sea language*. A ship is said to founder when, by an extraordinary leak, or by a great sea breaking in upon her, she is so filled with water, that she cannot be freed of it; so that she can neither veer nor steer, but lies like a log; and, not being able to swim along, will at last sink.

Foundery, or Foundry; the art of casting all sorts of metals into different forms. It likewise signifies the workshop, or smelting-house, in which these operations are performed. The sand used for casting is of a soft, yellowish, and clammy nature;

but it being necessary to strew charcoal-dust in the mould, it at length becomes of a black colour. This sand is worked over and over, on a board with a roller and a sort of knife; being placed over a trough to receive it, after it is by these means sufficiently prepared.

This done, they take a wooden board of a length and breadth proportional to the things to be cast, and putting a ledge round it they fill with sand, a little moistened to make it duly cohere. Then they take either wood or metal models of what they intend to cast, and, applying them to the mould, press them into the sand so as to leave their impression there. Along the middle of the mould is laid half a small brass cylinder, as the chief canal for the metal to run through, when melted, into the models or patterns; and from this chief canal are placed several others, which extend to each model or pattern placed in the frame. After this frame is finished, they take out the patterns, by first loosing them all round, that the sand may not give way.

Then they proceed to work the other half of the mould with the same patterns, in a similar frame, only that it has pins, which, entering into holes that correspond to it in the other, make the two cavities of the pattern fall exactly on each other.

The frame thus moulded is carried to the melter, who, after extending the canal of the counterpart, and adding the cross canals to the several models in both, and strewing dust over them, dries them in a kind of oven for that purpose.

Both parts of the mould being dry, they are joined together by means of the pins; and to prevent their giving way, by reason of the melted metal passing through the chief cylindrical canal, they are screwed or wedged in a sort of press.

While the moulds are thus preparing, the metal is fusing in a crucible, of a size proportionate to the quantity of metal intended to be cast.

Some of the founders' furnaces are like a smith's forge, others stand a few feet under ground, for the more easily and safely taking out a weighty pot of metal; which is done by means of circular tongs that grasp round the top of the crucible. When the metal is melted, the workman pours it through the chief canal of each mould, which conveys it to every distinct pattern.

When the moulds are cool, the frames are unscrewed, or unwedged, and the cast work taken out of the sand, which sand is worked over again for other castings.

Foundery of statues. The casting of statues depends on the due preparation of the pit, the core, the wax, the outer mould, the inferior furnace to melt off the wax, and the upper to fuse the metal. The pit is a hole dug in a dry place something deeper than the intended figure, and made according to the prominence of certain parts thereof. The inside of the pit is commonly lined with stone, or brick; or, when the figure is very large, they sometimes work on the ground, and raise a proper fence to resist the impulsion of the melted metal.

The inner mould, or core, is a rude mass to which is given the intended attitude and contours. Is is raised on an iron grate, strong enough to sustain it, and is strengthened within by several bars of iron. It is generally made either of potter's clay, mixed with hair and horse-dung, or of plaster of Paris mixed with brick-dust. The use of the core is to support the wax, the shell, and lessen the weight of the metal. The iron bars and the core are taken out of the brass figure through an aperture left in it for that purpose, which is soldered up afterwards. It is necessary to leave some of the iron bars of the core that contribute to the steadiness of the projecting part within the brass figure.

The wax is a representation of the intended statue. If it be a piece of sculpture, the wax should be all of the sculptor's own hand, who usually forms it on the core; though it may be modelled separately, in cavities moulded on a model, and afterwards arranged on the ribs of iron, filling the vacant space in the middle with liquid plaster and brick dust, whereby the inner core is proportioned as the sculptor carries on the wax.

When the wax, which is the intended thickness of the metal, is finished, they fill small waxen tubes perpendicular to it from top to bottom, to serve both as canals for the conveyance of the metal to all parts of the work, and as vent-holes to give a passage to the air, which would otherwise occasion great disorder when the hot metal came to encompass it.

The work being brought thus far, must be covered with its shell, which is a kind of crust laid over the wax, and which, being of a soft matter, easily receives the impression of every part, which is afterwards communicated to the metal upon its taking the place of the wax, between the shell and the mould. The matter of this outer mould is varied according as different layers are applied. The first is generally a composition of clay and old white crucibles well ground and sifted, and mixed up with water to the consistence of a colour fit for painting: accordingly they apply it with a pencil, laying it seven or eight times over, and letting it dry between whiles. For the second impression they add horse-dung and natural earth to the former composition. The third impression is only dung and earth. Lastly, the shell is finished by laying on several more impressions of this last matter, made very thick with the hand.

The shell, thus finished, is secured by several iron girts bound round it, at about half a foot distance from each other, and fastened at the bottom to the grate under the statue, and at top to a circle of iron where they all terminate.

If the statue be so large that it would not be easy to move the moulds with safety, they must be formed on the spot where it is to be cast. This is performed two ways: in the first, a square hole is dug under ground, much larger than the mould to be made therein, and its inside lined with walls of freestone or brick. At the bottom is made a hole of the same materials, with a kind of furnace, having its aperture outwards: in this a fire is made to dry the mould, and afterwards melt the wax. Over this furnace is placed the grate, and upon this the mould, &c., formed as above. Lastly, at one of the edges of the square pit is made another large furnace to melt the metal. In the other way, it is sufficient to work the mould above ground, but with the same precaution of a furnace and grate underneath. When finished, four walls are to be run around it, and a melting furnace prepared. For the rest, the method is the same in both. The mould being finished, and inclosed as described, whether under ground or above it, a moderate fire is lighted in the furnace under it, and the whole covered with planks, that the wax may melt gently down, and run out at pipes contrived for that

purpose, at the foot of the mould, which are afterwards exactly closed with earth, so soon as the wax is carried off. This done, the hole is filled up with bricks thrown in at random, and the fire in the furnace augmented till such time as both the bricks and mould become red hot. After this, the fire being extinguished and every thing cold again, they take out the bricks and fill up their places with earth, moistened and a little beaten, to the top of the mould, in order to make it the more firm and steady. These preparatory measures being duly taken, there remains nothing but to melt the metal, and run it into the mould. This is usually the office of a distinct workman. The furnace is commonly made in the form of an oven, with three apertures, one to put in the fuel, another for a vent, and a third to run the metal out at. From this last aperture, which is kept very close while the metal is in fusion, a small tube is laid, by which the metal is conveyed into a large earthen basin over the mould, into the bottom of which all the large branches of the jets or casts, which are to convey the metal into the various parts of the mould, are inserted.

These casts or jets are all terminated with plugs, which are kept close, that upon opening the furnace, the metal, which gushes out with violence, may not enter any of them till the basin be full enough of metal to run into them all at once: upon which occasion they pull out the plugs, which are long iron rods with a head at one end capable of filling the whole diameter of each tube. The whole of the furnace is opened with a long piece of iron fitted at the end of each pole, and the mould filled in an instant. This completes the work in relation to the casting part; the rest being the sculptor's or mason's business, who, taking the figure out of the mould and earth wherewith it is encompassed, saws off the jets with which it appears covered over, and repairs it with chisels, gravers, punches, &c.

Fount, or Font, in *typography;* a set of types, which includes running letters, large and small capitals, single letters, double letters, points, lines, numerals, &c.; as a fount of English, Pica, Bourgeois, &c. A fount of 100,000 characters, which is a common fount, would contain 5000 types of *a*, 3000 of *c*, 11,000 of *e*, 6000 of *i*, 3000 of *m*, and about 40 or 50 of *k*, *x*, and *z*. But this is only to be understood of the lower-case types, those of the upper case having other proportions, which we need not here enumerate.

Fountain, or Artificial Fountain, in *hydraulics;* a machine or contrivance by which water is violently spouted or darted up; called also a *jet d'eau*. There are various kinds of artificial fountains, but all formed by a pressure, of one sort or another, upon the water; viz. either the pressure or weight of a head of water, or the pressure arising from the spring and elasticity of the air, &c. When these are formed by the pressure of a head of water, or any other fluid of the same kind with the fountain or jet, then will this spout up nearly to the same height as that head, abating only a little for the resistance of the air, with that of the adjutage, &c., in the fluid rushing through; but, when the fountain is produced by any other force than the pressure of a column of the same fluid with itself, it will rise to such a height as is nearly equal to the altitude of a column of the same fluid, whose pressure is equal to the given force that produces the fountain.

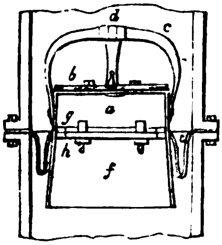
In Greece, every principal town had public fountains or conduits, some of which were of handsome design and of beautiful execution. In the city of Megara, in Achaia, there was a public fountain established by Theagenes, which was celebrated for its grandeur and magnificence. The *Pirene*, a fountain at Corinth, was encircled by an enclosure of white marble, which was sculptured into various grottoes, from which the water ran into a splendid basin of the same material. Another fountain in Corinth, which was called *Lerna*, was encircled by a beautiful portico, under which were seats for the public to sit upon during the extreme heats of summer, to enjoy the cool air from the falling waters. In the sacred wood of Æsculapius, at Epidaurus, there was a fountain that Pausanias cites as remarkable for the beauty of its decorations. At Messina there were also two elegant fountains, one called *Arsinoë*, and the other *Clepsydra*. Pausanias also alludes to several other fountains in various parts of Greece, celebrated for the grandeur and beauty of their architectural and sculptural decorations.

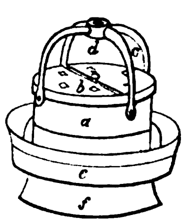
The ancient fondness for fountains still exists in Italy and the East. The French are celebrated for their fountains, but Italy, more particularly Rome, is still more so. The fountains of Paris and of the Tuileries, of the orangery at Versailles, at St. Cloud, and other places in the neighbourhood, are splendid structures. The principal and most admired fountains at or near Rome are those in front of St. Peter's, of the Villa Aldobrandini at Frascati, of the Termini, of Mount Janiculum, of the gardens of the Belvidere, in the Vatican, of the Villa Borghese, which has also in the audience chamber a splendid fountain of silver, five Roman palms in height, ornamented with superb vases and flowers; the fountains of Trevi, the three fountains of St. Paul, of the Acqua Acetosa, and many others described in the numerous works on that ancient city. Sir Henry Wotton describes, in his *Elements of Architecture*, a fountain by Michael Angelo, in the figure of a sturdy woman wringing a bundle of clothes, from whence the water issues that supplies the basin.

Fountain-Pump. This ingenious hydraulic machine is said to be the invention of Mr. Shalders. Bag-pumps on the same principle have, however, been used for many years. Mr. Shalders's pump has scarcely any friction, so that nearly the whole power of the person working the pump may be usefully employed in the elevation of water. Instead of being provided with a packed piston, moving up and down in a tube, the vacuum is formed by a leather chamber, which increases and diminishes in its dimensions according to the action of the pump lever. We give a wood-cut showing the general arrangement of its parts.

The pump cylinder is shown connected with its flange in the first figure. The bag and frame are raised by the stirrup *c d*, the valves being placed at *b*. In the external view of the piston, the cylinder to which the leather bag is attached is shown at *a*, and *c* represents that part of the leather by which it is attached to the pump-barrel. The bolts *g* and *h* show the mode by which the leather is held between the metallic flanges. The only inconvenience likely to result from working this pump will arise from the leather hardening when long out of use, which, in the summer season, would entirely destroy its usefulness. On ship-board, also, the same inconvenience would

be still more severely felt, as, in a long voyage, the pumps are sometimes but little resorted to, and on any sudden emergency it would not be practicable to new leather the bucket.





Fourteenth, in *music;* the octave, or replicate of the seventh; a distance comprehending thirteen diatonic intervals.

Fourth, in *music;* a distance comprising three diatonic intervals, or two tones and a half.

Fracture, in *surgery;* the separation of a bone by means of violence, into two or more fragments. A simple fracture is that where a bone is broken only in one part. A compound fracture is when two large bones, contiguous to each other, as the *ulna* and the *radius*, are both broken. A complicated fracture is that which is attended with a train of symptoms, as a wound or ulcer.

Fraction, in *arithmetic* and *algebra*, signifies a combination of numbers representing one or more parts of a unit or integer: thus four fifths is a fraction, formed by dividing a unit into five equal parts, and taking one part four times. Fractions are divided into *vulgar* and *decimal*. Vulgar fractions are expressed by two numbers with a line between them. The lower, the *denominator*, indicates into how many equal parts the unit is divided; and the number above the line, called the *numerator*, indicates how many of such parts are taken; as, in $\frac{7}{8}$, 8 is the denominator, 7 the numerator. Vulgar fractions have been divided, though not very accurately, into *proper, improper, simple, compound,* and *mixed,* viz:—A *proper fraction* is when the numerator is less than the denominator, as $\frac{3}{4}$, $\frac{3}{8}$, $\frac{7}{9}$, $\frac{9}{11}$, $\frac{101}{701}$, &c. An *improper fraction* is when the numerator is equal to or greater than the denominator, as $\frac{5}{5}$, $\frac{8}{4}$, $\frac{12}{12}$, $\frac{187}{8}$, &c. A *simple fraction* is that which consists of a single numerator and single denominator; and is either proper or improper, as $\frac{5}{7}$, $\frac{11}{7}$, $\frac{16}{81}$, &c. A *compound fraction* is a fraction consisting of two or more other fractions connected by the word *of;* thus $\frac{2}{3}$ of $\frac{3}{4}$, or $\frac{2}{3}$ of $\frac{7}{11}$ of $\frac{5}{8}$, &c., are compound fractions. A *complex fraction* is that whose numerator and denominator are both fractions; thus $\frac{\frac{3}{4}}{7\frac{1}{2}}$ is a complex fraction. These two distinctions, though frequently made by authors on arithmetic, are certainly improper, the former indicating an operation in multiplication, and the latter an operation in division. It is, therefore, improper to apply to them the denomination of *fractions*. An integer and fraction together is called a *mixed number;* that is, $7\frac{3}{4}$, $9\frac{1}{3}$, &c., are mixed numbers. The theory of vulgar fractions is one of the most important in algebra, but is rarely, we think, developed in a clear, simple, and easy manner in books on arithmetic. A correct understanding of them is of great importance for the proper prosecution of arithmetical and mathematical studies.—Decimal fractions include every fraction, the denominator of which is 10 or a power of it; as $\frac{6}{10}$, $\frac{7}{1000}$, &c.

Franc; a French silver coin, containing ten *decimes* and a hundred *centimes*.

Frankincense (called also *olibanum*, or simply *incense*) is a gum-resin, which distils from incisions made in the *boswellia thurifera*, a tree somewhat resembling the sumach, and belonging to the same natural family, inhabiting the mountains of India. It comes to us in semi-transparent, yellowish tears, or sometimes in masses, possesses a bitter and nauseous taste, and is capable of being pulverized. When chewed, it excites the saliva, and renders it white; and when burnt, it exhales a strong aromatic odour, on which account it was much employed in the ancient temples, and still continues to be used in Catholic churches. Formerly it was frequently administered medicinally, but myrrh and other similar articles have now taken its place. That which is brought from Arabia is more highly esteemed than the Indian.

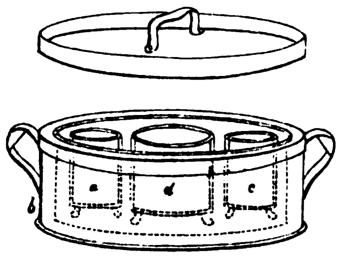
Freckles; small spots of a yellowish colour scattered over the face, neck, and hands. Freckles are either natural, or proceed accidentally from the jaundice, or the action of the sun upon the part. Heat, or a sudden change of the weather, will often cause the skin to appear of a darker colour than natural, and thereby produce what is called *tan, sunburn,* &c., which seem to differ only in degree, and usually disappear in winter. Persons of a fine complexion, and those whose hair is red, are the most subject to freckles, especially in those parts which they expose to the air.

The origin of freckles has been thus explained: in the spring, the skin, from the warm covering which the body has had in winter, and from various other causes, is peculiarly sensitive. The heat of the sunbeams now draws out drops of moisture, which do not dry as rapidly as in summer. These drops operate like a convex glass, to concentrate the rays, which are thus made to act powerfully on the *rete malpighii*, and the carbon which it contains is half acidified, and this substance, in this state, always has a dark colour. In the same manner arises the dark tint which the skin in general assumes in summer, and which fire communicates to artisans who labour constantly in its immediate vicinity. The only bad effect of freckles is, that they induce ladies to keep themselves shut up from the influences of the weather, or to apply injurious washes to the face to remove them.

Free Corps; a term used on the European continent for a corps which is organized to act merely till the end of the war, and consists of volunteers. It performs the service of light troops, and, as its losses are not heavily felt, is employed in all dangerous services, in harassing the enemy, &c.: on this account, more liberties are allowed to free corps than to regular troops. They are composed of persons of dubious characters, and there is always inconvenience, at the close of the war, in disbanding a numerous body of bold and active individuals, generally unfit for peaceful society. Napoleon employed none. Frederick the Great had some in his service, but, sensible of the danger of disbanding such desperadoes, at the close of the seven years' war, he, contrary to his promise, converted them into regular troops.

Freezing. The great sources of cold, and, as such, the production of ice by freezing, are rarefaction, evaporation, and chemical action. The operation of the first is scarcely felt in any but elastic fluids, as in those only can the volume be suddenly changed to any considerable extent. When a gas is rarefied, by removing pressure from it, its temperature always falls; and the more sudden the rarefaction is, so much greater is the cold produced. By allowing air, previously compressed, to expand suddenly, the temperature is reduced below 32°; and, by the condensed air being previously cooled, more intense cold is obtained.

The process of cooling by evaporation has been examined under Cold, and also the frigorific mixtures best fitted for freezing by chemical means. We now propose giving a diagram of a simple apparatus well fitted for carrying on the process of freezing, as well as that of keeping down the temperature of bodies already frozen.



This apparatus consists of an exterior and interior vessel of japanned iron, the interior vessel being one inch smaller than the inclosing case, *b*. In the interior case are placed detached vessels for containing the freezing mixtures.

When the apparatus is to be used with sulphate of soda and diluted sulphuric acid, it is advisable to prepare the acid the preceding day, in order that it may be of the same temperature as the surrounding air, when the experiment is to be performed. This being done, let two or three vessels, *a c d*, of about four ounces' capacity, be partly filled with diluted sulphuric acid, and placed in the middle of the internal vessel. They should then be surrounded by finely pulverized crystals of sulphate of soda, mixed with dilute acid, so as to fill the large internal vessel. The water or mercury should then be placed in the centre of the small vessels, the interstices being filled up with the sulphate of soda. The whole should then be covered up, and the process of freezing will speedily be accomplished.

Freezing Point denotes the point or degree of cold, shown by a mercurial thermometer, at which certain fluids begin to freeze, or, when frozen, at which they begin to thaw again. On Fahrenheit's thermometer this point is at + 32 for water, and at — 40 for quicksilver, these fluids freezing at those two points respectively. (See Thermometer.)

Freight is the consideration-money agreed to be paid for the use or hire of a ship, or, in a larger sense, the burden of such ship. The freight is most frequently determined for the whole voyage, without respect to time; sometimes it depends on time: in the former case it is either fixed at a certain sum for the whole cargo, or so much per ton, barrel, bulk, or other weight or measure, or so much per cent. on the value of the cargo. If a certain sum be agreed on for the freight of the ship, it must all be paid, although the ship, when measured, should prove smaller, unless the burden be warranted. If the ship be freighted for transporting cattle, at so much per head, and some of them die on the passage, freight is only due for such as are delivered alive; if for lading them, it is due for all put on board. When a whole ship is freighted, if the master suffer any goods besides those of the freight to be put on board, he is liable for damages. If the voyage be completed according to the agreement, without any accident, the master has a right to demand the freight before the delivery of the goods; but if such delivery is prevented by negligence, or accidents, the parties will be reciprocally responsible in the following manner: if the merchant should not load the ship within the time agreed on, the master may engage with another, and recover damages. If the merchant recal the ship after she is laden and sailed, he must pay the whole freight; but if he unload before the ship has actually sailed, he will in such case only be responsible for damages. If the merchant load goods which are not lawful to export, and the ship be prevented from proceeding on that account, he must nevertheless pay the freight. If the master be not ready to proceed on the voyage at the time stipulated, the merchant may load the whole or part of the cargo on board another ship, and recover damages; but any real casualties will release the master from all damages. If an embargo be laid on the ship before she sail, the charter-party is dissolved, and the merchant pays the expenses of loading and unloading; but if the embargo be only for a short limited time, the voyage shall be performed when it expires, and neither party is liable for damages. If the master sail to any other port than that agreed on, without necessity, he must sail to the port agreed on at his own expense, and is also liable for any damages in consequence thereof. If a ship be taken by the enemy, and retaken or ransomed, the charter-party continues in force. If the master transfer the goods from his own ship to another, without necessity, and they perish, he is responsible for the full value, and all charges; but if his own ship be in imminent danger, the goods may be put on board another ship, at the risk of the owner. If a ship be freighted out and home, and a sum agreed on for the whole voyage, nothing becomes due until the return of such ship. If the goods be damaged without fault of the ship or master, the owner is not obliged to receive them and pay the freight; but he must either receive or abandon the whole; he cannot receive those that are not damaged and reject the others. If the goods be damaged through the insufficiency of the ship, the master is liable for the same; but if it be owing to stress of weather, he is not accountable. If part of the goods be thrown overboard, or taken by the enemy, the part delivered pays freight. The master is accountable for all the goods received on board by himself and mariners, unless they perish by act of God, or the king's enemies. The master is not liable for leakage of liquors, nor accountable for contents of packages, unless packed in his presence.

Fresco Painting; that kind of painting which is executed with water-colours, upon a layer of fresh plaster, from which circumstance it derives its name. As great rapidity of execution is necessary to paint before the plaster becomes dry, cartoons are used for tracing the outlines of the figures, &c., and a small picture serves as a guide for the colours, if the cartoon does not indicate them. A great knowledge of colours and great skill in drawing are necessary for fresco painting, because there is no opportunity for

correcting: whatever the painter does is finished. The colours are mixed beforehand, and put on just as they are wanted; only in the dark parts a little retouching takes place. Fresco painting is one of the most durable kinds. It is pretended, that there are specimens of it extant of the time of Constantine the Great.

This art began to revive in the 16th century. The example of Michael Angelo and Raphael shows how worthy it is of the greatest artists. The painter cannot seduce the senses by soft tints and tender harmony of colours; he is, therefore, obliged to depend solely on form, character, and expression. If oil painting is better suited for nice expressions of the slightest emotions of the heart, fresco painting is the field which the true poet-painter will prefer. What can be more sublime than the Last Judgment of Michael Angelo, in the *Capella Sistina!* How rich and vast are Raphael's conceptions in the *Logyie Vaticano!* The Germans possess at present the most distinguished fresco painters, and Cornelius has established his fame by his grand fresco pictures in the *Glyptotheca* in Munich. Schnorr is also distinguished in this line, and the *Villa Massimi*, near Rome, is a fine monument of contemporary German art, as Overbeck, Schnorr, and Feith painted the three rooms in fresco. Fresco painting was long disregarded, when all noble and grand conceptions seemed to have fled from the art; and it is only in recent times that it has been taken up again, chiefly by the Germans.

Frets; certain short pieces of wire fixed on the finger-board of guitars, &c., at right angles to the strings, and which, as the strings are brought into contact with them by the pressure of the fingers, serve to vary and determine the pitch of the tones. The frets are always placed at such distances from each other, that the string which touches any particular fret is one semitone higher than if pressed on the next fret towards the head of the instrument, and one semitone lower than when brought into contact with the next fret towards the bridge. Formerly, these frets, or stops, consisted of strings tied round the neck of the instrument.

Friction; the act of rubbing two bodies together, or the resistance in machines caused by the motion of the different parts against each other. Friction arises from the roughness of the surface of the body moved on, and that of the moving body; for such surfaces consisting alternately of small eminences and cavities, these act against each other, and prevent the free motion that would ensue on a supposition of the two bodies being perfectly polished planes.

Ferguson found that the quantity of friction was always proportional to the weight of the rubbing body, and not to the quantity of surface: and that it increased with an increase of velocity, but was not proportional to the augmentation of celerity. He found also, that the friction of smooth soft wood, moving upon smooth soft wood, was equal to one third of the weight; of rough wood upon rough wood, one half of the weight; of soft wood upon hard, or hard upon soft, one fifth of the weight; of polished steel upon polished steel or pewter, one quarter of the weight; of polished steel upon copper, one fifth, and of polished steel upon brass, one sixth of the weight.

Coulomb made numerous experiments upon friction, and, by employing large bodies and ponderous weights, and conducting his experiments on a large scale, corrected several errors, which necessarily arose from the limited experiments of preceding writers. He brought to light many new and striking phenomena, and confirmed others, which were previously but partially established.

We cannot, in a work of this description, follow M. Coulomb through his numerous and varied experiments; all that can be expected will be a short abstract of the most interesting of his results; a few of which are as follows:—1. The friction of homogeneous bodies, or bodies of the same kind, moving upon each other, is generally supposed to be greater than that of heterogeneous bodies; but Coulomb showed that there are exceptions to this rule. 2. It was generally supposed that, in the case of wood, the friction is greatest when the bodies are drawn contrary to the course of their fibres; but Coulomb showed, that the friction in this case is sometimes the smallest. 3. The longer the rubbing surfaces remain in contact, the greater is their friction. 4. Friction is in general proportional to the force with which the rubbing surfaces are pressed together, and is commonly equal to between one half and one quarter of that force. 5. Friction is not generally increased by augmenting the rubbing surfaces. 6. Friction is not increased by an increase of velocity; at least it is not generally so; and, in some cases, even decreases with an increase of celerity. 7. The friction of cylinders, rolling upon a horizontal plane, is in the direct ratio of their weights, and in the inverse ratio of their diameters.

An easy method of experimenting on the friction of surfaces, is, to place a plank with its upper surface level, and on this a thin block of the matter to be tried, with a cord fixed to it, which block may be loaded with different weights; and a spring steelyard attached to the other end of the cord, to draw it along by, will show the force necessary to produce motion. It appears from experiments, that the friction of different combinations of matter differs very considerably, and that an immense quantity of power may be lost in a machine by using those substances for the rubbing parts which have great friction. In a combination where gun-metal moves against steel, the same weight may be moved with a force of 15½ pounds, which it would require 22 pounds to move when cast-iron moves against steel. The resistance called *friction* performs important offices in nature and in works of art. Friction destroys, but never generates motion.

D. Palcani made some interesting experiments on the means long known for obtaining fire by the friction of two pieces of wood. He gave to one of these rubbing pieces the form of a tablet; and to the other, that of a spindle, or cylinder: the result of these experiments will be sufficient to show, that, in the construction of machines and instruments, some attention should be paid to the wood destined to be exposed to mutual friction.

Cylinder.	Tablet.	Duration.	Effect.
Box-wood	Box	5 minutes	Sensible heat
Ditto	Poplar	Ditto	Ditto
Ditto	Oak	Ditto	Ditto
Ditto	Mulberry	3 minutes	Considerable heat and smoke
Ditto	Laurel	Ditto	Ditto
Laurel	Poplar	2 minutes	Ditto
Ditto	Ivy	Ditto	Ditto

Cylinder.	Tablet.	Duration.	Effect.
Ivy	Box	3 minutes	Considerable heat and smoke
Ditto	Walnut	Ditto	Ditto
Olive	Olive	Ditto	Ditto
Mulberry	Laurel	2 minutes	Considerable heat, smoke & blackness
Ash	Oak	5 minutes	Sensible heat
Ditto	Fir	Ditto	Ditto
Pear-tree	Oak	Ditto	Ditto
Cherry	Elm	Ditto	Ditto
Plumb	Apple-tree	Ditto	Ditto
Oak	Fir	Ditto	Ditto

By changing the experiment and rubbing a cylinder of one of the kinds of wood between two tablets of the other, a cylinder of poplar for example, between two tablets of mulberry-wood, the increased surfaces which were in contact with the air, produced a heat much more considerable, and almost the whole of the woods above enumerated took fire.

In large machines where there is much friction, heating may be prevented by continually directing a current of cold water on the rubbing surfaces; in common machines, carriages, &c., this is diminished by the use of an unctuous matter. Many instances are recorded, where, during the great heats of summer, carriages and other machines exposed to violent motion, have inflamed because care has not been taken to grease them: this was the occasion of a conflagration in the mills on the Surrey side of Blackfriar's Bridge, through which they were consumed. It is to be remarked that, if grease is permitted to harden upon rubbing surfaces, instead of lessening the friction, it increases it; and, as this covering is highly inflammable, it renders spontaneous inflammation more easy. In many cases, therefore, it is preferable to rub the machinery with soap, talc, plumbago, or some other such substance, which, without being oily, is unctuous to the touch.

Were there no friction, all bodies on the surface of the earth would be clashing against one another; rivers would dash with unbounded velocity, and we should see little besides collision and motion. At present, whenever a body acquires a great velocity, it soon loses it by friction against the surface of the earth; the friction of water against the surfaces it runs over soon reduces the rapid torrent to a gentle stream; the fury of the tempest is lessened by the friction of the air on the face of the earth; and the violence of the ocean is subdued by the attrition of its own waters. Its offices in works of art are equally important. Our garments owe their strength to friction; and the strength of ropes, sails, and various other things, depends on the same cause; for they are made of short fibres, pressed together by twisting; and this pressure causes a sufficient degree of friction to prevent the fibres sliding one upon another. Without friction, it would be impossible to make a rope of the fibres of hemp, or a sheet of the fibres of flax; neither could the short fibres of cotton have ever been made into such an infinite variety of forms as they have received from the hands of ingenious workmen. Wool also has been converted into a thousand textures for comfort or for luxury; and all these are constituted of fibres united by friction. In fine, if friction retards the motion of machines, and consumes a large quantity of moving power, we have a full compensation in the numerous and important benefits which it insures to us.

Friction, in *medicine* and *surgery;* the act of rubbing the surface of the body, whether with the hand only, with the flesh-brush, flannel, or other substances, or with oils, ointments, or other medicinal matters, with a view to the preservation of health, or to the removal of particular diseases. The wholesome effects of friction are well illustrated by the advantages of currying horses. Friction is an efficacious remedy in several conditions of disease; particularly in chronic rheumatisms of long standing; in muscular contractions, succeeding to rheumatism, &c., and connected often with effusions of lymph; in some states of paralysis; in certain indolent tumours, &c. In these cases, a variety of unguents and liniments is recommended; but the friction itself is the principal source of relief.

FRIEZE, in *architecture;* that part of the entablature of columns between the architrave and cornice. Anciently friezes were enriched with figures of animals; in modern times they are commonly ornamented by figures in bassi relievo.

FRIGATE, in *naval affairs;* a light vessel, now frequently prepared by cutting down larger ships of war.

FRONTAL, in *anatomy;* an epithet for what belongs to the forehead, as the *frontal bone*, and the *frontal sinus*.

FRONTALIS; the name of a muscle of the forehead, which serves to contract the eyebrows.

FRONTIS, OS; one of the bones of the skull, which joins the bones of the sinciput and temples, by the coronal suture.

FRONTIGNAC; a sweet muscatel wine, which is made at Frontignan, in Lower Languedoc, and is carried to Cette and Montpelier. There are two kinds, the red and the white. Epicures use it with some kinds of fish.

FROST is the name we give to that state of our atmosphere in which water is changed into ice. The degree of temperature at which this takes place, is called the *freezing point*. The cold air draws from water the portion of caloric which is necessary for its existence in a fluid state. The power of frost is immense; a freezing liquid will burst the strongest vessels in which it is enclosed. Organic bodies do not suffer so much from it, and many are entirely unhurt by it. Severe frosts are not so injurious to plants, after dry weather, as when they follow immediately after rain or a thaw. The cause of this probably is, that in damp weather, even in winter, the tender vessels of plants are filled with sap, which, expanding into ice at the time of the frost, breaks them, and thus injures their whole internal organization. From the same cause, the strongest oaks split in a severe frost; which is also dangerous, and sometimes fatal to men and animals. It appears wholly to destroy the irritability of the bodily frame, and to rob it of its internal heat. A person feels an irresistible inclination to sleep; he yields, though against his will, and, while lost in insensibility, his limbs begin to stiffen. If a man thus asleep be brought into a warm room, the sudden passage from cold to warmth causes his death; but if he be rubbed in the snow, he may often recover. The same is the case with regard to the frozen limbs of men and animals, which can only be saved by being gradually thawed, especially in snow.

Frost is also very injurious to certain kinds of food. All watery fruits are deprived by frost of their pleasant taste and their nourishing properties, and soon grow rotten after being thawed. Even meat, which appears to be preserved from tainting by the frost, corrupts soon after thawing. Liquids, as beer, for instance, lose their good taste. Violent winds always diminish the coldness of the air. Many fluids expand by frost, as water, which expands about one tenth part, for which reason ice floats in water; but others, again, contract, as quicksilver, and thence frozen quicksilver sinks in the fluid metal.

Frost, being produced by contact with the atmosphere, naturally proceeds from the external parts of bodies inwards: so, the longer a frost is continued, the thicker the ice becomes upon the water in ponds, and the deeper into the earth is the ground frozen. In about sixteen or seventeen days' frost, Mr. Boyle found it had penetrated fourteen inches into the ground. At Moscow, in a hard season, the frost will penetrate two feet deep into the ground; and Captain James found it penetrated ten feet deep in Charlton Island; and the water in the same island was frozen to the depth of six feet. Scheffer assures us, that, in Sweden, the frost pierces two cubits, or Swedish ells, into the earth, and turns what moisture is found there into a whitish substance, like ice, and penetrates standing water to three ells or more. The same author also mentions sudden cracks or rifts in the ice of the lakes of Sweden, nine or ten feet deep, and many leagues long, the rupture being made with a noise not less loud than if many guns were discharged together. By such means, however, the fishes are furnished with air, so that they are rarely found dead. The natural history of frosts furnishes very extraordinary results. The trees are often scorched and burnt up, as with the most excessive heat, in consequence of the separation of water from the air, which is therefore very drying. In the great frost in 1683, the trunks of oak, ash, walnut, &c., were split and cleft asunder, so that they might be seen through, and the cracks were often attended with dreadful noises, like the explosion of fire-arms. The close of the year 1708, and the beginning of 1709, were remarkable throughout the greatest part of Europe, for a severe frost. Doctor Derham says it was the greatest in degree, if not the most universal, in the memory of man; extending through most parts of Europe, though scarcely felt in Scotland or Ireland. In very cold countries, meat may be preserved by the frost six or seven months, and proves tolerably good eating. In those climates the frost seems never out of the ground, it having been found hard frozen in the two summer months. Brandy and spirit set out in the open air freeze to solid ice in three or four hours. Lakes and standing waters, not above ten or twelve feet deep, are frozen to the ground in winter, and all their fish perish. But in rivers, where the current is strong, the ice does not reach so deep, and the fish are preserved.—Hoar frost is the dew frozen or congealed early in cold mornings; chiefly in autumn.

We have collected some of the most remarkable instances of intense frost, and placed them in chronological order:

A.D.

223 Frost in Great Britain, which lasted five months.
250 The Thames frozen for nine weeks.
291 Almost every river in Britain frozen over for six weeks.
359 Severe frost in Scotland, which lasted for fourteen weeks.
508 The rivers in Britain all frozen over.
558 The Danube quite frozen over.
695 The Thames frozen for six weeks, and booths built on it.
759 Frost from October 1, till February 26, 760.
827 Frost in England for nine weeks.
859 Carriages used on the Adriatic Sea.
908 Nearly every river in England frozen over for two months.
923 The Thames frozen over for thirteen weeks.
987 Frost lasted 120 days, began December 22d.
998 The Thames frozen over for five weeks.
1035 Severe frost on June 24. All the corn and fruits destroyed.
1063 Thames frozen for fourteen weeks.
1096 Frost in England from November till April.
1114 Several wooden bridges carried away by ice.
1407 Frost, which lasted for fifteen weeks.
1434 From November 24, till February 10, the Thames frozen down to Gravesend.
1683 Frost of thirteen weeks.
1708-9 Severe frost for many weeks.
1715 The same for many weeks.
1739 Frost for nine weeks, began December 24.
1742 Severe frost for thirteen weeks.
1747 Severe frost in Russia.
1751 Severe frost many weeks in England.
1760 Severe frost in Germany.
1788 The Thames frozen below London bridge, and booths on it.
1794 Hard frost for many weeks, thermometer in London mostly at 20° below 0° of Fahrenheit.
1813-14 A frost for thirteen weeks, the Thames frozen over, and a fair kept on it.

FRUITFULNESS; the power of abundant production. This power exists in some organic beings in an incredible degree: in a poppy, 32,000 seeds have been counted. The elm produces annually 100,000 seeds. How numerous is the annual production of seeds from fruit-trees, &c.! As each of these seeds is capable of becoming an individual of the same sort, if each of them grew up, the whole surface of the earth would soon be covered with these trees. In the lower classes of animals, the fruitfulness is no less great: the queen-bee lays every year 5000 or 6000 eggs. The vast swarms of locusts, which sometimes lay waste immense tracts of cultivated country in Asia and Africa, and the caterpillars which are often so numerous in our own land, justify us in attributing to them the greatest fruitfulness.

The smallest herring has 10,000 eggs. A carp which weighs only half a pound, has 100,000, a larger one, 262,280; a perch, 324,640. The spawn of the sturgeon is calculated to contain 7,653,200 eggs. In the cod-fish, the number of eggs is reckoned at 9,344,000. In the higher classes of animals, there is less of fruitfulness; yet even in men it is greater than the mortality. In the last case, however, much depends upon climate, season, food, habits, manners, temperament, &c.

FRUSTUM, in *mathematics*; a part of some solid body separated from the rest. The frustum of a cone is the part that remains when the top is cut off

by a plane parallel to the base, and is otherwise called a *truncated cone*. The frustum of a pyramid is also what remains, after the top is cut off by a plane parallel to its base.

FUEL. Doctor Black divides fuels into five classes. The first comprehends the fluid inflammable bodies; the second, peat or turf; the third, charcoal of wood; the fourth, pit-coal charred; and the fifth, wood, or pit-coal, in a crude state, and capable of yielding a copious and bright flame. The fluid inflammables are considered as distinct from the solid, on this account, that they are capable of burning upon a wick, and become in this way the most manageable sources of heat; though, on account of their price, they are never employed for producing it in great quantities, and are only used when a gentle degree or a small quantity of heat is sufficient. The species which belong to this class are alcohol and different oils. The first of these, alcohol, when pure and free of water, is as convenient and manageable a fuel for producing moderate or gentle heats as can be desired. Its flame is perfectly clean, and free from any kind of soot; it can easily be made to burn slower or faster, and to produce less or more heat, by changing the size or number of the wicks upon which it burns; for as long as these are fed with spirit, in a proper manner, they continue to yield flame of precisely the same strength.

The cotton, or other materials, of which the wick is composed, is not scorched or consumed in the least, because the spirit with which it is constantly soaked is incapable of becoming hotter than 174° Fahrenheit, which is considerably below the heat of boiling water. It is only the vapour that arises from it which is hotter, and this too, only in its outer parts, that are most remote from the wick, and where only the combustion is going on, in consequence of communication and contact with the air. At the same time, as the alcohol is totally volatile, it does not leave any fixed matter, which by being accumulated on the wick, might render it foul, and fill up its pores. The wick, therefore, continues to imbibe the spirit as freely, after some time, as it did at the first. These are the qualities of alcohol as a fuel. But these qualities belong only to a spirit that is very pure. If it be weak, and contain water, the water does not evaporate so fast from the wick as the more spirituous part; and the wick becomes, after some time, so much soaked with water, that it does not imbibe the spirit properly. The flame becomes much weaker, or is altogether extinguished. When alcohol is used as a fuel, therefore, it ought to be made as strong, or free from water, as possible.

Oil, although fluid like spirit of wine, and capable of burning in a similar manner, is not so convenient in many respects. It is disposed to emit soot; and this, applying itself to the bottom of the vessel exposed to it, and increasing in thickness, forms by degrees a soft and spongy medium, through which heat is not so freely and quickly transmitted. It is true we can prevent this entirely by using very small wicks, and increasing the number, if necessary, to produce the heat required. Or we may employ one of those lamps, in which a stream of air is allowed to rise through the middle of the flame, or to pass over its surface with such velocity as to produce a more complete inflammation than ordinary. But we shall be as much embarrassed in another way; for the oils commonly used, being capable of assuming a heat greatly above that of common water, scorch and burn the wick, and change its texture, so that it does not imbibe the oil so fast as before.

Some have attempted a remedy, by making the wick of incombustible materials, as asbestos or wire; but still, as the oil does not totally evaporate, but leaves a small quantity of gross, fixed, carbonaceous matter, this, constantly accumulating, clogs the wick to such a degree, that the oil cannot ascend, the flame becomes weaker, and in some cases is entirely extinguished. There is, however, a difference among the different oils in this respect, some being more volatile than others. But the best are troublesome in this way, and the only remedy is, to change the wicks often, though we can hardly do this and be sure of keeping always an equal flame.

The second kind of fuel mentioned, peat, is so spongy, that, compared with the more solid fuels, it is unfit to be employed for producing very strong heats It is too bulky for this; we cannot put into a furnace, at a time, a quantity that corresponds with the quick consumption that must necessarily go on when the heat is violent. There is, no doubt, a great difference in this respect among different kinds of this fuel; but this is the general character of it. However, when we desire to produce and keep up, by means of cheap fuel, an extremely mild, gentle heat, we can hardly use any thing better than peat. But it is best to have it previously charred, that is, scorched, or burnt to black coal. The advantages gained by charring are considerable. When it is prepared for use in that manner, it is capable of being made to burn more slowly and gently, or will bear, without being extinguished altogether, a greater diminution of the quantity of air with which it is supplied, than any other of the solid fuels.

The next fuel in order is the charcoal of wood. This is prepared by piling up billets of wood into a pyramidal heap, with several spiracles, or flues, formed through the pile. Chips and brushwood are put into those below, and the whole is so constructed as to kindle throughout in a very short time. It would burst out into a blaze, and be quickly consumed to ashes, were it not covered all over with earth or clay, beaten close, leaving openings at all the spiracles. These are carefully watched; and whenever the white, watery smoke is observed to be succeeded by thin, blue, and transparent smoke, the hole is immediately stopped; this being the indication of all the watery vapour being gone, and the burning of the true coaly matter commencing. Thus is a pretty strong red heat raised through the whole mass, and all the volatile matters are dissipated by it, and nothing now remains but the charcoal. The holes being all stopped in succession, as this change of the smoke is observed, the fire goes out for want of air. The pile is now allowed to cool. This requires many days; for, charcoal being a very bad conductor of heat, the pile long remains red hot in the centre, and if opened in this state, would instantly burn with fury. Small quantities may be procured at any time, by burning wood in close vessels. Little pieces may be very finely prepared at any time, by plunging the wood into lead melted and red hot. This kind of fuel is very much used by chemists, and has many good properties. It kindles quickly, emits few watery or other vapours while burning, and, when consumed, leaves few ashes,

and those very light. They are, therefore easily blown away, so that the fire continues open, or pervious to the current of air which must pass through it to keep it burning. This sort of fuel, too, is capable of producing as intense a heat as can be obtained by any; but in violent heats it is quickly consumed, and needs to be frequently supplied.

Fossil coals charred, called *cinders*, or *coke*, have in many respects, the same properties as charcoal of wood; as kindling more readily in furnaces than when they are not charred, and not emitting watery or other gross smoke while they burn. This sort of charcoal is even greatly superior to the other in some properties. It is a much stronger fuel, or contains the combustible matter in greater quantity, or in a more condensed state. It is, therefore, consumed much more slowly on all occasions, and particularly when employed for producing intense melting heats. The only inconveniences that attend it are, that, as it consumes, it leaves much more ashes than the other, and these much heavier too, which are therefore liable to collect in such quantity as to obstruct the free passage of air through the fire; and, farther, that when the heat is very intense, these ashes are disposed to melt or vitrify into a tenacious, drossy substance, which clogs the grate, the sides of the furnace, and the vessels. This last inconvenience is only troublesome, however, when the heat required is very intense. In ordinary heat, the ashes do not melt, and though they are more copious and heavy than those of charcoal of wood, they seldom choke up the fire considerably, unless the bars of the grate be too close together. This fuel, therefore, is preferable in most cases to the charcoal of wood, on account of its burning much longer, or giving much more heat before it is consumed.

The heat produced by equal quantities, by weight, of pit-coal, wood-charcoal, and wood itself, is nearly in the proportion of 5, 4, and 3. The reason why both these kinds of charcoal are preferred, on most occasions, in experimental chemistry, to the crude wood, or fossil coal, from which they are produced, is, that the crude fuels are deprived, by charring, of a considerable quantity of water, and some other volatile principles, which are evaporated during the process of charring, in the form of sooty smoke or flame. These volatile parts, while they remain in the fuel, make it unfit (or less fit) for many purposes in chemistry. For, besides obstructing the vents with sooty matter, they require much heat to evaporate them; and therefore the heat of the furnace in which they are burnt, is much diminished and wasted by every addition of fresh fuel, until the fresh fuel is completely inflamed, and restores the heat to its former strength. But these great and sudden variations of the heat of a furnace are quite inconvenient in most chemical processes. In the greater number of chemical operations, therefore, it is much more convenient to use charred fuel, than the same fuel in its natural state.

It is proper to be on our guard against the dangerous nature of the burnt air which arises from charcoal of all kinds. Charcoal burns without visible smoke. The air arising from it appears to the eye as pure and as clear as common air. Hence it is much used by those persons who are studious of neatness and cleanliness in their apartments. But this very circumstance should make us more watchful against its effects, which may prove dangerous in the highest degree, before we are aware of it. The air arising from common crude fuel is, no doubt, as bad, but the smoke renders it disagreeable before it becomes dangerous. The first sensation is a slight sense of weakness: the limbs seem to require a little attention, to prevent falling. A slight giddiness succeeds, accompanied by a feeling of a flush or glow in the face and neck. Soon after, the person becomes drowsy, would sit down, but commonly falls on the floor, insensible of all about him, and breathes strong, snoring as in an apoplexy. If the person is alarmed in time, and escapes into the open air, he is commonly seized with a violent headache, which gradually abates. But when the effect is completed, as above described, death very soon ensues, unless relief be obtained. There is usually a foaming at the mouth, a great flush or suffusion over the face and neck, and every indication of an oppression of the brain, by this accumulation of blood. The most successful treatment is, to take off a quantity of blood immediately, and throw cold water on the head repeatedly. A strong stimulus, such as hartshorn, applied to the soles of the feet, has also a very good effect.

The fifth and last kind of fuel is wood, or fossil coals, in their crude state, which it is proper to distinguish from the charcoals of the same substances. The difference consists in their giving a copious and bright flame, when plenty of air is admitted to them, in consequence of which they must be considered as fuels very different from charcoal, and adapted to different purposes. Flaming fuel cannot be managed like the charcoals. If little air be admitted, it gives no flame, but sooty vapour, and a diminution of heat. And if much air be admitted, to make those vapours break out into flame, the heat is too violent. These flaming fuels, however, have their particular uses, for which the others are far less proper. For flame, when produced in great quantity, and made to burn violently, by mixing it with a proper quantity of fresh air, by driving it on the subject, and throwing it into whirls and eddies, which mix the air with every part of the hot vapour, gives a most intense heat. This proceeds from the vaporous nature of flame, and the perfect miscibility of it with the air.

As the immediate contact and action of the air are necessary to the burning of every combustible body, so the air, when properly applied, acts with far greater advantage on flame than on the solid and fixed inflammable bodies; for when air is applied to these last, it can only act on their surface, or the particles of them that are outermost; whereas, flame being a vapour or elastic fluid, the air, by proper contrivances, can be intimately mixed with it, and made to act on every part of it, external and internal, at the same time. The great power of flame, which is the consequence of this, does not appear when we try small quantities of it, and allow it to burn quietly, because the air is not intimately mixed with it, but acts only on the outside, and the quantity of burning matter in the surface of a small flame is too small to produce much effect. But when flame is produced in large quantity, and is properly mixed and agitated with air, its power to heat bodies is immensely increased. It is therefore peculiarly proper for heating large quantities of matter to a violent degree, especially if the contact of solid fuel with such matter is inconvenient. Flaming fuel is used, for this reason,

in many operations performed on large quantities of metal, or metallic minerals, in the making of glass, and in the baking or burning of all kinds of earthen ware. The potter's kiln is a cylindrical cavity, filled from the bottom to the top with columns of wares; the only interstices are those that are left between the columns; and the flame, when produced in sufficient quantity, is a torrent of liquid fire, constantly flowing up through the whole of the interstices, which heats the whole pile in an equal manner. Flaming fuel is also proper in many works or manufactories, in which much fuel is consumed, as in breweries, distilleries, and the like. In such works, it is evidently worth while to contrive the furnaces so, that heat may be obtained from the volatile parts of the fuel, as well as from the fixed; for when this is done, less fuel serves the purpose than would otherwise be necessary. But this is little attended to, or ill understood, in many of those manufactories. It is not uncommon to see vast clouds of black smoke and vapour coming out of their vents. This happens in consequence of their throwing too large a quantity of crude fuel into the furnace at once. The heat is not sufficient to inflame it quickly, and the consequence is a great loss of heat.

The quantity of watery fluid contained in fuel greatly affects the amount of heat it produces; much more, indeed, than is commonly admitted in practice. It is a well known law of chemistry, that the evaporation of liquids, or their conversion into steam, consumes, and renders latent, a great amount of caloric. When green wood, or wet coals, are added to the fire, they abstract from it, by degrees, a sufficient part of its heat, to convert their own sap or moisture into steam, before they are capable of being burnt. And as long as any considerable part of this fluid remains unevaporated, the combustion goes on slowly, the fire is dull, and the heat feeble. Green wood commonly contains a third, or more, of its weight of watery fluid, the quantity varying according to the greater or less porosity of different trees. Nothing is farther from true economy than to burn green wood, or wet coal, on the supposition that, because they are more durable, they will in the end prove more cheap. It is true, their consumption is less rapid; but to produce a given amount of heat, a far greater amount of fuel must be consumed. Wood that is dried under cover is better than wood dried in the open air, being more free from decomposition.

Fugue; a term derived from the Latin word *fuga* (a flight), and signifying a composition, either vocal or instrumental, or both, in which one part leads off some determined succession of notes called the *subject*, which, after being answered in the fifth and eighth by the other parts, is interspersed through the movement, and distributed amid all the parts in a desultory manner, at the pleasure of the composer; sometimes accompanied by other adventitious matter, and sometimes by itself. There are three distinct descriptions of fugues—the simple fugue, the double fugue, and the counter fugue.

The *simple fugue* contains but one subject, is the least elaborate in its construction, and the easiest in its composition.

The *double fugue* consists of two subjects, occasionally intermingled and moving together; and the *counter fugue* is that fugue in which the subjects move in a direction contrary to each other. In all the different species of fugues, the parts fly, or run after each other; and hence the derivation of the general name *fugue*.

Fuller; one employed in woollen manufactories to mill or scour cloths, serges, and other stuffs.

Fuller's Earth; a well-known mineral, generally of a greenish white colour, more or less mixed with brown, gray, or yellow; of a soft and friable texture, and somewhat unctuous to the touch. It consists chiefly of silex, alumine, and water. When thrown into water, it immediately absorbs it, and breaks down into a fine pulp. Its utility in removing grease from woollen cloths, and other fabrics, has given this earth a great value in commerce. There are very extensive beds of this earth in several counties in England, as Kent, Surrey, Sussex, and at Wavedon, near Woburn in Bedfordshire. We have noticed the valuable property of this earth of taking grease out of woollen and other cloths, which, on a large scale, is effected by the operation called *fulling*, whence its name has been derived. This, which is performed by a kind of water-mill, called a *fulling-mill*, is particularly necessary with respect to new cloths, for the purpose of depriving them of the grease and oil which have been used in their preparation, and thus enables their fibres to curl and intertwine during the fulling. The cleansing property of this earth depends entirely on its alumine, which readily absorbs the grease. The properties of good fuller's earth are a susceptibility of being diffused through water without forming a paste, and a great degree of fineness, as the particles of silex would otherwise injure the cloth. As an article of domestic utility, it might be more frequently used than it is for the cleaning and scouring of wooden floors and wainscots. In this respect, it might be rendered an excellent substitute for soap.

Fulling; the act of cleansing, scouring, and pressing stuffs, cloths, stockings, &c., to render them stronger, firmer, and closer; called also *milling*, because these cloths are in fact scoured by a *water-mill*. The principal parts of a fulling-mill are—the wheel, with its trundle, which gives motion to the tree or spindle, whose teeth communicate that motion to the pestles or stampers, which fall into troughs, wherein the cloth is put, with fuller's earth, to be scoured and thickened by this process of beating it.

Fulmination. In a variety of chemical combinations, it happens that certain of the principles assume the elastic state with such rapidity that the concussion of the air produced gives rise to a loud report. This is called *fulmination*, or, more frequently, *detonation*. Fulminating gold, fulminating silver, fulminating mercury, and gunpowder, are the most familiar substances of this kind. (For an account of them, see Gold, Silver, Mercury, and Gunpowder.)

Fulminic Acid; a peculiar acid, known in combination with certain metallic oxides, and first discovered with those of mercury and silver, with which it forms powerfully detonating compounds. The conditions necessary for forming these compounds are—that the silver or mercury be dissolved in a fluid which contains so much free nitric acid and alcohol, that, on the application of heat, nitric ether shall be freely disengaged. According to an analysis of fulminate of silver, made by MM. Gay-Lussac and Liebig, the acid of the salt is composed of 26 parts, or one atom, of cyanogen, and 8 parts, or one atom, of oxygen. It is therefore to be considered a true cyanic acid, and its salts may, with

propriety, be termed *cyanates*, and this notwithstanding it differs in so many respects from the cyanic acid of Wöhler (for an account of which, see PRUSSIC ACID).

FUMIGATION; means employed for the destruction of miasmata, or effluvia. The most efficacious substance for this purpose is chlorine; next to it the vapour of nitric acid; and, lastly, that of muriatic acid. The fumes of heated vinegar, burning sulphur, or the smoke of exploded gunpowder deserve but little attention as anti-contagionists.

FUNCTION, in *mathematics*. A quantity is said to be a function of another quantity when its value depends on that quantity and known quantities only; and it is said to be a function of several quantities when its value depends on those quantities and known quantities only.

FUNCTIONS, considered in regard to the actions of the body, are by physiologists divided into vital, animal, and natural. The vital functions are those necessary to life, and without which the individual cannot subsist; as the motion of the heart, lungs, &c. The natural functions are those which the body cannot subsist any considerable time without; as the digestion of the aliment and its conversion into blood. Animal functions include the senses of touching, tasting, seeing, &c., and the voluntary motions.

FUNDAMENTAL NOTE, in *music;* the principal note in a song, or composition, to which all the rest are adapted: it is called the *key* to the song.

FUNDS. See STOCKS and MONEY.

FURLONG, in *arithmetic;* a measure of length, consisting of forty poles, and equal to the eighth part of a mile.

FURLOUGH; leave granted to a soldier, or non-commissioned officer, to be absent for a given time from his regiment or company; in which case he is said to be on furlough.

FURNACE, in *manufactures;* a fire-place employed for melting, distilling, and other processes.

FUR TRADE. The fur trade with America commenced early in the seventeenth century, and was carried on by the early French emigrants. Quebec and Montreal were at first trading posts. The trade was then, as now, a barter of guns, cloth, ammunition, &c., for the beaver and other furs collected by the natives, and was effected by the intervention of the *voyageurs, engagés,* or *coureurs des bois*. These men carried burdens of merchandise on their backs to the Indian camps, and exchanged their wares for peltries, with which they returned in the same manner. Shortly after the discovery of the Mississippi, permanent houses, and in many places stockade forts, were built, and men of capital engaged in the trade. Detroit, Mackinac, and Green Bay, were settled in this manner. The manner of the fur trade has undergone no material alteration since. Traders now, at least with the more remote tribes, enter the Indian country with boats laden with goods, and manned with Canadian boatmen, who perform the same service above attributed to their ancestors. The *engagés* are a hardy, patient, and laborious race, habitually making exertions of which no other people are perhaps capable, and enduring all hardships and privations for small pay.

In 1670, shortly after the restoration of Charles II. that monarch granted to Prince Rupert and others, a charter, empowering them to trade, exclusively, with the aborigines in and about Hudson's Bay. A company, then and after called the *Hudson's Bay Company*, was formed in consequence. The trade was then more lucrative than at present. In the winter of 1783—4, another company was formed at Montreal, called the *North-west Fur Company*, which disputed the right of the Hudson's Bay, and actively opposed it. The Earl of Selkirk was at that time at the head of the Hudson's Bay, and conceived the plan of planting a colony on the Red River of Lake Winnepeg. Of this colony, the North-west Company was suspicious. In consequence of this, and the evil feelings naturally growing out of a contrariety of interest, a war ensued between the servants of the parties, and a loose was given to outrage and barbarity. Wearied, at last, the companies united, and are now known by the name of the *Hudson's Bay Fur Company*. The colony established by Lord Selkirk soon broke up, the settlers going to the United States.

Of all who have traded with the aborigines, the French were the most popular and successful. They did, and still do, conform to the manners and feelings of the Indians, better than the English and Americans ever could. Most of the persons now engaged in the fur trade, in the region north of the Missouri, are French; and they are much esteemed by the natives, with whom they frequently intermarry. The male offspring of these alliances are commonly employed as interpreters, *engagés*, &c. They are handsome, athletic men. Mixing the blood seems to improve the races. The Indian trade on the great lakes and the Upper Mississippi, with its branches, has long been in possession of the *North American Fur Company*, the principal directors of which are in the city of New York.

In the year 1822, a new company, entitled the *Columbian Fur Company*, was organized, to trade on the St. Peter's and Mississippi. It was projected by three individuals, who had been thrown out of employ by the union of the Hudson's Bay and North-west, as before mentioned. Its operations soon extended to the Missouri, whither its members went from the sources of the St. Peter's, with carts and waggons, drawn by dogs. When it had, after three years' opposition, obtained a secure footing in the country, it joined with the North American. There was another company on the Missouri at the same time.

Furs were also obtained from the Upper Missouri and the Rocky Mountains, as follows: Large bodies of men (under the pretence of trading with Indians, to avoid the provisions of the law) were sent from St. Louis, provided with traps, guns, and all things necessary to hunters and trappers. They travelled in bodies of from 50 to 200, by way of security against the attacks of the savages, till they arrived at the place of their destination, when they separated, and pursued the fur-clad animals singly, or in small parties. When their object was effected, they assembled with their peltry, and descended the Missouri. They did not always invade the privileges of the natives with impunity, but sometimes suffered severely in life and property. This system still continues, and its operatives form a distinct class in the state of Missouri. The articles used in the Indian trade are chiefly these: coarse blue and red cloth and fine scarlet, guns, knives, blankets, traps, coarse cottons, powder and ball, hoes, hatchets, beads, vermilion, ribbons, kettles, &c. The furs given in return are those of the beaver (but this is scarce on this side the Rocky Mountains), otter, musk-rat, marten, bear, deer, lynx,

and buffalo. Racoons are now of little value. The fur-clad animals, with the exception of the musk-rat, are now almost exterminated on the Mississippi and the great lakes, owing entirely to the fur trade. The skins of animals killed in summer are good for nothing; and the farther north the furs are taken, the better is their quality.

The course of a trader in the North-west is this: He starts from Michilimackinac, or St. Louis, late in the summer, with a Mackinac boat, laden with goods. He takes with him an interpreter, commonly a half breed, and four or five *engagés*. On his arrival at his wintering ground, his men build a store for the goods, an apartment for him, and another for themselves. These buildings are of rough logs, plastered with mud, and roofed with ash or linden slabs. The chimneys are of clay. Though rude in appearance, there is much comfort in them. This done, the trader gives a great portion of his merchandise to the Indians on credit. It is expected that the debtor will pay in the following spring, though, as many neglect this part of the business, the trader is compelled to rate his goods very high. Thus the honest pay for the dishonest. Ardent spirits were never much used among the remote tribes. It is only on the frontier, in the immediate vicinity of the white settlers, that the Indians get enough to do them physical injury, though, in the interior, the traders, in the heat of opposition, employ strong liquors to induce the savages to commit outrage, or to defraud their creditors. By this means, the moral principle of the aborigines is overcome, and often destroyed. Spirit is commonly introduced into their country in the form of high wines, they being less bulky, and easier of transportation, than liquors of lower proof. Indians, after having once tasted, become extravagantly fond of them, and will make any sacrifice, or commit any crime, to obtain them.

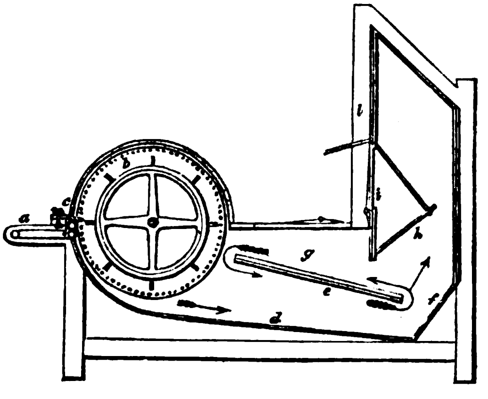
An interpreter is necessary to a fur trader, whether he speaks the language of the tribe with which he deals himself, or not. It is the duty of an interpreter to take charge of the house, and carry on the business in the absence of the principal. He also visits the camps, and watches the debtors. Those traders who are employed in the service of a company, as, for instance, the North American, are called *clerks*, though they seldom use a pen. Many of them cannot write or read. Some traders venture into the Indian country on their own account; but are usually overcome by the opposition of the established companies, whose servants employ every means to ruin them.

In the prairie region, dog-sledges are used for transportation in the winter. The sledge is merely a flat board turned up in front, like the runner of a sleigh. The dogs are harnessed and driven in line, and their strength and powers of endurance are very great. The laws regulating intercourse with the Indians require the traders to remain in their houses, and not to visit the Indians in their camps; but they are universally disregarded. It is better for the savage that they should be. Traders are always better clad and provided for travelling than Indians, and the latter are saved from the danger and hardship of exposure in the open prairie in winter. The competition that naturally results from the practice, is of advantage to them, as they get their wants supplied cheaper and more easily.

Those Indians who have substituted articles of European manufacture, for their primitive arms and vestments, are wholly dependent on the whites for the means of life, and an embargo on the trade is the greatest evil that can befal them. Did our limits permit, we could adduce instances. The fur trade demoralizes all engaged in it. The way in which it operates on the Indians has been already partially explained. As to the traders, they are, generally, ignorant men, in whose breasts interest overcomes religion and morals. As they are beyond the reach of the law (at least, in the remote regions), they disregard it, and often commit or instigate actions that they would blush to avow in civilized society. Most of them are connected with Indian women, after the custom of the country. In consequence of the fur trade, the buffalo has receded hundreds of miles beyond his former haunts. Fomerly, an Indian killed a buffalo, made garments of the skin, and fed on the flesh while it lasted. Now, he finds that a blanket is lighter and more convenient than the buffalo robe, and kills two or three animals, with whose skins he may purchase it. To procure a gun, he must kill ten. The same causes operate to destroy the other animals. Some few tribes, the Ottaways for example, hunt on the different parts of their domains alternately, and so preserve the game. But by far the greater part of the aborigines have no such regulation.

The fur-clad animals are now to be found in abundance only in the far north, where the rigour of the climate and the difficulty of transportation prevent the free access of the traders, and on the Upper Missouri, and towards the Rocky Mountains.

The preparation of hats is one of the principal uses to which fur is put in this country; we therefore select the present article for describing the mode of clearing the fur for that purpose. The process of felting has already been explained, and the complete formation of a hat will be given under HAT-MAKING. The patent improvements to which we are going to call the reader's attention, are exhibited in the diagram beneath, and are intended to separate the finer portions of the fur from those that are less costly.



An endless web, or feeding cloth, is shown at *a*. It is extended on two rollers, upon which web the materials to be cleared and separated are placed, and by which they are carried forward into the machine. *b*, is a hollow cylinder with a flanch at each extremity. From the rims of these flanches a number of cords of catgut are extended and made tight. A

peg or pin is so placed, the cords are put in vibration as they pass round, and thus take the material from the feeding cloth. To ensure a requisite current of air for carrying the fur onward, vanes are placed in the cylinder *b*. The precise amount of current is determined by the regulator, *e*, and the board *f*. The portions that are not sufficiently cleared are returned in the direction of the arrow towards *g*, while that which is completed goes out at *h*, and from thence into a larger upper chamber.

FUSTIC WOOD is of a yellow colour, and contains great quantities of colouring matter, forming the most durable of all the yellow dyes, which, however, is mostly used in compounding green and a variety of drab and olive colours, as, when employed alone, it is dull and deficient in clearness.

GADARA; a Turkish sabre with a large blade, somewhat curved.

GAILLIARDE; an ancient Italian dance, of a sportive character and lively movement, the air of which was in triple time. It was called, likewise, ***Romanesque***, because it was said to have come originally from Rome.

GALACTOMETER (*milk-measure*), invented by Cadet de Vaux. The first degree shows all pure milk; the second, milk with a fourth water; the third, milk with a third water; the fourth, milk with half water. Every one knows that the milk is richer towards the end than at the beginning of the milking. The milk of a pregnant cow, too, is richer than that of one which has just begun to be milked. Food, season, and rain, exercise a great influence on the quality of butter in the milk. The instrument seems, therefore, to be uncertain. (See LACTOMETER.)

GALAXY, in *astronomy*; that long, luminous track, or zone, which encompasses the heavens, forming nearly a great circle of the celestial sphere. It is inclined to the plane of the ecliptic at about an angle of 60°, and cuts it nearly at the two solstitial points. It traverses the constellations Cassiopeia, Perseus, Auriga, Orion, Gemini, Canis Major, and the Ship, where it appears most brilliant in southern latitudes; it then passes through the feet of the Centaur, the Cross, the southern Triangle, and returns towards the north by the Altar, the tail of the Scorpion, and the arc of Sagittarius, where it divides into two branches, passing through Aquila, Sagitta, the Swan, Serpentarius, the head of Cepheus, and returns into Cassiopeia. The ancients had many singular ideas as to the cause of this phenomenon; but modern astronomers have long attributed it to a great assemblage of stars, and Doctor Herschel has confirmed these conjectures, having discovered, in a space of about 15° long, by 2° broad, no fewer than 50,000 stars. This, however, instead of satisfying the curiosity of astronomers, only gave rise to farther inquiries and hypotheses; amongst others, that of Doctor Herschel, which is very interesting. He supposes the siderial universe to be distributed into nebulæ and clusters of stars, and the Milky Way to be that particular cluster in which our sun is placed.

In a paper on the construction of the heavens, Doctor Herschel says, It is very probable that the great stratum called the *Milky Way* is that in which the sun is placed, though perhaps not in the centre of its thickness, but not far from the place where some smaller stratum branches from it. Such a supposition wil l sati-factorily, and with great simplicity, account for all the phenomena of the Milky Way, which, according to this hypothesis, is no other than the appearance of the projection of the stars contained in this stratum and its secondary branch. Doctor Herschel then solves a general problem for computing the length of the visual ray. The telescope which he used will reach to stars 497 times the distance of Sirius. Now Sirius cannot be nearer than 100,000 × 190,000,000 miles; therefore Doctor Herschel's telescope will at least reach to 100,000 × 190,000,000 × 497 miles. And Doctor Herschel says that, in the most crowded part of the Milky Way, he has had fields of view that contained no fewer than 588 stars, and these were continued for many minutes; so that in a quarter of an hour he has seen 116,000 stars pass through the field of view of a telescope of only 15′ aperture; and, at another time, in 41 minutes, he saw 258,000 stars pass through the field of his telescope. Every improvement in his telescope discovered stars not seen before; so that there appears no bounds to their number, or to the extent of the universe.

GALBANUM is the concrete juice of the *bubon galbaniferum*, a shrubby plant, belonging to the natural order *umbelliferæ*, and is usually imported from Syria, Persia, and the East Indies. The galbanum of commerce, however, is perhaps obtained from several species of bubon. This gum-resin comes in large, soft, ductile masses, of a whitish colour, becoming yellowish with age, and possessing an acrid, bitter taste, with a strong disagreeable odour. In its medical properties, it is intermediate between ammoniac and assafœtida, which are likewise the products of plants of the same natural order. At present it is rarely used, but in combination with other articles it forms some officinal preparations.

GALEASSE; a low-built Venetian vessel with both sails and oars, which carries three masts, that cannot, however, be lowered as in a galley. It has thirty-two seats for rowers, and three tiers of guns at the head.

GALENA. See NATURAL HISTORY.

GALL, in the *animal economy*; the same with *bile*, which see.

GALL-BLADDER, called *vescicula* and *cystis fellia*, is usually of the shape of a pear, or the size of a small hen's egg. It is situated on the concave side of the liver, and lies upon the colon, part of which it tinges with its own colour. It is composed of four membranes, or coats—the common, the vesicular, the muscular, and the nervous one, which last is of a wrinkled or reticulated surface within, and furnished with an unctuous liquor. The use of the gall-bladder is to collect the bile secreted in the liver, and, mixing with its own peculiar produce, to perfect it farther, to retain it for a certain time, and then to expel it.

GALL-STONES; calculous concretions frequently formed in the gall-bladder, and sometimes occasioning great pain in their passage through the ducts into the *duodenum*, before they are evacuated. Gall-stones often occur in the inferior animals, particularly in cows and hogs; but the biliary concretions of these animals have not hitherto been examined with much attention. Soaps have been proposed as solvents for these *calculi*. The academy of Dijon has announced the success of a mixture of essence of turpentine and ether.

GALLATES; salts formed by the gallic acid with alkaline earths or metallic bases.

GALLEONS; formerly a kind of vessels of war, used by the Spaniards and Portuguese, with from three to four decks. They are no longer in use. In more recent times those vessels were called *galleons* in which the Spaniards transported treasure from their American colonies. The merchants engaged in this transportation were called *galleonists*.

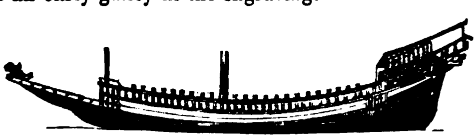
GALLERY, in *architecture;* a long, narrow room, the width of which is at least three times less than its length, by which proportion it is distinguished from a saloon. Corridors are sometimes also called *galleries*. Galleries are not destined to be occupied as sitting rooms, but for dancing, music, or dining on festival occasions; and are generally decorated with pictures in oil or fresco. Galleries have sometimes been built merely to receive collections of pictures, or to give a painter an opportunity for fresco paintings. Hence a large collection of pictures, even if contained in several adjoining rooms, is called *a gallery*.

The first gallery was established by Verres, the well-known spoiler of Sicily. Cicero describes it. It contained, among other beautiful works of art, a statue of Jupiter Οὔριος (the dispenser of favourable winds); the Diana Segestes, a grand and beautiful statue of bronze, veiled, bearing a quiver on her shoulder, holding a bow in her right hand, and a lighted torch in her left; Apollo and Hercules, the works of Myron; a Cupid by the hand of Praxiteles; a Sappho in bronze by Silanion; and the famous flute-player Aspendus. It also contained a splendid collection of vases, *pateræ*, &c., of gold and silver, decorated with costly gems and engraved stones. The pictures were of equal value and rarity, the tapestries embellished with rich borders of gold, and every part of the gallery enriched with all the splendour that art and wealth could bestow. In modern Europe, the gallery founded by Cosmo II., in Florence, was long considered as the most distinguished. At present, the *Galerie du Louvre*, at Paris, is the finest in the world, though, in 1815, it was stripped of many works of art, retaken by the different nations from whom they had been plundered.

Gallery; a balcony, projecting from the stern or quarter of a ship of war, or of a large merchantman.

Gallery, in *fortification;* a covered walk across the ditch of a town; and, as a *mine*, it is a narrow passage from one part of the mine to another.

GALLEY; a species of low, flat-built vessel, furnished with one deck, and navigated with sails and oars, particularly in the Mediterranean. The ancients employed galleys both in commerce and for military affairs. They thus sometimes formed large navies, manned almost entirely by soldiers; and, on account of the crowded state of the decks, seldom employed sails. The iron beak or prow was usually the most dangerous part of the galley, as it acted like a great battering-ram. We give a representation of an early galley in the engraving.



The largest sort of these vessels, called *galleasses*, were formerly employed by the Venetians. They were about 162 feet long above, and 133 feet by the keel, 32 feet wide, and 23 feet length of stern-post. They were furnished with three masts, and 32 banks of oars, each bank containing two oars, and every oar being managed by six or seven slaves, who were usually chained to it. In the fore-part, they had three small batteries of cannon, viz., two 36-pounders, two 24-pounders, and two 2-pounders. They had also three 18-pounders on each quarter, and carried from 1000 to 1200 men. The galleys next in size to these are called *half-galleys*, and are from 120 to 130 feet long, 18 feet broad, and 9 or 10 feet deep. They have two masts, which may be struck at pleasure, and are furnished with two large lateen sails, and five pieces of cannon. They have commonly 25 banks of oars, as described above. A size still less than these are called *quarter-galleys*, carrying from 12 to 16 banks of oars. They generally keep close under the shore, but sometimes venture out to sea to perform a summer cruise. France employs forty galleys for the use of the Mediterranean, the arsenal for which is at Marseilles. These galleys resemble the hulks in this country, in which the convicts labour and are confined.

Galley is also a name given to an open boat, rowing six or eight oars, and used on the river Thames by custom-house officers, press-gangs, and also for pleasure; hence the appellation of *custom-house galley, press-galley*, &c.

Galley, or *Gally*, is also the name of the kitchen of a ship of war, or the place where the grates are put up, fires lighted, and the victuals generally boiled or roasted. In East India ships, it is generally termed the *cook-room*, and on board of merchantmen, it is called the *caboose*.

GALLIC ACID has an intimate connection with tannin; they are generally associated in the vegetable astringents, and are similar in some of their most striking chemical relations. It derives its name from the gall-nut, in which it exists in large quantity, and from which it is usually obtained. Its presence is shown by the property which the infusion of galls has of reddening litmus; and it may be procured by a process given by Scheele,—merely allowing a strong infusion to remain in a vessel imperfectly closed for some months; a sediment is deposited; this being washed with cold water, and dissolved in boiling water, crystals of a grayish colour are procured, which are acid. Scheele observed, too, that by distillation, galls afford an acid liquor, and a portion of a concrete acid is condensed in a crystalline form. Other methods have been employed, such as dissolving the acid by highly concentrated alcohol, which leaves the tannin undissolved; abstracting the tannin and extract of the infusion of galls by the affinity of argil; or boiling in the infusion carbonate of barytes, and decomposing the gallate of barytes by sulphuric acid. But it is not certain if, by any of these processes, the acid is obtained in a state of purity, and in particular altogether free from tannin; this principle always adheres to the acid procured by the first process of Scheele, so as to render it capable of precipitating gelatin, and the other processes by chemical affinity succeed imperfectly. There remains, therefore, only the process of sublimation, and this probably gives the gallic acid in its purest state, a minute portion of oily matter only adhering to it, which gives it a slight aromatic odour; it gives no precipitate with gelatin, and therefore does not appear to have any intermixture of tannin. It is inferior, however, to the acid

procured by the spontaneous decomposition of the infusion of galls in acid powers, a difference which Lagrange considers as owing to the latter having combined with it a portion of acetic acid. With regard to the different states of this acid and its purity, there still remains, on the whole, considerable uncertainty.

The sublimed acid is procured in crystals of a white colour, if the heat has not been raised too high, so as to volatilize any vegetable matter, which gives it a brownish tinge. When purified by solution and crystallization, the acid is white; its crystals are slender prisms; its taste is sour; it reddens, though not very deeply, the vegetable colours, and excites effervescence in the alkaline carbonates; it requires 24 parts of cold water for its solution, but dissolves in less than 2 parts of boiling water, this solution crystallizing on cooling. It dissolves in 4 parts of alcohol, at a medium temperature.

Exposed to heat it fuses, exhaling an agreeable odour; a portion sublimes, and condenses in crystals, while a quantity of acid liquor is also produced, and a large quantity of charcoal remains in the retort. The concrete acid has nearly the same taste and odour as acid of benzoin. The products of its entire decomposition prove it to be a compound of carbon, hydrogen, and oxygen, containing a large proportion of carbon. By nitric acid it is converted into oxalic acid. According to Berzelius, it consists of 57 of carbon, 38 of oxygen, and 5 of hydrogen.

Gallic acid combines with the alkalies and earths. Its salts are named gallates; they have been little examined: those, with the alkalies, are soluble; they throw down dark-coloured precipitates from metallic solutions similar to those produced by the acid itself.

This property of forming dark-coloured precipitates with the solutions of metals, is the most important one belonging to the gallic acid, as rendering it a re-agent of considerable delicacy. The observations with regard to these, however, are of less value, as the acid has been usually employed in that state in which it has an intermixture with tannin; and we have no accurate comparative experiments with regard to the effects from it in a purer form. Its action on the salts of iron has been principally examined, and this is similar to that exerted by tannin. It strikes a violet or purple colour, more or less deep; but for the production of the colour, the iron requires to be in a high state of oxidation. It can also be rendered apparent, however, even in solutions at a lower state of oxidation, by causes which cannot change the state of oxygenation, as by dilution with water, or the addition of a little alkali: and the reason, therefore, of its not appearing when the salt contains the iron imperfectly oxidated, is, that the oxide in that state is retained by a stronger attraction in combination with the acid, than when the oxidation is more perfect. The colour, from the action of gallic acid, is less deep than that from tannin; and the precipitate is much finer, and remains longer suspended. There is some reason to suspect that the colour is always produced by tannin adhering to the acid, and that the acid, only by its re-action on the precipitate, holds it dissolved.

From this relation between gallic acid and tannin, and oxide of iron, arises the advantage derived from their combination in the formation of writing-ink, or black dyes, or the superiority of the infusion of a vegetable astringent, in producing the colour, to either of them in its separate state.

Galliot; a Dutch vessel, carrying a main and a mizzen mast, and a large gaff-main-sail. A galliot is a sort of a brigantine, or small galley, built very slightly, and designed only for chase. She can both sail and row, and usually carries about two or three *pedreros*, and has 16 or 20 oars. All the seamen on board are soldiers, and each has a musket by him on quitting his oar. Some also call the bomb-ketches *galliots*.

Gallon; a measure of capacity, being equal to four quarts, or eight pints. The standard of this measure, or the imperial gallon, is equal to ten pounds avoirdupois, or 277.274 inches of distilled water. The proportion of the imperial gallon to the old wine gallon is as 6 to 5 nearly.

Galloon, in *commerce;* a narrow kind of lace, used to edge or border cloths.

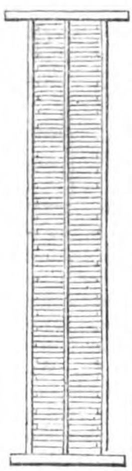
Gally, in *typography;* a frame into which the compositor empties the lines out of his composing-stick, and in which he ties up the page when it is completed. Some gallies are formed of an oblong square board, with a ledge on three sides, and a groove to admit a false bottom, called a *gally-slice.*

Galvanism. Although this agent is now generally admitted to be identical with electricity, yet its mode of production, and the laws which it observes when in action, are so far peculiar, that it is most advantageously treated of by itself.

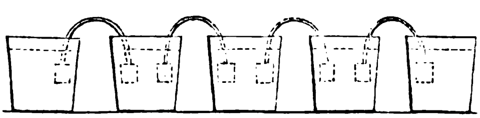
Its name is derived from *Galvani*, an Italian philosopher, who, in a course of experiments on animal irritability, observed the first striking phenomenon which led to its discovery. This observation related to the muscular contractions that take place in the leg of a frog recently killed, when two metals, such as zinc and silver, one of them touching the crural nerve, and the other the muscles to which it is distributed, are brought into contact with one another. The theory which he invented to account for this phenomenon was, that the different parts of an animal are in opposite states of electricity, and that the effect of the metal is merely to restore the equilibrium. The fallacy of this theory was fully shown, about ten years after, in the year 1800, by Volta, a celebrated professor of natural philosophy at Pavia, who excited similar contractions by making a connection between two parts of a nerve, between two muscles, or between two parts of the same muscle; but to produce the effect, two different metals were found to be requisite. He showed also, that in a similar way *sensations* can be excited; as, for example, a piece of silver being applied to one side of the tongue, and a piece of copper to the other, when their edges are brought into contact, or a connection is established between them by a conductor, a peculiar taste is felt, and often a flash of light appears to pass before the eyes. Hence he was led to infer, that the electricity is derived, not from the living system, but from the action excited between the metal and the humid animal fibre; that the animal matter acts merely as a medium conducting this electricity, and that the effects produced are to be ascribed to the stimulus of the electric fluid passing along the nerves and fibres, as in a shock from a Leyden jar.

In the farther demonstration of his views of the production of galvanism, Volta showed that plates of different metals, such as silver and zinc, in con-

tact with one another are excited, the silver negatively, and the zinc positively; and, by employing several pairs of these plates, connecting them in such a manner that the electricity excited by each pair should be diffused through the whole, he discovered a mode of greatly augmenting the galvanic energy, and presented to chemistry an unrivalled instrument of research. It consisted of any number of pairs of zinc and copper, or zinc and silver plates; each pair being separated from the adjoining ones by pieces of cloth, nearly of the same size as the plates, and moistened in a saturated solution of salt. The relative position of the metals in each pair was the same in the whole series; so that, if the copper was placed below the zinc in the first combination, the same order was preserved in all the others. The pile was contained in a frame, fixed into a piece of thick wood, which afforded the apparatus both support and insulation.



The pile is represented in the woodcut. The instrument thus arranged was found to be in the same state of excitement as the single pair of metallic plates, affecting the electrometer, and exciting muscular contractions, in a similar manner, but in a much greater degree. The opposite ends of the pile were also differently excited, the side which began with a zinc plate being positive, and the other negative; and hence, when they were made to communicate by means of a wire from each, electricity flowed from one to the other in a continued current. If the wires were applied to living matter, sensations and contractions were excited: they also gave the electric spark. This instrument, which is at present rarely used, in consequence of more convenient arrangements upon the same principle, has received the name of the *voltaic pile*. Another apparatus for the same purpose was invented by Volta, which he called the *couronne de tasses*. It consisted of a series of glass cups nearly filled with water or a saline solution. In each cup was placed a plate of zinc, and a plate of silver or copper; the plate of silver in the one cup being connected with that of zinc in the other, by a thin slip of metal bent into an arc, and the same order being preserved as in the construction of the pile. The best form of the *couronne de tasses* is given beneath.



Several improvements upon the voltaic pile were soon made by other philosophers; and the discoveries in galvanism multiplied with a rapidity, and to an extent, which surpass any thing before known in the history of science. In attempting to give an outline of these discoveries, we shall observe the following order:—1. *The construction of the galvanic apparatus, and the circumstances essential to the excitement of this modification of electricity; 2. its electrical effects; and 3. its chemical agency.*

1. The simple contact of *different conducting* bodies is all that is necessary for the excitement of galvanic electricity. Conductors of electricity have been divided into *perfect* and *imperfect;* the former comprehending the metals, plumbago and charcoal, the mineral acids, and saline solutions; the latter including water, alcohol and ether, sulphur, oils, resins, metallic oxides, and compounds of chlorine. The least complicated galvanic arrangement is termed *a simple galvanic circle.* It consists of three conductors; of which one, at least, must be solid, the second fluid; the third may be either solid or fluid. In the following tables, some different simple circles are arranged in the order of their powers; the most energetic occupying the highest place.

Table of electrical arrangements, which, by combination, form voltaic batteries, composed of two perfect conductors, and one imperfect conductor.

Zinc,	Each of these	Solution of nitric acid,
Iron,	is the positive	——— muriatic acid,

Table of electrical arrangements, consisting of one perfect conductor and two imperfect conductors.

Solution of sulphu-	Copper,	Nitric acid,
ret of potash,	Silver,	Sulphuric acid,
——— potash,	Lead,	Muriatic acid,
——— soda.	Tin,	Any solutions
	Zinc,	containing
	Other metals,	acids.
	Charcoal.	

In explanation of these tables, it may be observed, that in all those cases where the fluid menstrua afford oxygen, those metals which have the strongest attraction for oxygen are those which form the positive pole. But when the fluid menstrua afford sulphur to the metals, the metal, which, under the existing circumstances, has the strongest attraction for sulphur, determines the positive pole. Thus, in a series of copper and iron plates, introduced into a porcelain trough, the cells of which are filled with water or with acid solutions, the iron is positive, and the copper negative; but when the cells are filled with a solution of sulphuret of potash, the copper is positive, and the iron negative. When one metal only is concerned, the surface opposite the acid is negative, and that in contact with the solution of the alkali and sulphur, or of its alkali, is positive.

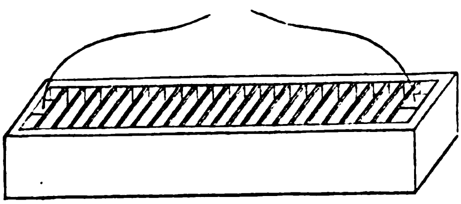
Simple galvanic circles are possessed of but feeble powers; yet these are often sufficiently obvious, as in the instance above alluded to, of a slip of zinc laid upon the tongue, and a piece of silver under it. In this case, we have an example of the arrangement of two perfect conductors (the metals) with one imperfect one (the tongue, or rather the fluids which it contains). A piece of zinc immersed in water which is freely exposed to the atmosphere, oxidises very slowly; but when placed in the same situation, in contact with a piece of silver, its oxidation is much more rapid. By immersing iron and silver (also in contact with each other) in dilute muriatic acid, the

action of the acid upon the iron is considerably increased; and hydrogen gas is evolved from the water, not only where it is in contact with the iron, but where it touches the silver. These facts explain why, in the sheathing of ships, it is necessary to use bolts of the same metal which forms the plates; for if two different metals be employed, they both oxidate very speedily, in consequence of their forming, with the water of the ocean, a simple galvanic circle.

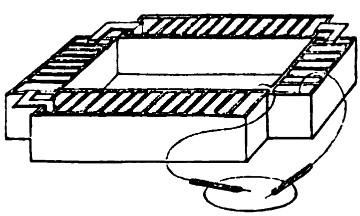
Compound galvanic circles, or galvanic batteries, are formed by multiplying those arrangements which compose simple circles. Thus, if plates of zinc and of silver, and pieces of woollen cloth of the same size as the plates, and moistened with water, be piled upon each other in the order of zinc, silver, cloth; zinc, silver, cloth; and so on, for twenty or more repetitions, we have the voltaic pile, the description of which was given in the previous page. The power of such a combination is sufficient to give a smart shock, as may be felt by grasping in the hands, previously moistened, the wires connecting the upper and lower extremities of the pile. The shock may be renewed at pleasure, until, after a few hours, the activity of the pile begins to abate, and finally ceases altogether.

But the galvanic apparatus by far the most convenient and generally used was invented by Mr. Cruickshank.

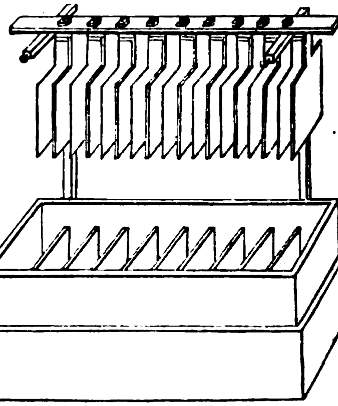
The *galvanic trough*, as it is named, and which consists of a long and narrow trough, made of baked wood, is shown beneath.



Grooves are cut in the trough, opposite to, and at the distance of ½ and ¾ of an inch from, each other; and into these are let down, and secured by a cement, square plates of zinc and copper, previously united together by soldering. The space, therefore, between each pair of plates forms a cell for the purpose of containing the liquid by which the combination is to be made active. The plates may be from 3 to 6 or 8 inches square; and care is to be taken, in their arrangement in the trough, that the order in which they are inserted be not in any instance reversed, but that the copper side of each double plate be always towards one hand, and the zinc side towards the other. The galvanic trough, thus constructed, is more easily put in action than the pile, and more easily kept clean; and, besides, it can be continued longer in action, as it contains more liquid.

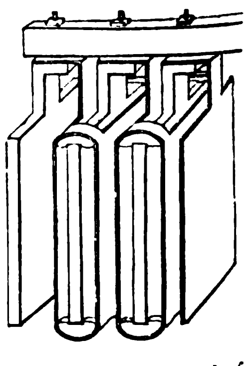


An improvement in the voltaic battery has been made, the hint for which was derived from the *couronne de tasses*: it consists in keeping the plates detached, instead of soldering them together. They are connected at the upper edge by a metallic arc, and are introduced into a trough divided into cells by partitions of glass (or sometimes into troughs wholly made of earthen ware), in such a manner that one plate is on one side of the partition, the other on the other. This arrangement has the advantage, that, both surfaces of each plate being acted on, a greater power is obtained.



In the above engraving the plates are shown suspended over a porcelain trough, which is the best form in which they can be constructed. The only practical objection to the arrangement is, that in some cases the acid acts on the glazed surface of the porcelain, and the troughs leak.

Dr. Wollaston has heightened the improvement, by placing in each cell one plate of the one metal, as the zinc, and two of the other, the copper, so that each surface of the zinc may be opposed to a surface of copper. The plates of copper are connected by metallic arcs, both at the top and bottom; and between them, supported by pieces of wood, is the plate of zinc, distant an eighth or a fourth of an inch from the copper on each side. The communication between these triple plates is established by arcs of lead or other metal, connecting each central zinc plate with the copper of the adjoining cell. This arrangement is very powerful in producing light and heat. A single series of this description is shown in the engraving.



An ingenious modification of this apparatus has been contrived by Dr. Hare, of Philadelphia. It consists of concentric coils of copper and zinc, so suspended by beams and levers as to be made to descend, at pleasure, instantaneously into the exciting fluid contained in glass jars or wooden troughs, without partitions. Each coil is formed from a zinc sheet of 9 inches by 6, and one of copper 14 by 6, more of the copper being required, as this metal is made to commence within the zinc, and completely

to surround it without. The sheets are so coiled as to leave between them interstices of a quarter of an inch. In the original apparatus, they were arranged in two rows, 40 coils in each: on their immersion in the appropriate fluid, the immediate evolution of heat and light was found to be most intense, far exceeding that of voltaic piles or troughs of an equal number of series and extent of surface; and on account of its superior power of causing the combustion of metallic wires and leaves, the instrument was named by its inventor the *galvanic deflagrator*.

The size of the plates composing the galvanic series has been varied from one or two inches square to that of a great number of feet. The battery of Mr. Children consisted of twenty pairs of copper and zinc plates, each plate being 6 feet long by 2 feet 8 inches broad. Each pair was connected by leaden straps at the top, and had a separate wooden cell. These cells were capable of containing 945 gallons of liquid. The plates were suspended from a wooden beam, by means of which they could at once be lowered into the cells, and again raised at pleasure.

Dr. Hare constructed an apparatus consisting of 20 sheets of copper and the same number of zinc, each 20 inches square, and so arranged as to be equivalent to a battery of two galvanic pairs, excepting that there is no insulation, all the plates being plunged into one vessel. This instrument, from its evolving caloric with scarcely any electricity, was called by Dr. Hare the *calorimotor*.

Different liquids are employed to fill the cavities of the trough; and it is essential to employ those which exert a chemical action upon one of the metals, the effect with pure water being very inconsiderable. In general, the galvanic effect is proportional to the rapidity with which the more oxidable metal is acted upon by the intervening fluid. Thus where the liquid employed is pure water, the electric excitement is very feeble, for the action on the metals is feeble; still the zinc is, even in this arrangement, observed to be oxidised more rapidly than it would be, were it not in contact with the copper. A saline solution, as of muriate of soda, or muriate of ammonia, is found to cause a more rapid oxidation of the zinc; and, accordingly, the electric power is greater; and, lastly, an acid fluid, which oxygenates and dissolves the metals much more rapidly, produces the highest activity of which the battery is capable. The fluid generally used is nitric acid, diluted with twenty or thirty times its weight of water.

The *electric column*, originally contrived by M. de Luc, is usually classed with galvanic arrangements. It is formed of discs of Dutch gilt paper, and similar discs of laminated zinc. These, in a perfectly dry state, are piled up into two columns, the different metals constantly alternating with each other in their position, until they attain the height of 18 inches, when they are coated over with a glass cylinder. They are then placed at the distance of 4 or 5 inches from each other, and between them is suspended, on a pivot, a light steel needle, which is attracted alternately to the one pile and the other, moving between them like a pendulum. This curious instrument, instead of being soon exhausted, like the pile, with humid substances, is found to continue active for several years, and has been applied to the measurement of time, by causing it to give motion to the pendulum of a clock.

2. *Electrical Effects of the Galvanic Battery*. Under this head are included all the effects which resemble the usual phenomena produced by the electrical machine. Galvanism, even when excited by a single galvanic circle, such as a piece of zinc, a similar one of copper, and a piece of cloth moistened with a solution of muriate of ammonia, distinctly affects the gold leaf of the condensing electrometer. If the zinc end be uppermost, and be connected directly with the instrument, the electricity indicated is positive. If the pin of the electrometer touch the copper, the electricity is negative. When wires connected with the opposite poles, or sides, of an active galvanic trough are brought near each other, a spark is seen to pass between them, accompanied with a slight snap or report; and on establishing a communication by means of the hands, previously moistened, a distinct shock is perceived, similar to that which is produced by the discharge of a Leyden jar. Both influences, also, are propagated through a number of persons without any perceptible interval of time.

On connecting the ends of a sufficiently powerful battery, by means of fine metallic wires, or slender pieces of freshly prepared charcoal, these conductors become intensely heated, and a vivid white light appears at the points of the charcoal; and as this phenomenon takes place equally in an atmosphere void of oxygen gas, or even under the surface of water, it manifestly cannot be ascribed to combustion. If the communication be established by metallic leaves, the metals burn with vivid scintillations: and if the galvanic fluid, in its circuit, be made to pass through gunpowder, phosphorus, and a mixture of hydrogen and oxygen gases, they are inflamed.

These observations induce the belief, that the agent or power excited by the voltaic apparatus is identical with that which is called into activity by the electrical machine: for not only may all the common electrical experiments be performed by means of galvanism, but it has been shown by Dr. Wollaston, that the chemical effects of the galvanic battery may be produced by electricity. The conditions required for producing the electrical effects of the voltaic battery are different. Electrical attractions and repulsions take place in the highest degree when a great number of small plates are employed, and the cells filled with water. For acting on the electrometer, therefore, a battery of numerous small plates is peculiarly suited, and common river water is the best material for its excitation.

For producing sparks, or giving shocks, a numerous series of plates, about four inches square, and excited with dilute acid, is required. For burning metallic leaves, fusing wire, and igniting charcoal, a small number of large plates answer better than a great number of small ones; a strong acid solution should also be employed.

3. *Chemical Effects of Galvanism*. The most simple chemical effect of the galvanic battery is the ignition and fusion of metals, which has already been alluded to above. The facility of being ignited, in the different metals, appears to be inversely proportional to their power of conducting heat. Hence platina, which has the lowest conducting power, is most easily ignited; and silver, which conducts heat with greater facility than any other metal, is ignited with more difficulty than any of the rest. The combustions produced by galvanic arrangements have also been spoken of above. The plates for this purpose should not be less than 4 inches square, and an aggregate of

not less than 150 pairs of plates employed. The metals are burnt, or rather deflagrated, in the form of very thin leaves. Gold emits a very vivid white light, inclining a little to blue; the flame of silver is a vivid green, somewhat like that of the emerald, and zinc a bluish white flame, fringed with red.

The most striking effect of the voltaic battery is the intense light which is produced by placing two pieces of charcoal, cut into the shape of pointed pencils, at the two ends of the wires of an interrupted circuit. When the battery is a very powerful one, and the charcoal points are brought within the 30th or 40th of an inch of each other, a bright spark is produced. By withdrawing the points from each other, a constant discharge takes place through the heated air, in a space of from one to four or more inches, according to the energy of the apparatus, producing a most brilliant arch of light, of considerable breadth, and in the form of a double cone. Platina, introduced into this arch, melts as wax does in the flame of a candle. This light equals the brilliancy of the sun, and cannot be borne by eyes of common strength, unless protected by glasses. That it does not arise from combustion, is proved by the fact, that very little of the charcoal is wasted by its continuance for some time.

In the use of the deflagrator, it was observed by Professor Silliman, that, during the discharge, the charcoal point of the positive pole shot out into a little stalactical knob, in the direction of the opposite point; while, in the charcoal of the negative pole, on the contrary, a crater-shaped cavity was formed at the same time, appearing as if matter was actually transferred from the negative to the positive side. The subsequent examination of the matter thus apparently transferred, as it had all the marks of having been fused, induced the belief that the charcoal passed, in the state of vapour, through the ignited arch of flame, and concreted again on arriving at the positive pole. The most important chemical effect of galvanism, however, is that of producing decomposition. The substance first decomposed by it was water. When two gold or platina wires are connected with the opposite poles of a battery, and their free extremities are plunged into the same cup of water, but without touching each other, hydrogen gas is disengaged at the negative wire, and oxygen at the positive side. By collecting the gases in separate tubes as they are formed, they are found to be quite pure, and in the exact proportion of two measures of hydrogen to one of oxygen.

If wires of a more oxidable metal are employed, the hydrogen gas will appear as usual, but the oxygen, instead of escaping, combines with the metal, converting it into an oxide. Numerous other compounds, such as acids and salts, are found to be decomposable in the same manner, one of these elements appearing at one side of the battery, and the other at the opposite extremity. A remarkable law in the circumstances attending the decomposition is also observed. Thus, in decomposing water, or any other compound, the same constituent principle is always disengaged at the same side of the battery; so that the principles which collect around each pole have a certain analogy; inflammable bodies and alkalies go to the negative side, while oxygen passes to the positive side.

It is also found, that not only are the elements of a compound fluid separated by galvanic energy to the opposite wires in distant parts of the containing vessel, without the movement of these elements being perceptible, but that the elements may even be evolved in separate portions of the fluid placed in distinct vessels, and connected only by some slight link, as a few fibres of moist cotton or amianthus. Thus two glasses may be filled with pure water and connected with moistened thread; the positive wire immersed in the water in one vessel, and the negative in that of the other; and immediately oxygen gas will be disengaged at the extremity of the former, and hydrogen gas at the extremity of the latter. Now, in this instance, it is obvious a difficulty immediately presents itself in attempting to account for the separate evolution of the elements. If they were both produced in one vessel, it might be conceived that they arose from the decomposition of one portion of water, and had been attracted to the opposite poles. But how can this happen in separate vessels? What becomes of the hydrogen in the vessel where the positive wire is placed, and why does oxygen not appear in the other vessel in which the negative wire is immersed? The only explanation that can be given, is to suppose that one or both of these ingredients must have passed from one vessel to the other, along the connecting fibres of thread, although we are unable to perceive such a transmission. Numerous other facts of a similar nature are also now known, particularly with respect to the decomposition of saline solutions. Thus, let two cups of agate or gold (as glass is liable to be acted upon) be connected by a few fibres of amianthus moistened by water, and a solution of sulphate of soda or potash, nitrate of potash, nitrate of silver, or any other compound salt, be placed in each of the cups. Now, if we introduce into one the positive wire, and into the other the negative wire of a galvanic battery in action, in a short time the principles of the salt will be separated, and all the acid will be collected in the vessel with which the positive pole communicates, and all the base in the other; each being conveyed by the medium of the moistened amianthus, and, as it would appear, in opposite currents, passing one another in so narrow a space, without combining or otherwise interfering with each other's movements. Again, if the saline solution be placed in one of the cups, and distilled water in the other, and the positive wire inserted in the latter, the acid will leave both the base with which it was united and the vessel in which it was, and pass by the amianthus wholly into the water, the base remaining in the first cup: and if, after this change be effected, the wires are reversed, the acid will immediately begin to quit the cup into which it had passed in the former experiment, and to return to the first cup, while the base will move in an opposite direction, till all of it is collected in the vessel in which the negative wire was placed.

Phenomena still more extraordinary present themselves in connection with these most interesting researches. The elements of compound bodies are actually conveyed by the influence of the electric current through solutions of substances, on which, under other circumstances, they would have exerted an immediate and powerful chemical action, without any such effect being produced. Acids, for example, may be transmitted from one cup, connected with the negative pole, to another cup on the opposite or positive side, through a portion of fluid in an intermediate cup tinged with any of the vegetable coloured

infusions, which are instantly reddened by the presence of an acid, without occasioning the slightest change of colour. The same happens also with alkalies. Sir H. Davy found that when three vessels were connected with each other by moistened amianthus, and there was placed in the first a solution of sulphate of potash, with a wire from the negative side, in the middle a vessel with a solution of ammonia (a substance having a strong attraction for sulphuric acid), and in the third water, with a wire from the positive side of the galvanic battery,—in five minutes (a battery of 150 pairs of plates being employed) acid was found collecting around the wire in the water. It had therefore passed through the ammonia without the affinity of this being sufficient to arrest it. When the disposition was reversed, and the saline solution connected with the positive side, the water with the negative, and an acid placed in the middle, the alkaline base was conveyed through the interposed acid, and collected in the pure water.

The same results were obtained in operating on a number of other salts, alkaline, earthy, and metallic. Where a strong force of cohesion, however, interfered, the substance was intercepted: thus sulphuric acid could not be transmitted through a solution of barytes or strontites; nor these earths through sulphuric acid: when it was attempted, these earths fell down in insoluble precipitates. Not only liquids, but solid substances, are decomposed by means of the galvanic energy, and their elements transferred to the opposite wires. And such is the force of this agent, that the most minute portion of a substance thus acted on by either of the wires is collected around it.

Portions of muriatic acid, of soda, and of other alkalies and acids, appear at the opposite poles, even when distilled water alone is employed; proving that these substances, in the condition of neutral salts, exist in all waters, however purified they may be by art. From these researches, the general law is established, that, when compounds are placed in the galvanic circuit, their elements are separated from the state of combination in which they exist, and, according to their peculiar nature, are collected, —some around the positive, others around the negative pole. How this is effected, whether by attractions alone exerted at each pole, or by repulsions, or by both, the element attracted to the one being repelled from the other, is not so apparent.

Grotthus, in explaining the galvanic decomposition of water, advanced the conjecture, that as, in the voltaic pile, each pair of plates has its negative and positive poles, it may establish a similar polarity among the elementary particles of the portion of water interposed between its principal poles. One element of the water may thus acquire the positive, the other the negative state; and, if this happens, then, according to the laws of electricity, that which has become negative (the oxygen in the case of water) will be repelled from the negative, and attracted to the positive pole; and that which has become positive (the hydrogen) will be repelled from the positive and attracted to the negative side. With regard to the mode of conveyance, it may be by successive decompositions and recompositions of the compound between the two poles; in water, for instance, the particle at each wire may be decomposed; the one element may be disengaged, and the residual element may attract a corresponding portion of the other from the next particle, and thus, by a series of successive decompositions and recompositions, each may be brought to the wire to which it is attracted and evolved; or, what is equally possible, the decomposition may be confined to the particles at each pole, and the element receiving the opposite electricity may be repelled from it, and, by this repulsion and the corresponding attraction at the opposite wire, be brought to that other pole; and analogy is in favour of this supposition. In atmospheric air, bodies rendered positively or negatively electrical are attracted and repelled at considerable distances. From the degree in which electricity exists in galvanic arrangements, water is a medium, with regard to it, nearly as atmospheric air is to electricity evolved in the common electrical machine; and it may therefore allow electric attractions and repulsions to operate in a similar manner.

A different theory has been proposed by Sir H. Davy, and which has received the appellation of the *electro-chemical theory*. It has been adopted by some eminent philosophers, and among others by Berzelius. He conceived that bodies possess natural electric energies, which are inherent in them, whether they are in a state of combination or not. Oxygen, chlorine, iodine, and acids, according to the theory, are naturally negative; while inflammables, as hydrogen, sulphur, &c., and metals, are naturally positive. Hence, when the combinations of these substances are subverted by the galvanic influence, the substances are evolved in the electric state natural to them; and, as it is a law of electricity that bodies in opposite states attract each other, the oxygen, being negative, is immediately attracted by the positive wire, while the inflammable or metallic base, being naturally positive, is attracted by the negative wire. In this way, the uniform appearances of these bodies at their particular poles is accounted for.

To explain how combination is subverted by the electric influence, a farther hypothesis was suggested by the author of this theory, viz. that chemical attraction may itself be a modification of electricity; that the same power which communicates attractive and repulsive properties to masses of matter may, when acting upon the ultimate particles of different bodies, induce them either to separate or unite, as their natural electrical states are the same or different. Thus, if hydrogen is naturally positive, and oxygen naturally negative, according to the laws of electricity, they must attract each other; and, if these opposite states are sufficiently elevated to give them an attractive force superior to the power of aggregation, they may be expected to combine; and, in like manner, other bodies, whose particles are in different states, may from this cause be united together. If a body also, whose electrical energy exceeds that of one of the substances combined, be brought to act upon these, it may expel that ingredient, and take its place; and this may be the cause of what is called decomposition from elective affinity.

The effect of heat, likewise, in promoting combination or decomposition, may often depend on its exciting electrical energy; and the elevation of temperature and production of light, so frequently attending chemical action, may depend on the changes attending the electrical states, since such changes are accompanied with the evolution of heat and light. The agency of the galvanic apparatus, then,

in producing decomposition, it is conceived on this hypothesis, is, that the two wires placed in contact with the compound are, in states of electricity, more intensely elevated than the natural states of the two ingredients; hence the attraction of these two highly electrified points overcomes that subsisting between these ingredients: they are separated, and immediately drawn to the respective poles,—the positive constituent to the negative wire, and the ingredient which is naturally negative to the positive wire. A number of facts are brought forward in support of these views. Thus, when dry acids, such as the oxalic and boracic, are touched with an insulated plate of copper, the electric equilibrium is immediately disturbed; the acids are found, after the contact, to be in the negative state of electricity, and the metal to be positive. Here then it was supposed, that their natural states are manifested, such as they are, inherently, at all times. Again, when the same plate is applied to earthy and alkaline substances, the opposite appearance is presented; the metal becomes negative, and the latter bodies positive. And, lastly, when acids are brought in contact directly with earthy and alkaline substances, the same relative states are exhibited—the former become negative, and the latter positive.

Regarding all compounds as constituted of oppositely electrical elements, Sir H. Davy conceived that none of them should resist decomposition, if exposed to a battery of sufficient intensity; and he accordingly subjected to galvanic action substances which till then had been regarded as simple, expecting that, if they were compound, they would be resolved into their elements. The alkalies and earths were in this manner successively decomposed; a substance, with the aspect and properties of a metal, appeared at the negative pole, while oxygen gas was disengaged at the positive surface.

Another instance of the successful application of these views is seen in the attempts of Sir H. Davy to protect the copper sheathings of ships from corrosion. It is well known that the copper sheathing of vessels oxidizes very rapidly in sea-water, and, consequently, wastes with such rapidity as to require frequent renewal. Sir H. Davy observed that the copper derived its oxygen from atmospheric air dissolved in the water, and that the oxide of copper then took muriatic acid from the soda and magnesia, forming with it a sub-muriate of the oxide of copper. Now, if the copper did not oxidize, it could not combine with muriatic acid; and, according to Sir H. Davy, it only combines with oxygen, because, by contact with that body, it is rendered positively electrical. If, therefore, the copper could by any means be made negative, then the copper and oxygen would have no tendency to unite.

The object was to render copper permanently negative. Now this is done by bringing copper in contact with zinc or iron; for the former then becomes negative, and the latter positive. Acting on this reasoning, it was found that the oxidation of the copper might be completely prevented. A piece of zinc as large as a pea, or the head of a small round nail, was found fully adequate to preserve 40 or 50 square inches of copper, and this wherever it was placed or under whatever form it was used. Every side and every surface of the copper remained bright, whilst the iron or the zinc was slowly corroded. Unhappily for the application of this principle in practice, it is found that unless a certain degree of corrosion takes place in the copper, its surface becomes foul, from the adhesion of sea-weeds and shell-fish. It is possible, however, that, by duly adjusting the proportion of iron and copper, a certain degree of corrosion may be allowed to occur, sufficient to prevent the adhesion of foreign bodies, and yet materially retarding the waste of the copper. A more successful application of these principles has been suggested by Mr. Pepys, of the Poultry, which is to preserve iron or steel instruments from rust by contact with a piece of zinc. The iron or steel is thereby rendered negative, while the zinc, being positive, oxidizes with increased rapidity. It is to the electro-chemical theory, also, that chemistry owes the most philosophical arrangement of which it appears capable. By it bodies are divided into groups, according as their natural electric energies are the same or different. The electric energies are ascertained by exposing compounds to the action of a galvanic battery, and observing the pole at which the elements appear. Those that collect around the positive pole are said to have a negative electric energy; and those are considered positive electrics which are attracted towards the negative pole.

The following list, showing the electric energy of the different elementary substances in relation to each other, is taken from Berzelius's *System of Chemistry*. They are given by their author as an approximation to their true order, rather than as rigidly exact. All bodies enumerated in the first row are negative to those of the second. In the first column, each substance is negative to those below it; and, in the second, each element is positive compared with the subsequent ones.

Before concluding this part of the subject, it should be remarked, that, in the production of the different effects arising from the operation of galvanism, a dif-

ferent law is observed with regard to each of these effects, according as the structure of the galvanic arrangement varies. Thus, a few metallic plates, of a surface containing two or three square feet, will be powerful in producing heat and light, and will therefore deflagrate metallic leaves placed in the circuit, and illuminate charcoal points vividly; but the battery which they form will display little power of electrical attraction and repulsion, will have comparatively little effect on sentient organs, scarcely producing any shock, and will act feebly in producing chemical decomposition. Thus the great battery of Mr. Children and the deflagrator of Dr. Hare, which melted many feet of platina with ease, had no very remarkable power in effecting decomposition, or in giving shocks. If the same amount of surface, however, as existed in either of these arrangements, had been disposed in a battery, so as to have formed four times the number of plates, the result would have been that the burning effect would have been diminished, while it would have exhibited more evidently the different electrical states, and been more powerful in exciting sensations in animal organs, and in giving rise to chemical decompositions.

Gamboge is the inspissated juice of a foreign tree, and is obtained in commerce in masses of a dull orange colour, with a conchoidal fracture, possessing no smell, but an acrid taste, which is very slowly developed. When ignited, it melts, throwing out a dense smoke with sparks; it is soluble, or, more properly, diffusible in water, affording a beautiful colour, very much employed by painters; it is also used to stain wood in imitation of box; and the tincture enters into the composition of the gold-coloured varnish with which white wood manufactures are overlaid. It is said to give also a beautiful and durable yellow stain to marble. Its medical properties are violently purgative. When taken in large quantities it produces death. The best remedy for an over-dose is milk with a little opium.

Gaming, Laws of, mathematically considered, involve the doctrine of chance or hazard. It is, or is supposed to be, an equality of chance upon which the gamesters set out: this equality is to be broken in upon in the course of the game, by the greater good fortune or address of one of the parties, upon which his chance becomes better; so that his share in the deposit, or stakes, is now proportionably improved. This increase and decrease of favourable circumstances is continually varying, and runs through all the ratios between equality and infinite difference; or from an infinitely great one, upon which the game is ended. The whole game, therefore, with respect to the event or issue thereof, is only a change of the quantity of each person's share, or chance, or of the proportion their two shares bear to each other; which mathematics alone can measure. Hence several authors have computed the variety of chance, in several cases and circumstances, that occur in gaming, particularly M. de Moivre, in a treatise entitled *The Doctrine of Chances*, the best edition of which was published in 1756.

It is not our intention to enter into a full investigation of the nature and laws of chance, but merely to explain the essential principles of the doctrine. The *probability* of the happening of any event is to be understood as the ratio of the chances by which that event may happen, to all the chances by which it may either happen or fail; and it may be expressed by a fraction whose numerator is the number of chances whereby the event may happen, and whose denominator is the number of chances whereby it may either happen or fail. Thus, if there be a chances for the happening of any event, and b chances for its not happening, then will the probability of such an event taking place be truly represented by $\frac{a}{a+b}$.

In like manner, the probability of any event failing (or of its not happening) may be expressed by a fraction whose numerator is the number of chances whereby it may fail, and whose denominator is, as before, the whole number of chances whereby it may either happen or fail. Thus, the probability of the above event failing will be truly expressed by $\frac{b}{a+b}$. Since the sum of the two fractions representing the probabilities of the happening and of the failing of any event is equal to unity, it follows that, one of them being given, the other may be found by subtraction. Thus, the probability of an event happening being denoted by $\frac{a}{a+b}$, the probability of the same event failing will be truly represented by $1 - \frac{a}{a+b} = \frac{b}{a+b}$; and *vice versâ*.

If, upon the happening of an event, a person be entitled to a given sum of money, his *expectation* of receiving that sum has a determinate value before the happening of the event; and such value is ascertained by multiplying the sum expected by the fraction which represents the probability of obtaining it. Thus, if a person has a chances of obtaining, and b chances of losing a certain sum of money, s, then will $s \times \frac{a}{a+b}$ denote his expectation of receiving such sum, and will be the true value of his interest therein.

These principles may be more familiarly explained by the following example:—Suppose that a person has three chances in five to obtain 100*l.*; the value of his *expectation* is the product of 100*l.* by the fraction $\frac{3}{5}$, and consequently it is worth 60*l.* For, supposing that an event may equally happen to any one of five different persons, and that the person to whom it does happen should, in consequence of it, obtain the sum of 100*l.*, it is plain that the right which each of them in particular has upon the sum is $\frac{1}{5}$ of 100*l.*; which right is founded upon this principle, that if the five persons concerned in the happening of the event should agree not to stand the chance of it, but to divide the sum expected among themselves, then each of them must have $\frac{1}{5}$ of 100*l.* for his pretension. Now, whether they agree to divide that sum equally among themselves, or rather choose to stand the chance of the event, no one has thereby any advantage or disadvantage, since they are all upon an equal footing, and consequently each person's *expectation* is worth $\frac{1}{5}$ of 100*l.* Let us farther suppose that two of the five persons concerned in the happening of the event should be willing to resign their chance to one of the other three; then the person to whom these two chances are thus resigned has three chances that favour him, and consequently he has now a right to triple of what he had before, and therefore his expectation will be worth $\frac{3}{5}$ of 100*l.* Now, if we consider that the fraction $\frac{3}{5}$ expresses the probability of obtaining

the sum of 100*l*., and that $\frac{3}{5}$ of 100 is the same as $\frac{3}{5} \times 100$, we must naturally fall into the conclusion laid down, that the expectation of receiving any sum is determined by multiplying such sum by the probability of obtaining it; and, though this method of reasoning is deduced from a particular case, it will easily be perceived that it is general, and applicable to any other case.

The probability of the happening of *several events* that are independent of each other is equal to the product of the probabilities of the happening of each event considered separately. Thus, if the probability of the happening of the first of any number of independent events be denoted by $\frac{a}{a+b}$, that of the second by $\frac{c}{c+d}$, that of the third by $\frac{e}{e+f}$, &c. &c.; then will $\frac{a}{a+b} \times \frac{c}{c+d} \times \frac{e}{e+f} \times$, &c., denote the probability of the happening of all these events. And this expression, multiplied by the given sum, will denote the value of the *expectation* of receiving such sum on the happening of those events.

For example: suppose that, in order to obtain 100*l*., two events must happen, the first of which has three chances to happen and two to fail, and the second of which has four chances to happen and six to fail; the value of the expectation will in such case be $\frac{3}{5} \times \frac{4}{10} \times 100 = 24l.$, the demonstration of which will be very easy, if it be considered that, supposing the first event had happened, the expectation (then depending entirely upon the second) would, before the determination of the second, be worth $\frac{4}{10} \times 100 = 40l.$ We may therefore look upon the happening of the first as a condition of obtaining an expectation worth 40*l*.; but the probability of the first event happening has been supposed $\frac{3}{5}$, wherefore the expectation sought for is to be estimated by $\frac{3}{5} \times \frac{4}{10} \times 100 = 40$; that is, by the product of the two probabilities of happening multiplied by the sum expected. The same method of reasoning may be applied to the happening of three, or any other number of events, as may be seen more at large in the various authors who have treated on this subject.

By a similar method of reasoning, it will be evident that the probability of the failing of any number of independent events is equal to the product of the probability of the failing of each event considered separately; and the probability of the happening of any one of a number of independent events is denoted by the difference between unity and the expression mentioned in the last article.

In like manner, if the expectation of receiving any sum depends upon the happening of any number of independent events, and upon the failing of any number of other independent events, its value will be equal to such sum multiplied by the probability of all the latter failing. And from these principles we may determine the value of an expectation depending on the happening or failing of as many independent events as may be assigned.

Gammut; the name given to the table or scale laid down by Guido, to the notes of which he applied the monosyllables *ut, re, mi, fa, sol, la*. Having added a note below the lowest tone of the ancients, he adopted for its sign the *gamma* of the Greek alphabet; and hence his scale was afterwards called *gammut*. This gammut consisted of 20 notes, viz. two octaves and a major-sixth. The first octave was distinguished by capital letters, as G, A, B, &c.; the second by small letters, as g, a, b, &c., and the supernumerary sixth by double letters, as gg, aa, bb, &c. By the word *gammut*, we now generally understand the whole present existing scale; and to learn the names and situations of its different notes is to learn the gammut. It, however, sometimes simply signifies the lowest note of the Guidonian or common compass.

Gangrene is a great and dangerous degree of inflammation, wherein the parts begin to be in a state of mortification.

Gangway; a narrow platform, or range of planks, laid horizontally along the upper part of a ship's side, from the quarter-deck to the forecastle, peculiar to ships that are deep waisted, for the convenience of walking more expeditiously fore and aft, than by descending into the waist. It is fenced on the outside by iron stanchions, and ropes or rails, and, in vessels of war, with a netting, in which part the hammocks are stowed. In merchant ships, it is frequently called the *gangboard*.

Gangway is also that part of a ship's side, both within and without, by which persons enter and depart. It is provided with a sufficient number of steps, or cleats, nailed upon the ship's side, nearly as low as the surface of the water, and sometimes furnished with a railed accommodation ladder, resembling a flight of stairs, projecting from the ship's side, and secured by iron braces.

Gangway is also used to signify a narrow passage left in the hold, when a ship is laden, in order to enter any particular place as occasion may require, whether to examine the situation of the provisions or cargo, to discover and stop a leak, or to bring out any article that is wanted.

Gardant, in *heraldry*; an epithet for a beast of prey that is borne full-faced guarding, as a *lion-gardant*. The leopard is not so termed, because it is always borne so.

Gardening. Herder, in his *Kalligone*, calls gardening the second liberal art, architecture the first. "A district," says he, "of which every part bears what is best for it, in which no waste spot accuses the indolence of the inhabitants, and which is adorned by beautiful gardens, needs no statues on the road; Pomona, Ceres, Pallas, Vertumnus, Sylvan, and Flora meet us with all their gifts. Art and nature are there harmoniously mingled. To distinguish, in nature, harmony from discord,—to discern the character of every region with a taste which developes and disposes to the best advantage the beauties of nature,—if this is not a fine art, then none exists." However true it may be that gardening deserves to be called a fine art, we can hardly agree with Herder, that it is the second in the order of time; for, though gardens must have originated soon after man had advanced beyond the mere nomadic life, yet the practice of gardening as a fine art, that is not merely as a useful occupation, must necessarily have been of a much later date.

The hanging gardens of Semiramis are reckoned among the wonders of the world; but that which astonishes is not therefore beautiful. Scaffoldings, supported by pillars, covered with earth, bearing trees, and artificially watered, are, no doubt, wonderful; but we have no reason to suppose them beautiful. The gardens of the Persians are called by

Xenophon delightful places, fertile and beautiful; but they seem rather to have been places naturally agreeable, with fruit-trees, flowers, &c., growing spontaneously, than gardens artificially laid out and cultivated. Whether the Greeks, so distinguished in the fine arts, neglected the art of gardening, is a question not yet decided.

The gardens of Alcinoüs were nothing but well laid out fruit orchards and vineyards, with some flowers. The grotto of Calypso is more romantic, but probably is not intended to be described as a work of art. The common gardens which the Greeks had near their farms were more or less like the gardens of Alcinoüs. Attention was paid to the useful and the agreeable, to culinary plants, fruits, flowers, shadowing trees and irrigation. Shady groves, cool fountains, with some statues, were the only ornaments of the gardens of the philosophers at Athens. The descriptions of gardens in the later Greek novelists do not show any great progress in the art of gardening in their time; and it would be worth while to inquire, whether the same cause, which prevented the cultivation of landscape-painting with the ancients, did not also prevent the progress of the art of gardening. The ancients stood in a different relation to nature from the moderns.

The true art of gardening is probably connected with that element of the romantic which has exercised so great an influence on all arts ever since the revival of arts and letters, and, in some degree, ever since the Christain era. Even the grottoes of the ancients owed their origin merely to the desire for the coolness they afforded. Natural grottoes led to artificial ones, which were constructed in the palaces in Rome, and in which, as Pliny says, nature was counterfeited. But a grotto does not constitute a garden; and that the Romans had no fine gardens, in our sense of the word, is proved by several passages of their authors, and by the accounts we have of their gardens. In Pliny's description of his Tuscan villa, we find, indeed, all conveniences—protection against the weather, an agreeable mixture of coolness and warmth; but every thing beautiful relates merely to buildings, not to the garden, which, with its innumerable figures of box, and in its whole disposition, was as tasteless as possible. Of the gardens of Lucullus, Varro says, that they were not remarkable for flowers and fruits, but for the paintings of the villa. A fertile soil, and a fine prospect from the villas, which were generally beautifully situated, seem to have satisfied the Romans.

Whatever the art of gardening had produced among them, was, with every other trace of refinement, swept away by the barbarians who devastated Italy. Charlemagne directed his attention to this art, but his views did not extend beyond mere utility. The Troubadours of the middle ages speak of symmetrical gardens. In Italy, at the time of the revival of learning, attention was again turned towards pleasure gardens, some of which were so famous, that drawings were made of them. They may have been very agreeable places, but we have no reason to suppose them to have exhibited much of the skill of the scientific gardener. At a later period, a new taste in gardening prevailed in France. Regularity was carried to excess; clipped hedges, alleys laid out in straight lines, flower-beds tortured into fantastic shapes, trees cut into the form of pyramids, haystacks, animals, &c., were now the order of the day. The gardens corresponded with the taste of the time, which displayed itself with the same artificial stiffness in dress, architecture, and poetry. Lenotre was the inventor of this style of French gardening, which, however, his successors carried to greater excess. Nothing natural was left, and yet nature was often imitated in artificial rocks, fountains, &c. Only one thing strikes us as truly grand in gardens of this sort—the fountains, which were constructed at great expense. The Dutch imitated the French. Our own countrymen were the first that felt the absurdity of this style. Addison attacked it in his Essays on Gardening, in the *Spectator;* and Pope, in his fourth *Moral Epistle*, lashed its petty, cramped, and unnatural character, and displayed a better taste in the garden of his little villa, at Twickenham; crowds followed him, and practice went before theory. (See Horace Walpole's ***History of Modern Taste in Gardening.***) This style, however, was also carried to excess. All appearance of regularity was rejected as hurtful to the beauty of nature, and it was forgotten, that if in a garden we want nothing but nature, we had better leave gardening altogether. This extreme prevailed, particularly after the Oriental and Chinese style had become known. What in nature is dispersed over thousands of miles, was huddled together on a small spot of a few acres square—urns, tombs; Chinese, Turkish, and New Zealand temples; bridges, which could not be passed without risk; damp grottoes; moist walks; noisome pools, which were meant to represent lakes; houses, huts, castles, convents, hermitages, ruins, decaying trees, heaps of stones;—a pattern-card of every thing strange, from all nations under heaven, was exhibited in such a garden. Stables took the shape of palaces, kennels of Gothic temples, &c.; and this was called nature! The folly of this was soon felt, and a chaster style took its place. At this point we have now arrived.

The art of gardening, like every other art, is manifold; and one of its first principles, as in architecture, is to calculate well the means and the objects. Immense cathedrals and small apartments, long epics and little songs, all may be equally beautiful and perfect, but can only be made so by a proper regard to the character of each. Thus the climate, the extent of the grounds, the soil, &c., must determine the character of a garden. Aikin justly observes, that nothing deviates more from nature than the imitation of her grand works in miniature. All deception ceases at the first view, and the would-be magnificent garden appears like a mere baby-house. Let the character of the agreeable, the sublime, the awful, the sportive, the rural, the neat, the romantic, the fantastic, predominate in a garden, according to the means which can be commanded. This is not so easy as might appear at first, and it requires as much skill to discover the disposition which should be made of certain grounds, as to carry it into effect; but, if such skill were not required, gardening would not be an art. Another principle, which gardening has in common with all the fine arts, is, that it is by no means its highest aim to imitate reality, because reality will always be better than imitation. A gardener ought to study nature, to learn from her the principles and elements of beauty, as the painter is obliged to do; but he must not stop there. As another general remark, we would observe, that the true style of gardening lies between the two extremes. It is by no

means a reproach to a garden, that it shows the traces of art, any more than it is to a drama. Both, indeed, should follow nature; but, in respect to the fine arts, there is a great difference between a free following of nature and a servile copy of particular realities.

Gari, in *commerce;* an imaginary specie, or nominal coin, used in many parts of the East Indies, equal to about 4000 rupees.

Garlic. This vegetable has a strong, penetrating odour, and pungent, acrid taste. It differs from the onion only by being more powerful in its effects.—In warm climates, where garlic is produced with considerably less acrimony than in cold ones, it is much used, both as a seasoning and as a food. When bruised and applied to the skin, it causes inflammation, and raises blisters. In the south of Europe, particularly in Spain, it is very much used, entering into the composition of almost every dish, not only among the common people, but among the higher classes of society; and it is every where prized by epicures. At all times, however, there has been much contrariety of opinion as to its value; for we find it admired by some nations, and detested by others, as by the ancient Greeks. Its cultivation is easy, being a hardy plant, growing in almost every kind of soil; and it is reproduced by planting the radical or floral bulbs.—Its medicinal virtues have also been much celebrated. It not only forms an excellent expectorant, but has been administered in a great variety of diseases, as hysteria, dropsy, cutaneous eruptions, obstructions, &c. The juice of garlic is a strong cement for broken glass. Snails, worms, and the larvæ of insects, as well as moles, and other vermin, may all be driven away by placing preparations of garlic in or near their haunts. The virtues of garlic are most perfectly and readily extracted by spirit of wine.

Garnet. See Natural History.

Garrison; a body of men stationed in a fortress, city, village, intrenchment, &c., for the sake of defending it. The rules, by which the proper force of a garrison is determined, differ. Some reckon, for every five feet in circumference, one man; others, for every bastion, 200 soldiers. Vauban assigns, if the fortress is provided with ravelins, and a covered-way, for every bastion, 500 or 600 men; for every hornwork, or other large outwork, 600 more; for every detached redoubt, 150 men; for every detached fort, 600 to 800, according to its extent. The cavalry is fixed by him in the proportion of one-tenth of the infantry

Garter, Order of the, in *heraldry;* a military order of knighthood, instituted by King Edward III. It consisted originally of 26 knights companions, generally princes and peers, whereof the king is the sovereign or chief. The number was increased to 32 in 1786. The college of the order is in the royal castle of Windsor, with the chapel of St. George, and the chapter house, erected by the founder. The habit and ensign of the order are a garter, mantle, cap, George, and collar. The garter, mantle, and cap were assigned to the knights companions by the founder, and the George and collar by Henry VIII. The garter is worn on the left leg, between the knee and the calf, and is enamelled with this motto: *Honi soit qui mal y pense* (literally, Evil to him that evil thinks).—The origin of the order is variously related. "A vulgar story," says Hume, "prevails, but is not supported by any ancient authority, that, at a court ball, Edward's (III.) mistress, commonly supposed to be the Countess of Salisbury, dropped her garter; and the king, taking it up, observed some of the courtiers to smile, as if they thought that he had not obtained this favour by accident; upon which he called out, *Honi soit qui mal y pense.*" Other accounts, equally uncertain, are given.

Gas is the name of every permanently elastic aëriform substance. Gas is distinguished from steam, or vapour, by this circumstance—that vapours are raised from fluids by heat, and are again condensable by cold into the same fluid form; but gases are obtained from the substances containing them only by chemical decomposition, whether this be spontaneous or artificial.

All air was considered as a uniform, homogeneous substance, till about the middle of the last century, when it was discovered that there existed at least as great differences among aëriform as among fluid substances. Accustomed, however, to regard the atmosphere as the only air, philosophers called these new forms of air *gases*, to distinguish them from it. This name had been already introduced to the sciences by Van Helmont, and was derived from the old German word *giesch*. Every gas consists of some ponderable base, or substance, which is maintained in its aëriform state by means of heat or caloric; thus all gases possess common properties of elasticity, &c., which they derive from the last substance; and also each one its distinguishing or peculiar characters, derived from the substance constituting its base. Each kind of gas has also its own peculiar and uniform specific gravity, or weight, although they are all several hundred times lighter than water. The density of all gases is, like that of air, proportioned to the pressure to which they are subjected; and, like air, they expand with the application of heat, and are rendered more dense by its abstraction. (For a description of the various gases, see the articles in their alphabetical order.)

Gas-lighting. The producing from coal an aëriform fluid capable of furnishing a pure and brilliant light, and conveying it to a distance of many miles from the reservoir where it is generated, may justly be considered as one of the proudest triumphs of practical chemistry. Not that the illumination with carburetted hydrogen gas is the exclusive property of the present age; for we find the Guebre at Baku falling down to worship the element of fire in the form of this gas many centuries back. Strictly speaking, we believe that Mr. Winsor was the first who practically applied gas to the illumination of streets and houses; and it is painful to find that neither he nor his family, after having expended a large fortune in bringing it into public use, met with any proper national requital. That coal evolves a permanently elastic and inflammable aëriform fluid, seems first to have been experimentally ascertained by the Rev. Dr. Clayton; and a brief account of his discovery is published in the *Philosophical Transactions* for the year 1739.

The following is an extract from his paper:—"I got some coal, and distilled it in a retort in an open fire. At first there came over only phlegm, afterwards a black oil, and then likewise a spirit arose, which I could no ways condense; but it forced my lute or broke my glasses. Once, when it had forced my lute, coming close thereto, in order to try to repair it, I observed that the spirit which issued from it caught fire at the flame of the candle, and continued burning with violence, as it issued out in

a stream, which I blew out and lighted again alternately for several times. I then had a mind to try if I could save any of this spirit, in order to which, I took a turbinated receiver, and putting a candle to the pipe of the receiver, whilst the spirit arose, I observed that it catched flame, and continued burning at the end of the pipe, though you could not discern what fed the flame. I then blew it out and lighted it again several times; after which I fixed a bladder, squeezed and void of air, to the pipe of the receiver. The oil and phlegm descended into the receiver; but the spirit, still ascending, blew up the bladder. I then filled a good many bladders therewith, and might have filled an inconceivable number more, for the spirit continued to rise for several hours, and filled the bladders almost as fast as a man could have blown them with his mouth; and yet the quantity of coals distilled was inconsiderable. I kept this spirit in the bladders a considerable time, and endeavoured several ways to condense it, but in vain. And when I had a mind to divert strangers or friends, I have frequently taken one of these bladders, and pricking a hole therein with a pin, and compressing gently the bladder near the flame of a candle till it once took fire, it would then continue flaming till all the spirit was compressed out of the bladder; which was the more surprising, because no one could discern any difference in the appearance between these bladders and those which are filled with common air. But then I found that this spirit must be kept in good thick bladders, as in those of an ox, or the like; for, if I filled calves' bladders therewith, it would lose its inflammability in twenty-four hours, though the bladders became not relaxed at all."

The mode of manufacturing gas is simple, and may easily be understood. The coal to be subjected to destructive distillation is placed in an iron retort or oven, and, a fire being applied beneath, gas is speedily driven off. The gas thus obtained is very impure, so that it becomes necessary to pass it through lime-water, and also to condense the tar, both of which processes are performed before it reaches the gasometer or reservoir.

Mr. Peckston, in his work on coal gas, states, that a chaldron of Newcastle Wall's End coal will yield 10,000 feet, supposing it decomposed under the most advantageous circumstances; 2 cwt. will therefore yield about 750 feet. At Edinburgh, 2 cwt. of Parrot coal yield, on an average, 860 feet of gas. According to Mr. Neilson, engineer, Glasgow, 2 cwt. of Lesmahago coal will produce 1008 cubic feet of gas, allowing four and a half each pound. Mr. Dewy, in a paper in the *Annals of Philosophy*, asserts, that at Liverpool Mr. King considers it good economy to procure 7000 feet from a ton of Wigan Orral coal, making it only 700 feet from 2 cwt., or very little more than 3 feet per pound. He has stated also, that, at Glasgow, 1200 feet are procured from 2 cwt. of cannel-coal, which is considerably above that mentioned by Mr. Neilson. From these various statements, the general conclusion has been drawn, that 2 cwt. of good coal ought to yield about 1000 feet of gas.

Carburetted hydrogen gas may be procured from a variety of substances. The Wall's End coals appear best fitted for the purpose; but we may briefly give the result of some very interesting experiments made in the laboratory of the Royal Institution with a variety of bodies.

1. The retort was charged with four pounds of coal. The quantity of gas amounted, after having passed the purifiers, to twenty cubic feet. The coke remaining in the retort weighed 2 lbs. 8.7 ozs.

The heating power of the gas flame was compared with that of a wax candle, by ascertaining the time required by each to raise two ounces of water, in a thin copper vessel, from 55° to 212°. The flames were made as similar in dimensions as possible, and so placed that their joints just touched the bottom of the vessel. The heating power of the candle being assumed as = 1, that of the coal gas flame was = 1.5.

2. Four pounds of the dried wood of the common willow yielded sixteen cubical feet of gas, and fourteen ounces of charcoal remained in the retort. The gas burned with a very pale blue flame, was unfit for the purpose of illumination, and contained no olefiant gas.

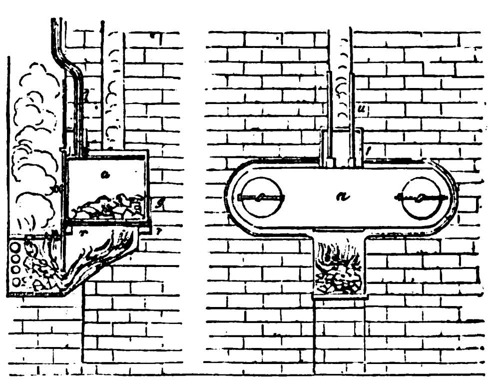
3. Four pounds of the wood of the mountain ash afforded fifteen cubical feet and a half of gas, and thirteen ounces and a half of charcoal. The flame was very pale and blue.

4. Four pounds of white birch-wood gave fourteen cubical feet of gas, and twelve ounces of charcoal. The flame similar to 2 and 3.

5. Four pounds of hazel-wood yielded thirteen cubical feet and a half of gas, and twelve ounces and a half of charcoal. Its heating power was = 1.2. It burned with a better flame than 2, 3, and 4; but the intensity was not sufficient for any useful purpose of illumination.

6. Four pounds of writing-paper gave eighteen cubical feet of gas; and the remaining charcoal, which beautifully retained the form and texture of the paper, weighed eleven ounces and a half. The heating power of the gas was = 1.6. It burned with a flame nearly approaching in illuminating power to that of coal gas.

These experiments, along with others which it is thought unnecessary to notice, prove that the gas from woods is not fit for the purposes of illumination.



In the above wood-cut a representation is given of a domestic gas apparatus, for the generation of gas, which will fully illustrate the general process. If the gas is to be made from resin, a quantity of coke, or even broken bricks, are first introduced into the box *a*. This is intended merely to increase the heated surface within the box. The fire is then lighted in the grate in the ordinary way, as it may

be employed for cooking or heating the apartment while the process is going on. A portion of the heated air and flame passes into the chamber *r*, and as such beneath the box *a*; it then proceeds up the flue *u*. The melted resin passes down the tube *f*, and proceeds direct to the gasometer by the other tube placed by its side.

If, instead of resin, it be advisable to employ coal for producing the gas, it will be necessary to remove the circular caps of iron each time the retort is charged. The trouble also of purifying the gas is considerable, so that for domestic purposes, or in a small establishment, it is most advisable to employ the resin or oil. The decomposition of oil is in fact no more than what we are constantly doing in the common lamp, which owes its light and heat to the application of flame to the wick, which afterwards serves to elevate new portions by capillary attraction, each succeeding portion being decomposed by the flame with which it is brought in contact.

In the *Plate* Gas-Lighting, we furnish a graphic illustration of the interior of a large gas-works, with the men engaged in charging the retorts, &c. The smoke and vapour issuing from the various furnaces and heated coke effectually prevent objects being distinguished at any considerable distance from the observer; so that the glare from the furnaces is thus rendered still more terrific. The small pipes serve to convey the gas to the great iron main leading to the purifying apparatus.

Mr. Taylor contrived a very compact apparatus for generating gas from oil; but, owing to the expense of the material, it has never been very generally adopted.

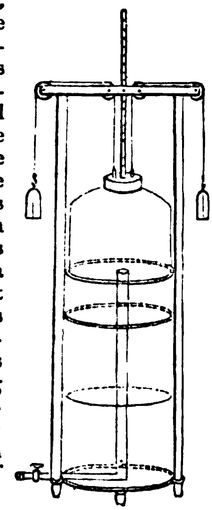
The apparatus for generating gas from common resin is shown at the top of the same plate. The resin, mixed with a little turpentine, is placed in the upper vessel, *a*, and the waste heat from the chimney serves to reduce it to a semi-fluid state. This vessel is divided into two portions by a wire-gauze screen at *b*, through which the melted resin percolates to *c*, so that it may be drawn off at the stop-cock. Here it is received by a funnel, and, descending by the syphon, enters the retort, *d*. The decomposition of the resin is effected before it reaches the condensing vessel, *e*. The condenser serves to retain the turpentine which is not acted upon, and the permanently elastic gas passes along by the pipe *f*, and is conveyed to the gasometer by the pipe *h*.

The turpentine is all collected in the tanks at *g* and *i*, and may be employed any number of times.

An apparatus similar to that now described was employed in the London Institution; and the Editor is enabled to state, from his own observation, that one hundred weight of brown resin usually produced about 1200 feet of gas, which required no subsequent purification.

Gasometer; an instrument for containing gas, which might with more propriety be called a *gas-holder*. One of the most simple gasometers is represented in the accompanying cut. It is made of tinned iron, the surfaces of which are japanned, and consists of two principal parts—a vessel, somewhat bell-shaped, which is designed to contain the gas, and a cylindrical vessel of rather greater depth, in which the former is placed, and which is designed to contain the water by which the gas is confined.

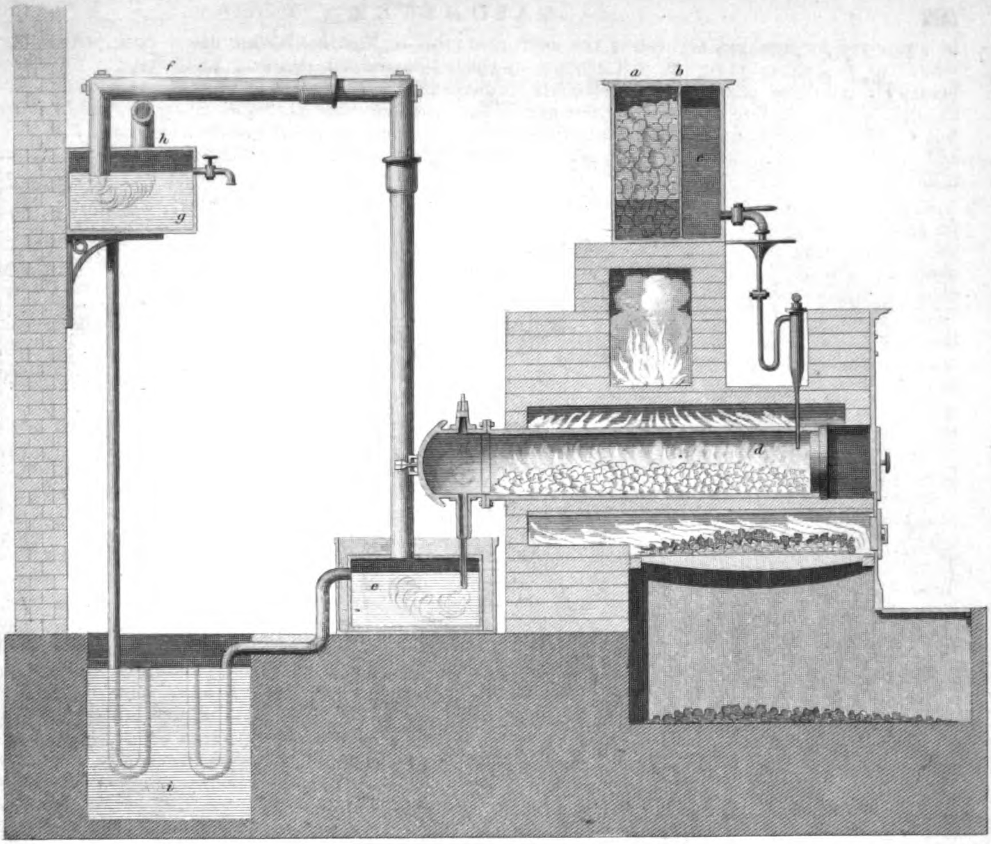
To diminish, however, the quantity of water, this cylindrical vessel has a cone within it, also of japanned tinned iron, adapted to the shape of the gas-holder, so that this latter, when pushed down, slides between this and the cylindrical vessel, and a small quantity of water fills up the space between them. The vessel designed to contain the gas is suspended by cords hung over pulleys, to which weights are attached, so as to counterpoise it. From a stop-cock at the under part of the apparatus, there runs a tube under the cylinder, which rises and passes through the cone, the opening by which it passes being soldered so as to be air-tight: it terminates by an open mouth at the upper part of the bell-shaped iron vessel. This tube, at the part where

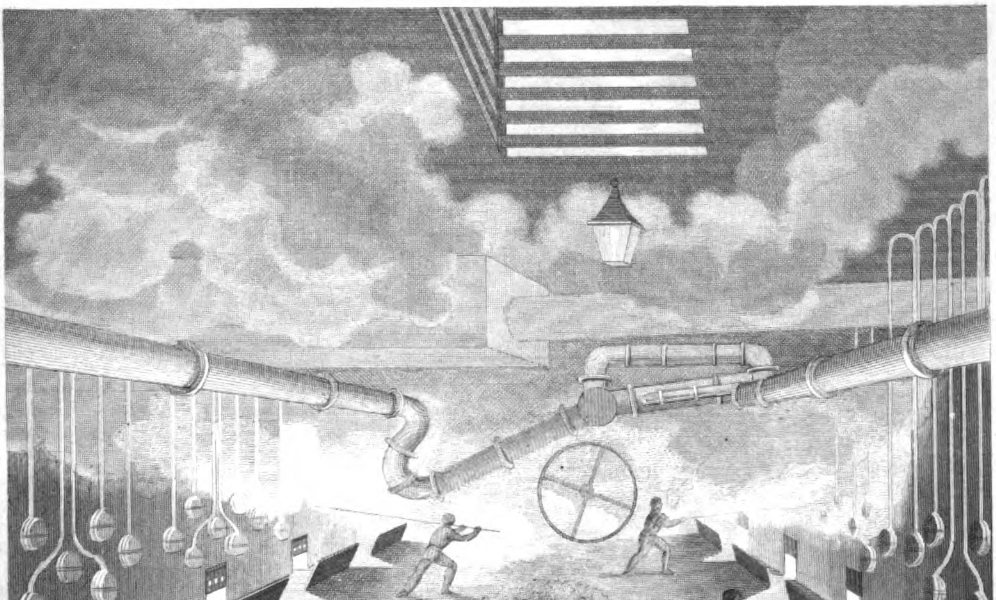


it is bent at right angles, to ascend as has been described, is, in some cases, connected with another, which also runs under the bottom, and ascends on the outside, terminating in a stop-cock; so that from the one stop-cock to the other through the gas-holder, there is an uninterrupted passage. When the instrument is to be used, the stop-cock is opened, and the vessel pressed down; a sufficient quantity of water being in the outer cylinder, the air of the vessel is forced out by the pressure, and its place is occupied by the water in which it is thus immersed. When this is effected, the stop-cock is closed; and now, if we wish to introduce any gas into the apparatus, a bent funnel, the mouth of which is placed in a vessel of water, is attached to the tube of the second stop-cock, and this stop-cock is opened. If the extremity of a retort, or of a tube, conveying gas, terminate below the orifice of the funnel, the gas will rise along the tube, and will ascend to the top of the gas-holder, and this, being counterpoised, will, as the gas enters, rise in the water, until it is filled, a quantity of water remaining around the mouth of it, by which the air is confined. When the gas is to be expelled, the second stop-cock is closed, and the other opened, a flexible tube is adapted to it, and the gas-holder being pressed down, either by the hand or by its own weight from the removal of the counterpoising weights, a stream of gas issues from the extremity of a flexible tube, and may be transferred into a jar, or be applied to any other purpose, and its quantity may be measured by the instrument being graduated by a scale marked on a brass rod.

For experiments on gases which require much accuracy, mercury must be substituted for water, and the internal cone, to which we have alluded, then becomes valuable on the score of economy. The experiments may be performed by means of it on a tolerably large scale, although the necessary quantity of mercury to fill the gasometer, &c., is comparatively small. The mercurial apparatus, however, is too costly, and too easily put out of order, to be accepted with welcome among the generality of the cultivators of chemical science.

GAS MANUFACTURE.

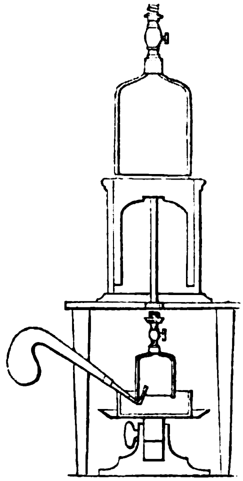




INTERIOR OF A GAS HOUSE.

Drawn by Charles Blunt. London Published by William Orr Paternoster Row. Sept. 1835. Engraved by J. Dower.

Beneath is a representation of the bell of the gasometer, made of glass, furnished with a cock at the top, and able to contain 34 ounces Troy of distilled water. The divisions of capacity, determined by actual measurement, are marked on the glass. Still lower is a section of two cylinders of cast-iron, the outward one screwed upon the solid internal one, which is made to project at its lower extremity, and furnished with a male screw, to work into a female screw with which the lower end of the external cylinder is furnished. The space between these is so adjusted as to be almost filled up by the substance of the glass bell when dropped into it, so that the quantity of mercury necessary to fill up that space is proportionally small. The internal cylinder has a conducting tube up through its axis, the lower end of which is furnished with a female screw answering to the male screw of the cock of the small receiver. This receiver is made of glass, and open at bottom. When used, it is screwed into its place, and rests upon a small cup or cistern of mercury, in which the beak of a retort, furnished with a bent glass tube, may be introduced under the receiver. At the bottom is a section of a wooden stand upon which the cast-iron cylinders are supported, having an opening through the top to permit the cock of the receiver to be joined to the conducting tube of the internal iron cylinder. The cistern is adjusted to hold a given quantity of air.



GASKET; a sort of plaited cord, fastened to the sail-yards of a ship, and used to furl or tie up the sail firmly to the yard by wrapping it round both.

GASTRIC; that which relates to digestion.

GASTRIC JUICE; a fluid of the utmost importance in the process of digestion. It does not act indiscriminately on all substances; nor is it the same in all animals; nor does it continue always of the same nature, even in the same animal, changing according to circumstances. It acts with a chemical energy in dissolving food; attacking the surface of bodies, and uniting to the particles of them. It operates with more energy and rapidity the more the food is divided; and its action is increased by a warm temperature. The food is not merely reduced to very minute parts; its taste and smell are quite changed; its sensible properties are destroyed; and it acquires new and very different ones. This fluid does not act as a ferment; it is a powerful antiseptic, and even restores flesh already putrefied.

GASTRIC SYSTEM comprehends all the parts of the body which contribute to digestion. *Gastric disorders* are those in which the digestion particularly is deranged. As the precepts of health, with regard to eating and drinking, are so often transgressed, the quality of the food itself often bad, the gastric system composed of many parts, and much affected by the influence of the external temperature, gastric disorders must necessarily be frequent. Their symptoms are, want of appetite, a bitter and disagreeable taste, a furred tongue, frequent and unpleasant rising from the stomach, a sense of weight and oppression in the stomach, looseness or costiveness, &c. From the close connection of the organs of digestion with the other parts of the body, gastric disorders are often combined with others, as with fever.

GASTRONOMY; the science of eating and drinking. The gastronomy of the Romans was the most gross and luxurious, as that of the French is the most refined and delicate, combined with the rules of health and social merriment. (See the Paris *Almanach des Gourmands*. The new series, from 1825, contains songs by Béranger and others.)

GAUZE, in *commerce;* a thin, transparent stuff, sometimes woven of silk, and sometimes of thread and worsted. Gauzes are either plain or figured. The latter are worked with flowers of silver or gold on a silk ground, and are chiefly imported from China. Gauzes of excellent quality have, of late years, been manufactured at Paisley.

GELATINE, in *chemistry,* is one of the constituent parts of animal substances, and may be obtained by repeatedly washing the fresh skin of an animal in cold water, afterwards boiling it, and reducing it to a small quantity by slow evaporation, and allowing it to cool. It then assumes the form of jelly, and becomes hard and semi-transparent. It is a principal ingredient both of the solid and fluid parts of animals, and is employed in the state of glue, size, and isinglass.

Gelatine is used in a new kind of bread, called *pain animalisé,* now manufactured in Paris. It having been found that the gelatine of bones used for soups was exceedingly nutritious, it was imagined that if this gelatine could be introduced into bread from potato flour, which is much less nutritious than wheaten flour, the former would be equally pleasant, and even more nutritive than wheaten bread. The experiment has been tried with great success; and beautiful loaves of bread, made in this way, are now sold in Paris at a much lower price than bread from wheat flour. The gelatine is so purified as to impart no unpleasant flavour, and the potato bread, thus manufactured, is as agreeable as it is wholesome. As a cheap, nutritious, and useful article of food for the poor, the potato bread thus made is unequalled. A large quantity of the biscuit sent out with the African expedition to Algiers was prepared in this way.

GEMS, or PRECIOUS STONES, are sometimes found of regular shapes and with a natural polish, and sometimes of irregular shapes and with a rough coat. The first sort may be considered as of the pebble kind, and are said to be found near the beds of rivers, after great rains; the others are found in mines, and in the clefts of rocks. The gems of the first sort were what the ancients most usually engraved upon. These are commonly called *intaglios;* and they are mostly of a long, oval figure, inclining to a point at each end, convex as well on the engraved face as on the others, with a ridge running from end to end on the under side, which is hereby, as it were, divided into two faces; both which are also, though not so distinctly, parted from the upper face by another ridge running quite round the oval.

The stone most commonly found engraved is the beryl. The next is the emerald; and then the jacinth. The chrysolite is very rarely found engraved, as are also the crystal, or Oriental pebble, the garnet,

and the amethyst. The following is a general list of what are usually called *precious stones:*—the beryl, red, yellow, or white; emerald, green; jacinth, of a deep tawny red; chrysolite, of a light grass-green; crystal, or Oriental pebble, of a silvery white; garnet, of a deep red claret colour; amethyst, purple; diamond, white; ruby, red or crimson-coloured; emerald, of a deep green; aqua marina, of a bluish sea-green, like sea-water; topaz, of a ripe citron yellow; sapphire, of a deep sky-blue, or of a silver white; cornelian, red or white; opal, white and changeable; vermilion-stone, more tawny than the jacinth. All these stones are more or less transparent. The following are all opaque:—the cat's eye, brown; red jasper, called also *thick cornelian*, of the colour of red ochre; jet, black; agates of various sorts; blood-stone, green, veined or spotted with red and white; onyx, consisting of different parallel strata, mostly white and black; sardonyx, of several shades of brown and white; agate-onyx, of two or more strata of white, either opaque or transparent; alabaster, different strata of white and yellow, like the agate-onyx, but all opaque; toad's eye, black; turquoise, of a yellowish blue, inclining to green; lapis-lazuli, of a fine deep blue. Of most of the species beforementioned, there are some of an inferior class and beauty. These are commonly called, by jewellers, *Occidental stones*. They are mostly the produce of Europe, and found in mines or stone quarries; and are so named in opposition to those of a higher class, which are always accounted Oriental, and supposed to be produced only in the East.

The onyx, sardonyx, agate-onyx, alabaster of two colours or strata, as also certain shells of different coats, were frequently engraved, by the ancients, in relief; and these sorts of engravings are commonly called *cameos*. They also sometimes ingrafted a head, or some other figure in relief, of gold, upon a blood-stone. Besides which there are some antiques, mostly cornelians, that are covered with a stratum of white. This stratum has by some been looked upon as natural, but it was really a sort of coat of enamel that was laid on, in the same way as two surfaces of glass are made to adhere by the aid of heat in the beautiful incrustations of the present day. The ancients engraved most of their stones, except the onyx and the sardonyx, just as they were found; their natural polish excelling all that can be given by art; but the beauty of the several species of onyx could be discovered only by cutting. The merit of intaglios and cameos depends on their *erudition*, as it is termed, or the goodness of the workmanship, and the beauty of their polish.

The antique Greek gems are most esteemed; and, next to them, the Roman ones of the times of the higher empire. Lapidaries employ a considerable quantity of diamond in powder, which they use with steel instruments, to divide pebbles and precious stones. The small pieces of diamond, of which the powder is made, are worth 28 shillings a carat. The use of the diamond in this way is very extensive. Had nature withheld the diamond, the pebble, the agate, and a variety of other stones, would have been of little value, as no other substance is hard enough to operate upon them. In this way, rock crystal, from Brazil, is divided into leaves, and ground and polished with diamond dust for spectacles and other optical instruments.

The great value of the precious stones has led to artificial imitations of their colour and lustre, by compositions in glass. In order to approximate as near as possible to the brilliancy and refractive power of native gems, a basis, called a *paste*, is made from the finest flint glass, composed of selected materials, combined in different proportions, according to the preference of the manufacturer. This is mixed with metallic oxides capable of producing the desired colour. A great number of complex processes are in use among manufacturers of these articles.

A method is sometimes resorted to for taking the impressions and figures of antique gems, with their engravings, in glass, of the colour of the original gem. Great care is necessary in the operation, to take the impression of the gem in a very fine earth, and to press down upon this a piece of proper glass, softened or half melted at the fire, so that the figures of the impression made in the earth may be nicely and perfectly expressed upon the glass. The yellowish tripoli has been found best adapted for this purpose.

GEM-SCULPTURE; the glyptic art, or lithoglyptics; the art of representing designs upon precious stones, either in raised work (*cameos*), or by figures cut into or below the surface (*intaglios*). The former method may have been practised at a very early period, and probably had its origin with the Babylonians, who worshipped the heavenly bodies, and were accustomed to wear figured talismans, which served as symbols of their influences. From them the custom of wearing engraved stones passed to the Hebrews. According to others, this art originated in India. The Egyptians cut the hardest kinds of stones. The custom of wearing cut stones as seal rings appears to have been general among the Greeks in the time of Solon. One of the earliest artists in this branch of whom mention is made is Mnesarchus, the father of the philosopher Pythagoras, consequently a contemporary of that Theodorus of Samos who engraved the ring of Polycrates, of which such wonderful stories are told by the ancients. These ancient works were probably *intaglios;* the artist made use of the lathe, the *maxium*, the *ostracitis*, the diamond point, and diamond powder.

Whether the Egyptian *scarabæi*, of which many specimens are seen in the British Museum, and the Græco-Etruscan imitations of them, are the most ancient specimens of this interesting art, may be doubted on account of the form of the stones (cut into the shape of beetles). Yet the specimens of the early period of the art are so rare, that we have not sufficient data for fixing on any class as prior to that just mentioned. The flourishing period of the *glyptic art* seems to have been the age of Alexander the Great; but we are able to judge of the works of Pyrgoteles, Apollonides, and Cronius only from tradition, as there are no works of these masters extant. Pyrgoteles was distinguished for works in relief; and from his time the art may have risen, gradually, to that degree of perfection of which we possess such rich specimens. The artists, some of whose names we learn from their works themselves (of whom Gr. Clarac has given a list in his *Description des Antiques du Musée Royal de France*, Paris, 1820), took the master-pieces of sculpture for their subjects and models. Under the Roman emperors, in particular, this was very common.

The names of Dioscorides, Apollonides, Aulos, Hyllos, Cneius, Solon, remind us of the most perfect works in this branch of art. But the works of greatest

value which have come down to us—the onyx, in the chapel at Paris, the apotheosis of Augustus in Vienna, the onyx, at the Hague, representing the apotheosis of the emperor Claudius, Achilles lamenting Patroclus, the head of Julius Cæsar—these, and the Brunswick vase, and the Trivulcian and Neapolitan cups, bear no distinguished names.

Names of Greek composition were frequently put on engraved stones in the fifteenth century, when the patronage of the Medici revived the taste for gems and dactyliothecæ, which had so powerfully promoted this branch of art under the later Roman emperors. Pompey consecrated the dactyliotheca of Mithridates, as a votive offering, in the capitol; Julius Cæsar, six tablets, with six gems, in the temple of Venus. At a later period, the collections of Herodes Atticus, of Vespasian, &c., were celebrated; yet this general taste was not able to preserve the art from decline. We find proofs of this degeneracy in the times of the later emperors, in the numerous class of gems called *abraxas* and *abraxides*, in some rare works of the Byzantine period, and in some artificial gems at an early period of the Christian era. From the time of Gallienus, these marks of degeneracy are particularly striking. As no use could be made of the material of these works, gems continued to be highly prized, even in the times of the greatest barbarism, and served to ornament the shrines of saints, royal badges, and ceremonial dresses, and thus passed safely through the ages of destruction and ignorance, in which the finest statues were valued as materials for mortar or for building, down to ages which could appreciate their value.

If we may judge from the remains which have come down to us, engraved gems seem to have been more common in Byzantium and Constantinople than in the West. The stone with the head of Richilde, the wife of Charles the Bold, is a relic of a period of which hardly any other works of art remain, except, perhaps, a few on religious subjects. The earliest gem-engraver of modern times is Vittore Pisanello, who lived at Florence about the year 1406. Among the Germans, Daniel Engelhard, of Nuremberg, was the earliest. He died in 1512. The discovery of some fine specimens in Italy, particularly at Florence, and the display of gems by the emperor Palæologus, at the council of Florence, in 1438, were perhaps the original cause of the taste of the Medici for engraved stones. The popes and that family were the first patrons of this art in modern times.

A Florentine artist, by the name of *John* (generally called, on account of his great skill, *Giovanni delle Corniole*), distinguished himself in this early period of the modern art. There are but few gems which can be ascribed to him, with any confidence, besides the famous cornelian in the Florentine museum, with the portrait of Savonarola, bearing the inscription *Hieronymus Ferrariensis ordinis prædicatorum, propheta, vir et martyr*. This stone, which must have been engraved later than 1498, is given in *Agincourt's Sculpture* (tab. 48, number 82). Contemporaries and rivals of Giovanni were Nanni di Prospero dalle Carniole, in Florence, whom Francesco Salviati directed in his works, and Domenico Compagnie (*dei camei*), a Milanese, whose portrait of Ludovico Sforza, called *Moro*, cut in a ruby, is still preserved in the Florentine museum. After Bernardi (*delle Corniole*), Valerio Vicentino (under Leo X.) rendered himself famous as a gem-engraver.

This art found patrons in all the Italian princes; the number of artists constantly increased, and the sphere of their art was extended. The names of the artists, however, are not generally known, because they were rarely put upon the stones. Many gems, too, are still concealed in the cabinets of the wealthy or the treasuries of princes. Until these are as accurately described as those of the Ambrosian collection, it will be difficult to obtain a complete general view. Subjects of antiquity were treated by these artists in preference, and with such ability that it often requires the skill of the most accomplished connoisseur to distinguish them from genuine antiques. The dispute concerning the famous seal ring of Michael Angelo is well known. It is not improbable that this cornelian is the work of Pietro Maria de Pescia, as the figure of the fisherman in the exergue may indicate that artist, who, with Michelino, belonged to the age of Leo X.—(Fiorillo, *Essays* vol. ii., page 188.)

In order to give the gems more completely the appearance of antiques, some artists engraved their names in Greek, but with so little knowledge of the language that they sometimes betrayed themselves by this artifice. To this time we must ascribe the gems with the name *Pyrgoteles*, which Fiorillo endeavours to prove were the works of an Italian of Greek descent (Lascaris). The art of engraving was also applied to glass and gold. The crystal box of Valerio Belli, the most skilful and industrious artist in this branch during the 16th century, deserves particular mention. It was intended by Clement VII. as a present to Francis I., when Catherine of Medici went to Marseilles in 1533. At present it is in Florence. Drawings of it are to be found in *Agincourt's Sculpture* (table 43) and in *Cicognara* (ii., table 87).

The Milanese particularly distinguished themselves, as the wealth of the principal citizens of Milan enabled them to patronise this art. Jacopo de Trezza—the same artist who, in 1564, executed for Philip II. the famous tabernacle of the Escurial—made the first attempts at engraving on the diamond, in Milan. The greatest cameo work of modern times is the stone in the Florentine museum, seven inches in breadth, upon which Cosmo, Grand Duke of Tuscany, with his wife Eleonore and seven children, are represented. A Milanese, John Anthony de Rossi, who was a contemporary of the Saracchi family (about 1570), is the artist. The Saracchi were five brothers, and the crystal helmet of Albert of Bavaria is a proof of their skill.

The first traces of gem-engraving in Germany are found in the 14th and 15th centuries, in Nuremberg and Strasburg. Natter, himself a distinguished artist in this branch, has given an account of his predecessors in his *Traité de la Méthode Antique de graver en Pierre Fine, comparée avec la Méthode Moderne* (London, 1755). Natter himself, Pichler, and Marchant, are considered as the restorers of this art in that country. Facius and Hecker are also esteemed. It is still practised with great success by several artists, and by Polish Jews with particular skill, but only for coats of arms. France and England have not produced any first-rate gem-engravers. The most distinguished artist of the age is, perhaps, Berini, a native of Rome, now at Milan, who, with Cervara and Giromelli, at Rome, and Putinati, at Milan, has produced the finest works in recent times.

GENERAL, in *military affairs;* he who commands in chief.

General is also used for a particular march or beat of drum, being the first which gives notice for the infantry to be in readiness to march.

GENERATED is used by mathematicians to denote whatever is formed by the motion of a point, line, or surface. Thus a line is said to be *generated* by the motion of a point; a surface, by the motion of a line; and a solid, by the motion of a surface. The same term is also sometimes used in a similar sense in arithmetic and algebra. Thus 20 is said to be generated by the two factors 4 and 5, or 2 and 10; $a\,b$, of the factors a and b, &c.

GENERATOR. See STEAM-ENGINE.

GENEVA, or GIN; a hot, fiery spirit, much used by the lower classes of people as a dram, and unquestionably as injurious to their bodily health as to their moral character. A liquid of this kind was formerly sold in the apothecaries' shops, drawn from the juniper-berry; but distillers have now completely supplanted the trade of the apothecary, and sell it under the name of *geneva* or *gin*, of which, it is believed, juniper-berries make no part of the composition. It is usually composed of malt and other spirits. A better sort is said to be drawn off, by a slow fire, from juniper-berries, proof-spirits, and water, in the proportion of three pounds of berries to four gallons of water and ten of spirit. The celebrated Holland geneva is manufactured chiefly at a village near Rotterdam, from the same materials, French brandy being used instead of malt spirits.

GENS D'ARMES; the name originally given in France to the whole body of armed men *(gens armata)*, but, after the introduction of standing armies, to a body of heavy-armed cavalry, which composed the chief strength of the forces, and was provided with helmets, cuirasses, pistols, horses protected with armour, &c. After the time of Louis XIV. they had only pistols, helmets, and swords. Part of them were under the immediate orders of the king, part composed the first body of the French cavalry. The latter consisted of men of rank, and belonged to the troops of the royal household. At the revolution this body was broken up. The name *gens d'armes* has since been given to a corps which succeeded the former *(maréchaussée)*, employed in the protection of the streets. It was composed of infantry and cavalry, and belonged to the military, but served principally to enforce the police regulations.

Under Napoleon it was a distinction to serve in this corps, because only veterans were employed in it; but the members were hated in a high degree, because they had to execute so many odious orders. When the German nations rose against Napoleon, *gens d'armes* were killed wherever they were found. The Bourbons retained this corps; and they are said to have behaved generally with great moderation; yet the people continued to hate them as the instruments of tyranny. On one occasion, however,—the massacre of the Rue St. Denis—they seemed to take revenge for all the insults they had suffered so long. This hastened Villèle's downfal. August 16, 1830, a royal ordinance abolished the gens d'armes, and established a new body called the *municipal guard* of Paris, to consist of 1443 men, under the direction of the prefect of police.

GEOCENTRIC; what relates to the centre of the earth, or is considered as if from the centre of the earth. (See HELIOCENTRIC.)

GEOCYCLIC MACHINE; a machine intended to represent in what manner the changes of the seasons, the increase and decrease of the days, &c., are caused by the inclination of the axis of the earth to the plane of the ecliptic, at an angle of 66½ degrees, and how the axis, by remaining parallel to itself in all points of its path round the sun, invariably preserves this inclination.

GEOMETRY (from the Greek, signifying the *art of measuring land*); the branch of pure mathematics which treats of the magnitudes of dimensions. It is divided into *longimetry*, occupied exclusively with lines, *planimetry*, occupied with planes or surfaces, and *stereometry*, treating of solid bodies, their contents, &c., and the doctrine of the functions of the circle, and its application to certain figures, formed by lines, from which originate (*a.*) *trigonometry*, (*b.*) *tetragonometry*, (*c.*) *polygonometry*, (*d.*) *cyclometry*, which teach us to find, from the dimensions of certain parts of a figure, those of certain other parts, by which particular altitudes and depths are to be measured.

Geometry is divided into *elementary* and *applied*. The former, or theoretical geometry, treats of the different properties and relations of the magnitudes of dimension in theorems and demonstrations, which the latter applies to the various purposes of life in problems and solutions. Geometry is taught in different ways; as, for instance, by diagrams, which is called *constructive geometry*, or by the application of algebra to dimension, which is called *analytical geometry*.

The invention of this important science is ascribed by some to the Chaldæans and Babylonians; by others to the Egyptians, who were obliged to determine the boundaries of their fields, after the inundation of the Nile, by geometrical measurements. According to Cassiodorus, the Egyptians either derived the art from the Babylonians, or invented it after it was known to them. Thales, a Phœnician who died 548 B. C., and Pythagoras of Samos, who flourished about 520 B. C., introduced it from Egypt into Greece. The discovery of five regular geometrical bodies, the *cube*, *tetraedron*, *octaedron*, *icosaedron*, and *dodecaedron*, is ascribed to the latter. He distinguished himself particularly by the invention of the theorem which is called from him the *Pythagorean*, and, on account of his important improvements, has received the name of *magister matheseos*.

In elementary geometry, Euclid of Alexandria is particularly distinguished. About a hundred years after him, Archimedes extended the limits of geometry by his measure of the sphere and the circle. Aristæus, and, at a later period, Apollonius of Perga (who flourished 260—230 B. C.), did much for the higher geometry. In Italy, where the sciences first revived after the dark ages, several mathematicians were distinguished in the 16th century; the French, and particularly the Germans, followed. Justus Byrge laid the foundation of logarithms, and, according to some, was the inventor of the proportional circle; others ascribe the invention to Galileo. Reinerus Gemma Frisius, who died in 1555, invented the instrument used in surveying, called the *plain table*. Simon Stevin of Bruges applied the decimal measure to geometry.

In 1635, Bonaventus Carallieri opened the path to the higher geometry of infinites; and, in 1684, Leibnitz advanced the science by the invention of the

differential calculus, and Newton by the theory of the fluxions. Robert Hook, who died in 1703, was the first who considered the influence of the refraction of light in measuring heights. Ludolph of Ceuln, or Cologne, who died at Leyden in 1610, discovered the proportion between the diameter and the circumference of the circle. In recent times, the French have been most distinguished in geometry, and have produced the best elementary works for schools in this branch; as, for instance, those of Legendre and Mongé. The Germans have a number of elementary works on geometry, some of which are excellent. Among the most approved modern works on the elements of geometry are those of Euclid, as translated by Simson, Ingram, and Playfair, and the treatises of Professor Leslie, and M. Legendre.

From a perusal of the above history of the progress of geometrical science, it must be evident that any attempt at a complete consecutive treatise on the subject would swell the present article to a most inconvenient length, and indeed that it would be completely incompatible with the general arrangement of the work. We purpose, therefore, confining ourselves to a series of useful definitions, which may be said to form the alphabet of the science. Problems illustrative of the application of geometry to the useful arts will be found under the various articles which need mathematical illustration.

A *point* has neither length, breadth, nor thickness. From this definition it may easily be understood that a mathematical point cannot be seen nor felt; it can only be imagined. What is commonly called a point, as a small dot made with a pencil or pen, or the point of a needle, is not in reality a mathematical point; for, however small such a dot may be, yet, if it be examined with a magnifying glass, it will be found to be an irregular spot, of a very sensible length and breadth; and our not being able to measure its dimensions with the naked eye arises only from its smallness. The same reasoning may be applied to every thing that is usually called a point, as even the point of the finest needle appears like that of a poker when examined with the microscope.

A *line* is length, without breadth or thickness.—What was said above of a point is also applicable to the definition of a line. What is drawn upon paper with a pencil or pen is not, in fact, a line, but the representation of a line. For, however fine you may make these representations, they will still have some breadth. But, by the definition, a line has no breadth whatever; yet it is impossible to draw any thing so fine as to have no breadth. A line, therefore, can only be imagined. The ends of a line are points.

Parallel lines are such as always keep at the same distance from each other, and which, if prolonged ever so far, would never meet. (See *fig.* 1.)

Fig. 3.

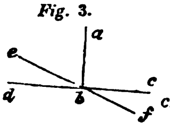


Fig. 2.

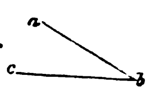

Fig. 1.

A *right line* is what is commonly called a *straight* line, or one that tends every where the same way.

A *curve* is a line which continually changes its direction between its extreme points.

An *angle* is the inclination or opening of two lines meeting in a point. (*Fig.* 2.)

The lines *a b*, and *b c*, which form the angle, are called the legs or sides; and the point *b*, where they meet, is called the *vertex* of the angle, or the *angular point*. An angle is sometimes expressed by a letter placed at the vertex, as the angle *b*, *fig.* 2; but most commonly by three letters, observing to place in the middle the letter at the vertex, and the other two at the end of each leg, as the angle *a b c*.

When one line stands upon another, so as not to lean more to one side than to another, both the angles which it makes with the other are called *right angles*, as the angles *a b c* and *a b d*, *fig.* 3; and all right angles are equal to each other, being all equal to 90°; and the line *a b* is said to be *perpendicular* to *c d*.

Beginners are very apt to confound the terms *perpendicular* and *plumb* or *vertical line*. A line is vertical when it is at right angles to the plane of the horizon, or level surface of the earth, or to the surface of water, which is always level. The sides of a house are vertical. But a line may be perpendicular to another, whether it stands upright or inclines to the ground, or even if it lies flat upon it, provided only that it makes the two angles formed by meeting with the other line equal to each other; as, for instance, if the angles *a b c* and *a b d* be equal, the line *a b* is perpendicular to *c d*, whatever may be its position in other respects.

When one line, *b e* (*fig.* 3), stands upon another, *c d*, so as to incline, the angle *e b c*, which is greater than a right angle, is called an *obtuse* angle; and that which is less than a right angle is called an *acute* angle, as the angle *e b d*.

Two angles which have one leg in common, as the angles *a b c*, and *a b e*, are called *contiguous* angles, or *adjoining* angles; those which are produced by the crossing of two lines, as the angles *e b d* and *c b f*, formed by *c d* and *e f* crossing each other, are called *opposite* or *vertical* angles.

A *figure* is a bounded space, and is either a *surface* or a *solid*.

A *superficies*, or *surface*, has length and breadth only. The extremities of a superficies are lines.

A *plane*, or *plane surface*, is that which is every where perfectly flat and even, or which will touch every part of a straight line, in whatever direction it may be laid upon it. The top of a marble slab, for instance, is an example of this, which a straight-edge will touch in every point, so that you cannot see light any where between. Water furnishes another striking example of what is termed a plane surface, although strictly speaking it is a curved one, as the effects of gravity must in every case produce a rounding of the upper side.

A *curved surface* is that which will not coincide with a straight line in any part. Curved surfaces may be either convex or concave.

A *convex surface* is when the surface rises up in the middle, as, for instance, a part of the outside of a globe.

A *concave surface* is when it sinks in the middle, or is hollow, and is the reverse of convex.

A surface may be bounded either by straight lines, curved lines, or both these.

Every surface bounded by straight lines only is called a *rectilinear figure*.

Three is the fewest number of sides that a rectilinear figure can have, and it is then called a *triangle*.

Triangles are of different kinds, according to the *lengths of their sides*.

An *equilateral triangle* has all its sides equal, as *a b c*, *fig.* 4.

Fig. 7.

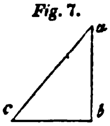

Fig. 5.

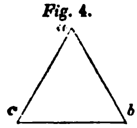
Fig. 6.

Fig. 4.



An *isosceles triangle* has two equal sides, as *d e f*, *fig.* 5.

A *scalene triangle* has all its sides unequal, as *g h i*, *fig.* 6.

Triangles are also denominated according to the *angles they contain.*

A *right-angled* triangle is one that has in it a right angle, as *a b c*, *fig.* 7.

A triangle cannot have more than one right-angle. The side opposite to the right-angle *b*, as *a c*, is called the *hypothenuse*, and is always the longest side.

An *obtuse-angled* triangle has one obtuse angle, as *fig.* 8.

Fig. 11.

Fig. 10.

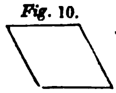


Fig. 9.

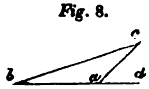
Fig. 8.



An *acute-angled* triangle has all its angles acute, as *fig.* 4.

An isosceles, or a scalene triangle, may be either right-angled, obtuse, or acute.

Any side of a triangle is said to *subtend* the angle opposite to it; thus *a b*, *fig.* 7, subtends the angle *a c b*.

If the side of a triangle be drawn out beyond the figure, as *a d* (*fig.* 8), the angle *a*, or *c a b*, is called an *internal* angle, and the angle *c a d*, or that without the figure, an *external* angle.

Figures with four sides are called *quadrilateral* figures. They are of various denominations, as their sides are equal or unequal, or as all their angles are right angles or not.

Every four-sided figure whose opposite sides are parallel is called a *parallelogram*. Provided that the sides opposite to each other be parallel, it is immaterial whether the angles are right or not. *Fig.* 9, 10, 11, and 12, are all parallelograms.

Fig. 15.

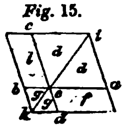


Fig. 14.

Fig. 13.

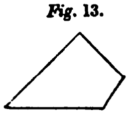

Fig. 12.

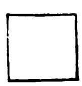

When the angles of a parallelogram are all right angles, it is called a *rectangular parallelogram*, or a *rectangle*, as *fig.* 11 and 12.

A rectangle may have all its sides equal, or only the opposite sides equal. When all its sides are equal, it is called a *square*, as *fig.* 12.

When the opposite sides are parallel, and all the sides equal to each other, but the angles not right angles, the parallelogram is called a *rhombus*, as *fig.* 10.

A parallelogram having all its angles oblique, and only its opposite sides equal, is called a *rhomboid*, as *fig.* 9.

When a quadrilateral or four-sided figure has none of its sides parallel, it is called a *trapezium*, as *fig.* 13; consequently every quadrangle or quadrilateral which is not a parallelogram is a trapezium.

A *trapezoid* has only one pair of its sides parallel, as *fig.* 14.

A *diagonal* is a right line drawn between any two angles that are opposite in a quadrangle, as *i k*, *fig.* 15. In parallelograms the diagonal is sometimes called the *diameter*, because it passes through the centre of the figure.

Complements of a parallelogram. If any point, as *e* (*fig.* 15), be taken in the diagonal of a parallelogram, and through that point two lines are drawn parallel to the sides, as *a b*, *c d*, it will be divided into four parallelograms, *d d*, *l*, *f*, *g g*. The two divisions, *l*, *f*, through which the diameter does not pass, are called the complements.

Figures having more than four sides are called *polygons*. If the sides are all equal, they are called *regular polygons*: if they are unequal, they are called *irregular polygons*.

A pentagon is a polygon of five sides.
A hexagon has six sides.
A heptagon seven sides.
An octagon eight sides.
A nonagon nine sides.
An undecagon eleven sides.
A duodecagon twelve sides.

When they have a greater number of sides, they are called polygons of thirteen sides, of fourteen sides, and so on.

Base of a figure is the side on which it is supposed to stand erect, as *d e* (*fig.* 16).

Fig. 19.

Fig. 18.

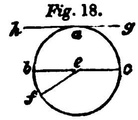

Fig. 17.

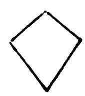

Fig. 16.

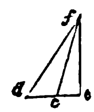

Altitude of a figure is its perpendicular height from the base to the highest part, as *c f* (*fig.* 16).

Area of a plane figure, or other surface, means the quantity of space contained within its boundaries, expressed in square feet, yards, or any other superficial measure.

Similar figures are such as have the same angles, and whose sides are in the same proportion, as *fig.* 17.

Equal figures are such as have the same area or contents.

A *circle* is a plane figure, bounded by a curve line returning into itself, called its *circumference*, *a b c*, (*fig.* 18), every where equally distant from a point, *e*, within the circle, which is called the *centre*.

The *radius* of a circle is a straight line drawn from the centre to the circumference, as *e f* (*fig.* 18). The radius is the opening of the compass when a circle is described; and consequently all the radii of a circle must be equal to each other.

A *diameter* of a circle is a straight line drawn from one side of the circumference to the other through the centre, as *c b* (*fig.* 18). Every diameter divides the circle into two equal parts.

A *segment* of a circle is a part of a circle cut off by a straight line drawn across it. This straight line is called the *chord*. A segment may be either equal to, greater, or less, than a *semicircle*, which is a segment formed by the diameter of the circle, as *c e b*, and is equal to half the circle.

A *tangent* is a straight line drawn so as just to touch a circle without cutting it, as *g h* (*fig.* 18). The point *a*, where it touches the circle, is called

the *point of contact*. And a tangent cannot touch a circle in more points than one.

A *sector* of a circle is a space comprehended between two radii and an arc, as *i k* (*fig*. 19).

The circumference of every circle, whether great or small, is supposed to be divided into 360 equal parts, called *degrees;* and every degree into 60 parts, called *minutes;* and every minute into 60 *seconds*. To measure the inclination of lines to each other, or angles, a circle is described round the angular point as a centre, as *i k* (*fig*. 19); and according to the number of degrees, minutes, and seconds, cut off by the sides of the angle, so many degrees, minutes, and seconds, it is said to contain. Degrees are marked by °, minutes by ′, and seconds by ″; thus an angle of 48 degrees, 15 minutes, and 7 seconds, is written in this manner, 48° 15′ 7″.

A *solid* is any body that has length, breadth, and thickness: a book, for instance, is solid—so is a sheet of paper; for, though its thickness is very small, yet it has some thickness. The boundaries of a solid are *surfaces*.

Similar solids are such as are bounded by an equal number of similar planes.

A *prism* is a solid of which the sides are parallelograms, and the two ends or bases are similar polygons, parallel to each other. Prisms are denominated according to the number of angles in the base, *triangular* prisms, *quadrangular*, *pentangular*, and so on, as *fig*. 20, 21, 22, 23.

Fig. 23.

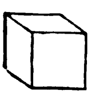

Fig. 22.

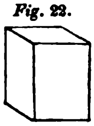

Fig. 21.

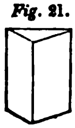

Fig. 20.

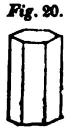

If the sides are perpendicular to the plane of the base, it is called an *upright* prism; if they are inclined, it is called an *oblique* prism.

When the base of a prism is a parallelogram, it is called a *parallelopipedon*, as *fig*. 22 and 23. Hence a parallelopipedon is a solid terminated by six parallelograms.

When all the sides of a parallelopipedon are squares, the solid is called a *cube*, as *fig*. 23.

A *rhomboid* is an oblique prism, whose bases are parallelograms.

Fig. 26.

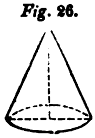

Fig. 25.

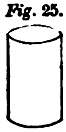

Fig. 24.

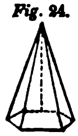

A *pyramid* (*fig*. 24) is a solid bounded by, or contained within, a number of planes, whose base may be any rectilinear figure, and whose faces are triangles terminating in one point, commonly called the *summit* or *vertex* of the pyramid.

When the figure of the base is a triangle, it is called a *triangular pyramid;* when the figure of the base is quadrilateral, it is called a *quadrilateral pyramid*, &c.

A pyramid is either *regular* or *irregular*, according as the base is regular or irregular.

A pyramid is also *right* or *upright*, or it is *oblique*. It is *right*, when a line drawn from the vertex to the centre of the base is perpendicular to it, and *oblique* when this line inclines.

A *cylinder* is a solid (*fig*. 25) generated or formed by the rotation of a rectangle about one of its sides, supposed to be at rest; this quiescent side is called the *axis* of the cylinder. Or it may be conceived to be generated by the motion of a circle in a direction perpendicular to its surface, and always parallel to itself.

A cylinder is either *right* or *oblique*, as the axis is perpendicular to the base or inclined.

Every *section* of a right cylinder taken at right angles to its axis is a *circle;* and every section taken across the cylinder, but oblique to the axis, is an *ellipsis*.

As a circle may be considered to be a polygon of an infinite number of sides, so a cylinder may be conceived as a prism having such polygons for bases.

A *cone* is a solid (*fig*. 26), having for its base a circle, and its sides a convex surface, and terminating in a point, called the *vertex* or *apex* of the cone. It may be conceived to be generated by the revolution of a right-angled triangle about its perpendicular.

A line drawn from the vertex to the centre of the base is the *axis* of the cone.

When this line is perpendicular to the base, the cone is called an upright or *right* cone; but, when it is inclined, it is called an *oblique* cone.

If a cone be cut through the axis from the vertex to the base, the section will be a *triangle*.

If a right cone be cut by a plane at right angles to the axis, the section will be a *circle*.

If a cone be cut oblique to the axis, and quite across from one side to the other, the section will be an *ellipsis*, as *fig*. 27.

Fig. 30.

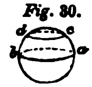

Fig. 31.

Fig. 29.

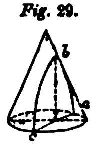

Fig. 28.

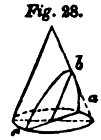

Fig. 27.

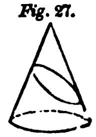


A section of a cylinder made in the same manner is also an ellipsis; and this is easily conceived; but it does not appear so readily to most people, that the oblique section of a cone is an ellipsis: they frequently imagine that it will be wider at one end than the other, or what is called an *oval*, which is of the shape of an egg. But that this is a mistake any one may convince himself, by making a cone, and cutting it across obliquely: it will be then seen that the section, in whatever direction it is taken, is a regular ellipsis; and this is the case whether the cone be right or oblique; except only in one case in the oblique cone, which is when the section is taken in a particular direction, which is called *sub-contrary* to its base.

When the section is made parallel to one of the sides of the cone, as *fig*. 28, the curve *a b c*, which bounds the section, is called a *parabola*.

When the section is taken parallel to the axis, as *fig*. 29, the curve is called an *hyperbola*.

The curves which are formed by cutting a cone in different directions are called *conic sections*, and have various properties, which are of great importance in astronomy, gunnery, perspective, and many other sciences.

A *sphere* is a solid terminated by a convex surface, every point of which is at an equal distance from a point within called the *centre*. *Fig*. 30.

It may be conceived to be formed by making a semicircle revolve round its diameter. This may be illustrated by the process of forming a ball of clay by the potter's wheel, a semicircular mould being used for the purpose. The diameter of the semicircle round which it revolves is called the *axis* of the sphere.

The ends of the axis are called *poles*.

Any line passing through the centre of the sphere, and terminated by the circumference, is a *diameter* of the sphere.

Every section of a sphere is a circle; every section taken through the centre of the sphere is called a *great circle*, as *a b*, *fig.* 30; every other is a *lesser circle*, as *c d*.

Any portion of a sphere cut off by a plane is called a *segment;* and, when the plane passes through the centre, it divides the sphere into two equal parts, each of which is called a *hemisphere*.

A *conoid* is a solid produced by the circumvolution of a section of the cone about its axis; and consequently may be either an *elliptical conoid*, a *hyperbolical conoid*, or a *parabolical conoid*. When it is elliptical, it is generally called a *spheroid*. These solids are also called *ellipsoid, hyperboloid*, and *paraboloid*.

A *spheroid* is a solid (*fig.* 31) generated by the rotation of a semi-ellipsis about the transverse or conjugate axis; and the centre of the ellipsis is the centre of the spheroid.

The line about which the ellipsis revolves is called the *axis*. If the spheroid be generated about the conjugate axis of the semi-ellipsis, it is called a *prolate spheroid*.

If the spheroid be generated by the semi-ellipsis by revolving about the transverse axis, it is called an *oblong spheroid*.

Every *section* of a spheroid is an *ellipsis*, except when it is perpendicular to that axis about which it is generated, in which case it is a circle.

All sections of a spheroid parallel to each other are similar figures.

A *frustum* of a solid means a piece cut off from the solid by a plane passed through it, usually parallel to the base of the solid; as the frustum of a cone, a pyramid, &c.

There is a *lower* and an *upper* frustum, according as the piece spoken of does or does not contain the base of the solid.

Ratio is the proportion which one magnitude bears to another of the same kind, with respect to quantity; and is usually marked thus, A : B.

Of these, the first is called the *antecedent*, and the second the *consequent*.

The *measure* or *quantity* of a ratio is conceived by considering what part of the consequent is the antecedent; consequently it is obtained by dividing the consequent by the antecedent.

Three magnitudes or quantities, A, B, C, are said to be *proportional* when the ratio of the first to the second is the same as that of the second to the third; thus, 2, 4, 8, are proportional, because 4 are contained in 8 as many times as 2 in 4.

Four quantities, A, B, C, D, are said to be *proportional* when the ratio of the first, A, to the second, B, is the same as the ratio of the third, C, to the fourth D.

They are usually written A : B : : C : D, or, if expressed in numbers, 2 : 4 : : 8 : 16.

Of *three* proportional quantities, the middle one is said to be a *mean proportional* between the other two; and the last a *third proportional* to the first and second.

Of *four* proportional quantities, the last is said to be a *fourth proportional* to the other three, taken in order.

Ratio of equality is that which equal numbers bear to each other.

Inverse ratio is when the antecedent is made the consequent, and the consequent the antecedent. Thus if 1 : 2 : : 3 : 6; then *inversely*, 2 : 1 : : 6 : 3.

Alternate proportion is when antecedent is compared with antecedent, and consequent with consequent. Thus if 2 : 1 : : 6 : 3; then, by *alternation*, 2 : 6 : : 1 : 3.

Proportion by *composition* is when the antecedent and consequent, taken as one quantity, are compared either with the consequent or with the antecedent. Thus if 2 : 1 : : 6 : 3; then by *composition* $2+1 : 1 : : 6+3 : 3$, and $2+1 : 2 : : 6+3 : 6$.

Divided proportion is when the difference of the antecedent and consequent is compared either with the consequent or with the antecedent; thus if 3 : 1 : : 12 : 4; then by *division* $3-1 : 1 : : 12-4 : 4$, and $3-1 : 3 : : 12-4 : 12$.

Continued proportion is when the first is to the second as the second to the third; as the third to the fourth; as the fourth to the fifth; and so on.

Compound ratio is formed by the multiplication of the several antecedents and the several consequents of ratios together, in the following manner:—

If A be to B as 3 to 5, B to C as 5 to 8, and C to D as 8 to 6; then A will be to D as $\frac{3\times5\times8}{5\times8\times6}=\frac{120}{240}=\frac{1}{2}$; that is, A : D : : 1 : 2.

GERMAN SCHOOL OF PAINTING. With the decline of the Eastern empire, Byzantine art and science were spread over Europe. In Germany as well as in Italy, and particularly on the Rhine, the gloomy, dry style of the Byzantine school prevailed. Many pictures of this early period have been preserved; they are distinguished by a gold ground and ornamented glories made of silver, shaded with brown; their colours are bright, without harmony and without life; their outlines are delicate. In Austria, the Abbot Reginbald, founder of the monastery of Murr, awakened a taste for the arts about 900. He was followed by St. Thiemo, at Saltzburg, and, in particular, by Gisela, the wife of St. Stephen of Hungary. Louis the Debonnaire received costly works of art as presents from the Byzantine emperor. The Silesian and Moravian princes kept up a friendly connection with the Greek emperors. St. Methodius, the missionary to the Sclavonians (863), is mentioned as a distinguished painter; and the first Silesian bishops, who came from Italy, made use of sacred pictures for spreading their religion.

In the churches of St. Elizabeth and St. Barbara, at Breslau, there are some remarkable pictures of this period. The church of St. Bernardine contains the Hedwig's Table, upon which events in the life of St. Hedwig are painted, in 32 compartments. In Bavaria, Theodore II. endeavoured to propagate Christianity by the instrumentality of St. Rupert, whom he called from Worms (696); and here also the introduction of painting followed that of Christianity. The arts were most zealously cultivated in the monasteries of the Benedictines. Alfred and

Ariram, the latter a monk of St.-Emmeran, were the most distinguished Bavarian artists of this time. In Franconia, we find the first traces of art in the time of St. Bruno, who (1042) rebuilt the cathedral at Würtzburg. The Emperor Henry II., and his Queen St. Cunigund, were patrons of the arts.

In the monastery of Heilsbronn, there are several paintings of the time of St. Otho, Bishop of Bamberg, who died 1139. Nuremberg deserves to be mentioned as a place where painting and carving in wood were early carried to a high degree of perfection. The churches of the Virgin Mary and St. Sebaldus contain some very old pictures. In Suabia, the monastery of Hirschau was early celebrated for its treasures of art. Many monasteries and churches contained manuscripts with excellent miniatures. In Augsburg, Culm, and Nördlingen, there were skilful artists at a very early period. From the time of Charlemagne, many branches of art were practised in the cities on the Upper Rhine. Mentz, Treves, and particularly Cologne, were the most distinguished seats of German art at that time. The period from 1153 to 1330 was not less celebrated for German art than for German poetry and language. The oldest German school of painters, which far surpassed the later school of Nuremberg in purity of style, depth of expression, and quiet loveliness, flourished at Cologne during this period. Their pictures are generally on wood, which was first covered with a layer of chalk, and then with linen, upon which was laid another ground of chalk and bole, and, lastly, a gold ground. They preserve their colours with a remarkable freshness. The most celebrated of these works is the altar-piece in the cathedral of Cologne, which some ascribed to William of Cologne, others to Peter Calf.

The collections of Wallraf, Boisserée, and Bettendorf, contain the finest specimens of this period. In Frankfort, the painters on glass were distinguished. The most poetical of the old German masters, Hemmelink, whose works are full of boldness and fire, lived in this period. The builder of the Wartburg, Count Louis II., was a patron of the arts in Hesse and Thuringia. The old church of St. Elizabeth, at Marburg, contains many early monuments. Henry I. protected the arts in Saxony. There were distinguished artists in the abbeys of Corvey, Minden, Hildesheim, and Osnabrück, in Lower Saxony and Westphalia. The number of the monuments of art, from this early time, is incredible. They are found every where in Germany, not only in altar-pieces in the churches and monasteries, but also in elegantly ornamented manuscripts, in chasubles embroidered by the nuns, in needle-work, and altar-cloths.

The Emperor Charles IV. invited many skilful painters to Bohemia, where, as early as 1348, a corporation of painters was formed. In 1450, a distinguished school of painters began to flourish in Breslau, still earlier than that of Nuremberg. Werner of Tegernsee was distinguished for his excellent glass-paintings. In the 15th century, Gleissmyller, Maier, Mächselkircher, Füterer, and Zawnhack were celebrated Bavarian painters; in Nuremberg, Hans Traut, Kulenbach, Hans Bäuerlein, and Michael Wohlgemuth, the latter the teacher of Albert Durer, were eminent.

A second period of German art begins with Albert Durer, who was esteemed by Raphael (from 1471 to 1528). After having studied in the school of Wohlgemuth, he travelled through Germany, the Netherlands, and Italy. Martin Schön may be called the *German Perugino;* his works bear a great resemblance to those of that master. The paintings of Luke Cranach (born 1470, died 1553) have acquired a particular interest from containing the portraits of the most distinguished persons of his time. The Holbein family produced many skilful painters; the most distinguished was Hans Holbein (born 1495, died 1554).

Most of the principal painters of the German school, in the 16th century, were at the same time engravers. Their ideas were truly poetical, but sometimes too allegorical. The execution is finished, but they are deficient in beauty of forms and correctness of outline. Their glowing colours, the expressive attitudes of the figures, the piety which breathes in their countenances, and, particularly, the spirit of their landscapes and back-grounds, must strike every eye. In the 17th and in the first half of the 18th century, art in Germany was in a low state. The German school hardly survived Albert Durer and Holbein. The difficult and artificial only was admired; nature and spirit gave way to laboured ornament. The causes of this decline were the Reformation and the thirty years' war. A melancholy period of imitation followed, in which the taste of Louis XIV. and the exaggerated modern Italian school was the standard. Although Mengs cannot be considered as a restorer of art, at least for Germany, as his plastic principle was entirely opposed to the spirit of painting in general, and, in particular, to the German school, yet he improved the taste of his time by his severe manner. Most of his scholars, however, inclined to a gaudy and often superficial style; but they have produced many pleasing pieces. Among them are Maron, Unterberger, Oser, and Angelica Kaufmann.

William Tischbein, who was born in Hesse, and lived for a long time in Eutin, is among the best artists of our time. His taste is pure, his style noble, his imagination creative and poetical; and his sketches from Homer are celebrated. Many young German artists in Rome have imitated the manner of the old German school, even so far as to copy its faults. More extensive information on German painting may be obtained in Fiorillo's *Geschichte der zeichnenden künste in Deutschland und den Niederlanden,* and in Göthe's *Kunst und Alterthum.*

Ghost, Holy, Order of the; an order of male and female hospitallers. Guy, son of William, Count of Montpelier, founded this order, towards the end of the twelfth century, for the relief of the poor, the infirm, and foundlings. He took the vows himself, and gave a rule to the order. Pope Innocent III. confirmed the order in 1198, and founded an hospital in Rome, on which all the hospitals of the order on the Italian side of the Alps were dependent: all north of the mountains were dependent upon that of Montpelier. This order, which was peculiar for the splendour of its heraldic badges and costume at its first foundation, has now retired into a much more Christian degree of usefulness than that of the knights hospitallers, which was founded for nearly similar purposes in crusading times.

Gilding is the art of applying gold-leaf or gold-dust to surfaces of wood, stone, and metals. The Egyptian monuments present numerous traces of the existence of the art in Egypt. The process was nearly the same with that now used. The artists employed

a sort of paste, like that now used in gilding wood, even for gilding metals; but they were also acquainted with the art of applying the gold directly to the substance to be gilt. The Persians were also skilful in the art of gilding, as appears from the ruins of Persepolis. The Greeks and Romans employed gilding for many purposes. The Greeks used to gild the hoofs and horns of victims. The practice of gilding statues prevailed in the infancy of the art of sculpture, and was never entirely dropped by the ancients. The Romans used to gild sweetmeats; and many articles of furniture and utensils which have come down to us are gilt. There are also specimens of gilt glass and metal.

The gilding, which still remains on some ancient bronze monuments, is remarkable for its brilliancy. This is owing, in part, to the great accuracy of the finish, and in part to the thickness of the leaf, which was much greater than that of the leaf used by the moderns. Besides, we must consider that, in the most common way of gilding brass, with an amalgam of gold and quicksilver, the gold is reduced to a state of much greater subdivision than in the leaf—the only state in which the ancients employed it. The account of Pliny shows that they did not fix the leaf merely by the aid of fire, as is now done in gilding metals, but that they first covered the substance, which was then evaporated by heat, in a manner somewhat similar to the modern practice of gilding with amalgam. The ancients carried the practice of gilding to a greater extent than the moderns; they gilded almost all their statues of bronze, wood, or plaster, and frequently those of marble, the ceilings of rooms, and even marble columns, eatables, and victims. The *bracteatores*, or *inauratores*, were in high esteem among them, and enjoyed an exemption from taxes.

In architectural ornaments, gilding may please the eye either from its appearance of richness, or merely from its agreeable colour. The most remarkable examples of gilding, employed with taste and effect, in architecture, are the ceiling of St. Peter's, and that of Santa Maria Maggiore. But artists often fall into the error of mistaking richness of appearance for beauty. The art of gilding, at the present day, is performed either upon metals, or upon wood, leather, parchment, or paper; and there are three distinct methods in general practice: namely, *wash*, or *water-gilding*, in which the gold is spread, whilst reduced to a fluid state, by solution in mercury; *leaf-gilding*, either burnished or in oil, performed by cementing thin leaves of gold upon the work, either by size or by oil; and *japanner's gilding*, in which gold-dust or powder is used instead of leaves.

Gilding on copper is performed with an amalgam of gold and mercury. The surface of the copper, being freed from oxide, is covered with the amalgam, and afterwards exposed to heat till the mercury is driven off, leaving a thin coat of gold. It is also performed by dipping a linen rag in a saturated solution of gold, and burning it to tinder. The black powder thus obtained is rubbed on the metal to be gilded, with a cork dipped in salt-water, till the gilding appears. Iron or steel is gilded by applying gold-leaf to the metal, after the surface has been well cleaned, and heated until it has acquired the blue colour, which at a certain temperature it assumes. The surface is previously burnished, and the process is repeated, when the gilding is required to be more durable. It is also performed by diluting the solution of gold in nitro-muriatic acid, with alcohol, and applying it to the clean surface. This last process has been improved by Mr. Stoddart. A saturated solution of gold in nitro-muriatic acid, being mixed with three times its weight of sulphuric ether, dissolves the muriate of gold, and the solution is separated from the acid beneath. To gild the steel, it is merely necessary to dip it, the surface being previously well polished and cleaned, in the ethereal solution, for an instant, and, on withdrawing it, to wash it instantly by agitation in water. By this method, steel instruments are very commonly gilt.

GIMBALS; the brass rings by which a sea compass is suspended in its box, so as to counteract the effect of the ship's motion, and keep the card horizontal.

GIN. See GENEVA.

GINSENG. The root of this plant has been celebrated for a long time among the Chinese, entering into the composition of almost every medicine used by the higher classes; and, indeed, so highly is it prized as to have received the appellations of "pure spirit of the earth" and "plant that gives immortality." Volumes have been written on its virtues, and recourse had to it in every difficulty. The plant, which is the *panax quinquefolium* of botanists, is herbaceous, about a foot high, upright, and very simple, furnished above with three petiolate leaves, disposed verticillately: these leaves are composed of five unequal leaflets, which are oval, lanceolate, acute, and dentate on the margin: from the centre of the three leaves arises a peduncle, terminated by a small umbel of greenish inconspicuous flowers, which are succeeded by rounded and slightly compressed scarlet berries. It is said to be a native of Tartary, growing wild in a mountainous and wooded region between lat. 39° and 47°, where it is collected with many precautions by the Chinese and Tartars, at the commencement of spring and in the latter part of autumn, and is so rare as to bring three times its weight in silver. An early traveller relates, that the Emperor of China employed, in one year, 10,000 Tartars in procuring this root. From China it is imported into Japan, where it was obtained by the Dutch, who first brought it to Europe. Notwithstanding the extravagant price and high reputation of ginseng in China, it appears to be really a plant of very little efficacy; the taste is sweet and mucilaginous, accompanied with some bitterness, and also slightly aromatic.

GLACIERS. The summits and sides of mountains, above the limit of perpetual snow (see SNOW), are covered with a crust, which is harder than common snow, yet not like common ice. More ice is formed on the sides of mountains than on their summits; but this does not constitute the *glaciers*, properly so called. The glaciers are vast fields of ice, extending from the declivities of the mountains down into the valleys, below the snow-line. They are often horizontal, generally, however, a little inclined.

The ice of the glaciers is entirely different from that of sea or river water. It is not formed in layers, but consists of little grains of congealed snow; and hence, though perfectly clear and often smooth on the surface, it is not transparent. Its fracture is not radiated, like that of sea-ice, but granular. In the numerous fissures, however, the ice near the surface has a greenish, near the bottom a blue cast. Along the edges of the glaciers are the *moraines*, as they are called in Savoy (in Iceland, jökelsgiärde). They consist of an accumulation of earth, which is

often several fathoms high, and, in summer, present the appearance of bottomless morasses, producing no vegetation. It is probable that these *moraines* are produced by the melting of the lower part of the glacier, which always takes place in summer, without which the annual accumulation of snow, in winter, would form an endless crust. The great ice-fields are also continually extending farther down into the valleys, where, in summer, they are at last partially melted by the warmer temperature.

In Lapland, where the sun has less power, glaciers slide down in the region of the Sulitelma, which render the air so cool, that the line of perpetual snow extends as low as 3000 feet above the level of the sea. The descent of the glaciers, which is assisted in summer by the avalanches, is greater or less, according to the inclination of the glacier. This is shown by the changes in the position of large masses of rock around the glaciers. They are evidently pushed along by the ice, and, near the Grindelberg, in Switzerland, it has been found, by examination, that stones have been pushed forward 25 feet in one year. Stones of considerable bulk are also seen in the *moraines* of an entirely different formation from those of the valley, and must therefore have been pushed down from the higher regions in the course of time. As glaciers, in some positions, and in hot summers, decrease, they often also increase for a number of years, so as to render a valley uninhabitable. Their increase is caused partly by alternate thawing and freezing; their decrease, by the mountain rivers, which often flow under them, and thus form an arch of ice over the torrent. Streams are seen at the bottom of the deepest fissures, which, in the Helvetic Alps, are called *dust* or *powder avalanches*, because they consist of newly fallen snow, which is carried by the wind into the depths. There are also, particularly in the Norwegian Alps, *dirt avalanches*, so called, which carry along stones and earth with them, and increase the *moraines* of the glaciers.

In the Tyrol, Switzerland, Piedmont, and Savoy, the glaciers are so numerous that they have been calculated to form altogether a superficial extent of 1484 square miles. There are some glaciers, in Savoy, more than 14 miles long, 2½ miles wide, and from 60 to 600 feet thick. One of the most famous glaciers is the *mere de glace* (sea of ice) in the valley of Chamouni, about 5700 feet above the level of the sea. In France, near Beaume, and in the Carpathian mountains, near Dselitz, are subterraneous glaciers, which never melt, because the sun cannot act upon them. From this account it is evident that there can be no glaciers in the Andes, because the temperature continues the same the whole year between the tropics. The noise which is produced by the opening of fissures in the glaciers is immense, and resembles thunder among the mountains. These fissures are often immediately covered with snow, and are therefore very dangerous to travellers.

Glacis, in *fortification*, is the sloping covering of the outer breastwork along the covered-way, which descends to the level ground, and covers the ditch upon the outside. It must be so placed, that the guns of the fort will rake it at every point.

Glass. This valuable manufacture commenced early. Pliny informs us that Sidon was the first city distinguished for its glass-works, and that the manufacture of glass was not introduced into Rome until the reign of Tiberius. He farther states, that, in the reign of Nero, the art of making vases and cups of a white, transparent glass, was invented. De Pauw is of opinion that the Egyptians carried the art to the highest perfection; and that the glass-works at Diospolis, capital of the Thebaïd, formed the first regular manufactory of this material. The Egyptians, according to the same author, performed the most difficult operations in glass-cutting, and manufactured cups of glass of an astonishing purity, of which kind were those called *alassontes*, supposed to be ornamented with figures in changeable colours. Winckelmann says that the ancients, in general, made much greater use of glass than the moderns. Besides the ordinary utensils, of which a great quantity have been found in Herculaneum, we find many funeral urns constructed of it. Some of the fragments of cups examined by Winckelmann appeared to have been cut; others of raised ornaments having the appearance of being soldered to the surface of the vessels, and bearing marks of the lapidary's wheel on their *facettes*. The ancients also used glass to ornament their rooms; for this purpose, they employed it of various colours, and composed a sort of mosaic of it.

Some blocks of glass, used for paving rooms, have been found of the thickness of a common-sized brick. Winckelmann cites some specimens of mosaic of remarkable beauty and delicacy. One of them represented a bird on a dark and coloured ground. The colours of the bird were very brilliant and various, and the whole effect very soft. The artist had made use of opaque, or transparent glass, according to the exigencies of the case. What was not the least remarkable was, that the reverse offered precisely the same figure, without the slightest difference in the details. A little glass ring, which was in the possession of Sir W. Hamilton, showed the method in which this was performed. The exterior of the ring was blue, and the interior represented a species of rose, of different colours, extending the whole circuit of the ring. As melted glass may be drawn out into an amazingly fine wire, this operation may be performed on pieces of glass, compounded of different colours and melted, the colours preserving the respective layers when wire-drawn. Caylus thinks this was the manner in which these works of art were made. The most valuable remains of the ancients, in glass, are the impressions and casts of sculptured gems, both in sunk and raised work, and the larger works in relief, of which one whole vase has come down to us. The glass casts of intaglios often imitate the veins of different colours in the original. These pastes have preserved the impressions of many beautiful gems which are lost. Of the larger works in relief we have only some fragments: they served as ornaments to the walls of palaces. The most considerable work of this kind is the cameo described by Buonarotti, and preserved in the Vatican: it is an oblong tablet of glass, about 8 inches by 6, representing Bacchus and Ariadne, with two satyrs. But the most beautiful specimens of this art are the vases adorned with figures in relief: they were sometimes transparent, sometimes of different colours on a dark ground, and so delicately executed, that they were hardly to be distinguished from the vases of sardonyx. The Portland Vase is the only one of this sort preserved entire. It was formerly called the *Barberini Vase*, as it belonged to the Barberini palace at Rome. It is about a foot high, and was at first

described as a sardonyx. It is now preserved in the British Museum under the name of the Portland Vase.

Glass is made by melting silicious earth or sand, alkaline substances, and a metallic oxide, at a white heat. The name is an old German word, and is connected with *gleissen* (to shine), and with the English word *glisten*, and even with *glacies* (ice) and *glanz* (splendour). The manufacture of glass is now brought to a high degree of perfection, especially in this country.

The English glass-houses are commonly large conical buildings, from 60 to 100 feet high, and from 50 to 80 feet in diameter. A representation of one is given in our *Plate* of GLASS MANUFACTURE. The furnace is in the middle, over a large vault, which is connected with it by means of an opening. This opening is covered with an iron grate, upon which the fire is made, and it is kept up by the draught of air from the vault. The most important part, however, of the apparatus of the glass-house, is the crucible. These instruments are made from a particular kind of clay, which is found at Stourbridge. This is first pounded fine, then sifted, moistened, and worked into a thick dough. Sometimes old crucibles are used, which are broken into powder, and then mixed with a red clay. Some pots, for bottle and flint glass, are made 40 inches deep and wide. They are from two to four inches in thickness. They remain several days at a white heat, before they are placed in the furnace for use. The basis of glass is *silica*.

When flints or quartz are used, they are first reduced to powder by being heated red hot, and then plunged into cold water. This causes them to whiten and fall to pieces, after which they are ground and sifted. The second ingredient is an alkaline substance, potash or soda. The alkali used is more or less pure, according to the fineness of the glass to be made. Lime is often employed in small quantities; also borax. Of the metallic oxides added in different cases, the deutoxide of lead is the most common. It renders flint-glass more fusible, heavy, and tough, and more easy to be ground and cut, and increases its brilliancy and refractive power. A small quantity of black oxide of manganese renders the glass more transparent; too much gives a purple tinge, which, however, may be destroyed by a little charcoal or wood. Arsenious acid (white arsenic), in small quantities, promotes the clearness of glass; too much of it gives the glass a milky whiteness. Its use in drinking-vessels is not free from danger, if the glass contains so much alkali that any part is soluble in acids. The following are the processes employed in making glass:—

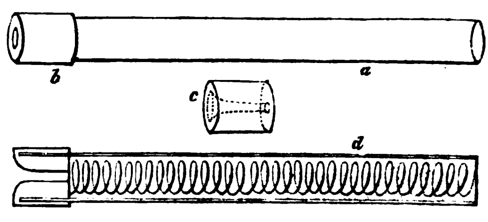
Fritting. The various materials are carefully washed, and, after the extraction of all the impurities, are conveyed to the furnace in pots made of pipe-clay. The produce of this process is called the *frit*, which is again melted in large pots or crucibles, till the whole mass becomes beautifully clear, and the dross rises to the top.

Blowing is the next process, which, in round glass, as phials, drinking-glasses, &c., is thus performed:— The workmen dip the end of long iron pipes, red hot, into the liquid glass, then roll it on a polished iron plate to give it an external even surface; they next blow down the iron pipe, till it enlarges the metal like a bladder, and, if necessary, roll it again on the iron plate, and proceed to form it into a globular form, or any other one required. The glass is then transferred from the blowing-pipe, by dipping the end of another iron rod into the liquid glass, which adheres to the heated rod, and with which the workman sticks it to the bottom of the vessel; then, with a pair of pincers, wetted with water, he touches the neck, which immediately cracks, and, on being slightly struck, separates at the end of the blowing-pipe, and becomes attached to the iron rod. The vessel is next carried up to the mouth of the furnace, to be heated and softened, that the operator may finish it. If the vessel require a handle, the operator forms it separately, and unites it while melting hot, forming it with pincers to the requisite shape and pattern.

We have now to notice a most important improvement in the process of blowing glass. It is effected by what is termed a glass-blower's artificial lungs.

This simple little instrument is the invention of a French workman; it enables the glass-blower to give a blast of any power that he wishes through the pipe or cane, and thereby blow much larger objects than by the lungs, and that with nearly the sharpness of cut glass. This discovery has reduced the price of crystal upwards of 30 per cent., as all melon ribbed glasses, decanters, &c., are now blown as perfectly as if they were cut. The Institute of France decreed M. Montyon's prize of 5000 francs, "for the best invention for preserving the health of workmen," to the inventor.

Sir John Byerley brought one of these instruments from Paris, and exhibited it at the Royal Institution in 1832. The instrument is composed of a tin tube about 15 inches long and 1½ inch in diameter: in this is a spiral spring, in the cup of which is an air-tight piston, about 2 inches long, perforated in the centre. The diameter of the orifice is the same, or rather less, than that of the blowing-cane, to the other end of which the glass is attached. The vitreous matter being placed in the mould in the usual way, instead of blowing through the tube or cane, as formerly, the instrument is applied to the end of it, and pressed smartly down—the spring is compressed, and the air in the instrument forced into the cane, and thence into the object.



a is the instrument ready for work; *b*, the tin cap, which fixes on to the tube with a latch, to keep down the piston, which the spring would otherwise force out. The cap is perforated with a hole rather larger than the diameter of the cane.

The lower figure is a section of the instrument, in which is seen the piston and the spiral spring, *d*. The top of the piston is hollowed off towards the middle, that the cane may be sure to be applied to the orifice. This upper part of the piston is covered with leather, which is oiled, so that the cane pressing upon it no air can escape laterally. A separate view of the mouth is seen at *c*. The instrument is made of tin; and the price in France is half a crown.

GLASS MANUFACTURE.

INTERIOR OF A GLASS HOUSE.

Drawn by Charles Blunt. *London Published by William Orr Paternoster Row* *Engraved by J. Dower*

Annealing is the removing of the glass, after it has been blown or cast, into a furnace whose heat is not sufficiently intense to melt it, and gradually withdrawing the article from the hottest to a cooler part of the annealing chamber, till it is cold enough to be taken out for use. If cooled too suddenly, it is extremely brittle.

Colouring. The different coloured glasses owe their tints to the different metallic oxides mixed with the materials while in a state of fusion. In this manner are made those elegant *pastes*, which so faithfully imitate, and not unfrequently excel, in brilliancy, their originals, the gems of antiquity. The glass, however, for this purpose, is prepared in a peculiar manner, and requires great nicety. It combines purity and durability. *Opaque* glass is made by the addition of the oxide of tin, and produces that beautiful imitation of enamel which is so much admired. Dials for watches and clocks are thus made. The principal sorts of glass may be now described:—

Crown-glass is the best sort of window glass, and differs from the flint-glass in containing no lead, nor any metallic oxide, except manganese, and sometimes oxide of cobalt in minute portions, not as flux, but for correcting the natural colour. This glass is much harder and harsher to the touch than the flint-glass; but, when well made, it is a very beautiful article. It is compounded of sand, alkali, either potash or soda, the vegetable ashes that contain the alkali, and generally a small portion of lime. A small dose of arsenic is often added, to facilitate the fusion. Zaffre, or the oxide of cobalt, with ground flint, is often used to correct the dingy yellow of the inferior sort of crown-glass; and, by adding the blue, natural to glass coloured with this oxide, to convert the whole into a soft light green. One ounce of zaffre is sufficient for 1000 lbs. But when the sand, alkali, and lime are very fine, and no other ingredients are used, no zaffre, or corrective of bad colour, is required. A very fine glass of this kind may be made by 200 parts of pretty good soda, 300 of fine sand, 33 of lime, and from 250 to 300 of the ground fragments of glass. We had formerly in London two kinds of crown glass, distinguished by the places where they were wrought; viz. 1. Ratcliff crown-glass, which is the best and clearest, and was first made at the Bear Garden, on the Bank-side, Southwark, but since at Ratcliff: of this there are twenty-four tables to the case, the tables being of a circular form, about three feet six inches in diameter. 2. Lambeth crown-glass, which is of a darker colour than the former, and more inclining to green.

The following composition has been recommended for the best window or crown-glass: white sand, 60lbs.; purified pearl-ashes, 30 lbs.; salt-petre, 15lbs.; borax, 1lb.; and arsenic, half a pound. If the glass should prove yellow, manganese must be added. A cheaper composition for window-glass consists of 60lbs. of white sand, 25lbs. of unpurified pearl-ashes, 10lbs. of common salt, 5lbs. of nitre, 2lbs. of arsenic, and 1½ oz. of manganese. The common or green window-glass is composed of 60lbs. of white sand, 30lbs. of unpurified pearl-ashes, 10lbs. of common salt, 2lbs. of arsenic, and 2 oz. of manganese. But a cheaper composition for this purpose consists of 120lbs. of the cheapest white sand, 30lbs. of unpurified pearl-ashes, 60lbs. of wood ashes, well burnt and prepared, 20lbs. of common salt, and 5lbs. of arsenic.

The manufacture of the common window-glass, though made by blowing, is conducted differently from that of the flint-glass articles, as it is the object to produce a large, flat, and very thin plate of glass, which is afterwards cut by the glazier's diamond into the requisite shape. Without minutely detailing the several gradations of the process, it may be here mentioned that the workman takes a very large mass of melted glass on his hollow iron rod, and, by rolling it on an iron plate and swinging it backwards and forwards, causes it to lengthen by its own weight into a cylinder, which is made hollow and brought to the required thinness by blowing with a fan of breath, which persons accustomed to the business know how to command. The hollow cylinder is then opened by holding it to the fire, which, by expanding the air confined within it (the hole of the iron rod being stopped), bursts it at the weakest part, and, when still soft, it is opened out into a flat plate by the centrifugal force, and finished by annealing, as usual.

Newcastle glass is of an ash colour, frequently speckled, streaked, and blemished. It is made from white sand, unpurified barilla, common salt, arsenic, and manganese.

The *bottle* or *green glass*, usually made of common sand, lime, and some clay, fused with an impure alkali, is very hard, and resists the corrosive action of all liquids much better than flint-glass: the green colour is owing to the iron: and it is well adapted for chemical vessels.

Flint-glass, the most fusible of any, is used for bottles, utensils intended to be cut and polished, and for various ornamental purposes. The best kind is composed of white silicious sand, pearl-ash, red oxide of lead, nitrate of potash, and the black oxide of manganese. It fuses at a lower temperature than crown-glass, has a beautiful transparency, a great refractive power, and a comparative softness, which enables it to be cut and polished with ease. On this account it is much used for glass vessels of every description, and especially those which are intended to be ornamented by cutting. It is also employed for lenses and other optical glasses. Flint-glass is worked by blowing, moulding, pressing, and grinding. Articles of complex form, such as lamps and wine-glasses, are formed in pieces, which are afterwards joined by simple contact, while the glass is hot. It appears that the red lead used in the manufacture of flint-glass gives up a part of its oxygen, and passes to the state of a protoxide.

Plate-glass, so called from its being cast in plates or large sheets, is the most valuable, and is used for mirrors and the windows of carriages. It is composed of white sand, cleansed with purified pearl-ashes and borax. But, should the metal appear yellow, it is restored to its pellucid transparency by the addition (in equal proportions) of a small quantity of manganese and arsenic. It is cast on a large horizontal table, and all excrescences are pressed out by passing a large roller over the metal. To polish the glass, it is laid on a large horizontal table of freestone, perfectly smooth; and then a smaller piece of glass, fastened to a plank of wood, is passed over the other till it has received its due degree of polish. But, to facilitate this process, water and sand are used, as in the polishing of marble; and, lastly, Tripoli, smalt, emery, and putty, to give it lustre.

Grinding and *polishing* give plate-glass a fine lustre. The grinder takes it rough out of the hands of the caster, and, laying it upon a stone table, to which it is fixed with stucco, he lays another rough glass, half the size of the former, upon it. To the smaller glass a plank is fastened, by means of stucco, and to the whole a wheel, made of hard, light wood, about six inches in diameter, by the pulling of which from side to side, and from end to end, of the glass, a constant attrition is kept up; and, by allowing water and fine sand to pass between the plates, the whole is very finely polished; but, to give the finishing polish, powder of smalt is used. As the upper glass grows smoother, it is taken away, and a rougher one substituted in its stead; and so on till the work is done. Except in the very largest plates, the workmen polish their glass by means of a plank, having four wooden handles to move it; and to this plank a plate of glass is cemented, as above.

Achromatic flint-glass. The excise laws of England have prevented our artists from attempting to melt glass on a proper scale for making lenses for achromatic telescopes; but in France, where no such restrictions exist, numerous attempts have been made to perfect the manufacture of flint-glass for optical purposes; and M. Guinaud's labours have been finally crowned with complete success. The almost total impossibility of procuring flint-glass exempt from striæ, suggested to this artist the construction of a furnace capable of melting two cwt. of glass in one mass, which he sawed vertically, and polished one of the sections, in order to observe what had taken place during fusion. He discovered his metal to be vitiated by striæ, specks or grains, with cometic tails; and, from time to time, as he obtained blocks, including portions of good glass, his practice was to separate them by sawing the blocks into horizontal sections, or perpendicular to their axes. A fortunate accident conducted him to a better process. While his men were one day carrying a block of this glass, on a hand-barrow, to a saw mill which he had erected at the fall of the Doubs, the mass slipped from its bearers, and, rolling to the bottom of a steep and rocky declivity, was broken to pieces.

M. Guinaud, having selected those fragments which appeared perfectly homogeneous, softened them, in circular moulds, in such a manner that, on cooling, he obtained disks that were afterwards fit for working. To this method he adhered, and contrived a way for clearing his glass while cooling, so that the fractures should follow the most faulty parts. When flaws occur in the large masses, they are removed by cleaving the pieces with wedges; then melting them again in moulds, which give them the form of disks; taking care to allow a little of the glass to project beyond one of the points of the edge, so that the optician may be enabled to use that portion of glass in making a prism, which shall give the measure of the index of refraction, and thus obviate the necessity of cutting the lens. The Astronomical Society of London have tried disks of M. Guinaud's flint achromatic glass, which seems entirely homogeneous, and exempt from fault. This material grinds and polishes much easier than the English flint-glass. (For Professor Faraday's improvements in the manufacture of glass for lenses, see LENS.)

Various ornamental forms are given to the surface of glass vessels by metallic moulds. The mould is usually of copper, with the figure cut on its inside, and opens with hinges to permit the glass to be taken out. The mould is filled by a workman, who blows fluid glass into its top. The chilling of the glass, when it comes in contact with the mould, impairs its ductility, and prevents the impression of the figure from being sharp. Some moulds, however, are made in parts, which can be suddenly brought together on the inside and outside of the glass vessel, and produce specimens nearly equal to cut-glass.

Cut-glass, so called, is produced by grinding the surface with small wheels of stone, metal, or wood. The glass is held to the surface of the wheels. The first cutting is with wheels of stone; then with iron, covered with sharp sand or emery; and, finally, with brush wheels, covered with putty. A small stream of water is kept continually running on the glass, to prevent the friction from exciting too much heat.

The physical properties of glass are of the highest importance. One of these is that of preserving its transparency in a considerable heat, and remaining with very little extension. Its expansibility is less affected by heat and cold than that of most other solid substances which have been accurately examined. It may be cut by the diamond, and also by a hot iron, although the latter manner is rather unsafe. Should this plan be resorted to, a pointed iron wire must be employed; and, as soon as the line of division is well indicated, the glass should be moistened with cold water, which causes it to separate.

Drops of Glass, which have been let fall, while melted, into water, commonly called *Prince Rupert's drops*, assume the form of an oval body, terminating in a long slender stem. They are also called *glass tears*. The large part may be struck with a hammer, or filed, without breaking; but, if the stem is broken, the whole flies to pieces.

Glass Galls; a substance which floats upon melted glass, like scum or froth, called by the French *siel*, or *suif de verre*. It is principally alkaline, and attracts moisture from the air, so as even to become fluid. It is chiefly used for soldering silver, stands a strong heat, is a good flux for substances difficult to fuse, and keeps them long in a state of fusion. Potters also use it for glazing.

Glass Threads. The great ductility of glass enables it to be drawn into the finest threads. A piece of glass is held over the flame of a lamp, till it becomes soft: a hook is then fixed into it, and it is drawn out into a thread. The hook being fixed in the circumference of a small revolving cylinder, the glass thread is wound round the cylinder. Réaumur succeeded in obtaining these threads as fine as a spider's web.

Glass Windows. The mode of preparing glass was known long before it was thought of making windows of it. Houses in Oriental countries had commonly no windows in the front, and towards the court-yard they were provided with curtains or a moveable trellis-work; and in winter they were covered with oiled paper. The Chinese made use, for windows, of a very fine cloth, covered with a shining varnish; and, afterwards, of split oyster shells. They had also the art of working out the horns of animals into large and thin plates, with which they covered their windows. In Rome, the *lapis specularis* supplied the place of glass, and, from the description, seems to have been nothing but thin leaves of talc. Rich people had the windows or openings in their baths filled with thin plates of agate or marble. It was hastily concluded

that glass was used for windows in the time of Titus, because fragments of glass plates have been found at Pompeii, which town was destroyed in his reign; but the first certain information of this mode of using glass is to be found in Gregory of Tours, who speaks of the churches having windows of coloured glass in the fourth century after Christ, that is, in the reign of Constantine the Great, when they were to be seen in the church of St. Paolo Fuori le Mura. In France, talc or isinglass, white horn, paper soaked in oil, and thin shaved leather, were used instead of glass. The oldest glass windows at present existing are of the twelfth century, and are in the church of St. Denis: they appear to have been preserved as part of the old church, which was erected before the year 1140, by the Abbot Suger, a favourite of Louis le Gros. Suger had sapphires pounded up and mixed with the glass, to give it a blue colour. Æneas Sylvius accounted it one of the most striking instances of splendour which he met in Vienna, in 1458, that most of the houses had glass windows. Felibien says that, in his time (1600), round glass disks were set in the windows in Italy. In France, on the other hand, there were glass windows in all the churches, in the sixteenth century, although there were but few in dwelling-houses.

Glass, painting on. This art was, perhaps, known to the ancients, as Morisoli attempts to prove from passages in Seneca and Vopiscus Firmius; and some persons consider the fact established by a relic of art, described in Buonarotti's *Observations upon some Fragments of Ancient Vases of Glass*, &c.—Painted glass was much used, formerly, to ornament windows in churches and other public buildings, and, in unison with the whole style of Gothic churches, threw a gloomy shade over the whole interior. Speth distinguishes between the painting on glass, or glass-enamel, and two inferior kinds of the art; one painting upon, or rather behind, glass which is not perfectly transparent; and the other, which requires transparent glass, but makes use only of coloured varnishes, or transparent colours, which do not resist moisture. Painting upon glass, properly so called, had its origin in the 3d century, about the time of the first specimens of mosaic. The more extensive knowledge, as well as use, of coloured glass, was communicated from France to England; and from thence, in the 8th century, by means of missionaries, to Germany and Flanders, and, in the 9th century, was carried to the north. Although the Italians used painted glass for mosaic work, yet they appear not to have applied it to church windows before the 8th century. We find undoubted traces of it in Bavaria towards the end of the 10th century. There was a glass-house at Tegernsee, near Münich. In the 11th century, the imitation of the best pieces of mosaic work in paintings upon glass was commenced. This art derived great advantages, at the end of the 14th century, from the important invention of enamel painting, or the art of fixing the metallic colours in glass. The art flourished most during the 15th and 16th centuries. France, England, and the Netherlands, boasted first-rate artists in this department, as Henriet, Monier of Blois, and Ab. von Diepenbecke. In Germany, Durer gained celebrity in the same art. It declined in the 17th century, and, yielding to the force of fashion, it ceased to be heard of in the 18th. It was then carried on in England chiefly by foreign artists. In the reign of James I., a school was founded by a Netherlander, Bernh. de Linge, who may be regarded as the father of modern painting upon glass. The school has continued to this day. There were some artists, in the 17th and 18th centuries, who gained reputation by their paintings upon glass, as Eginton of Birmingham, Wolfgang Baumgärtner of Kufstein, in the Tyrol (who died 1761), and their contemporary Jouffroy, who painted, in a chapel in London, the Resurrection of the Saviour. The knowledge acquired by experience was not lost, but the practice of the art was very limited. The great window of New College, Oxford, affords a fine specimen of British art.

In Germany, painting upon glass was revived in the 19th century. M. S. Frank, of Nuremberg, first attempted to restore it to its proper rank. He was employed as a painter on glass at the royal porcelain manufactory, at Münich. The royal cabinet of medals possesses a Birth of Christ by him, and the chapel a Supper, which was made in imitation of Durer's small Passion. The works in painted glass produced at Berlin and Vienna are not comparable with his. In the castle of Marienburg, in Prussia, recently rebuilt, are some paintings upon glass, which may even be compared to the ancient specimens.

GLAUBER SALTS. See SULPHATE OF SODA.

GLAZING. To prevent the penetration of fluids, it is necessary that earthen vessels should be glazed, or covered with a vitreous coating. The materials of common glass would afford the most perfect glazing to earthenware, were it not that the ratio of its expansion and contraction is not the same with that of the clay; so that a glazing of this sort is liable to cracks and fissures, when exposed to changes of temperature. A mixture of equal parts of oxide of lead and ground flints is found to be a durable glaze for the common cream-coloured ware, and is generally used for that purpose. These materials are first ground to an extremely fine powder, and mixed with water to form a thin liquid. The ware is dipped into this fluid and drawn out. The moisture is soon absorbed by the clay, leaving the glazing particles upon the surface. These are afterwards melted by the heat of the kiln, and constitute a uniform and durable vitreous coating. The English and French manufacturers find it necessary to harden their vessels by heat, or bring them to the state of biscuit, before they are glazed; but the composition used by the Chinese resists water, after it has been once dried in the air, so as to bear dipping in the glazing liquid without injury. This gives them a great advantage in the economy of fuel.

GLEE, in *music;* a vocal composition in three or more parts, generally consisting of more than one movement, the subject of which may be either gay, tender, or grave, bacchanalian, amatory, or pathetic.

GLOBE, or ARTIFICIAL GLOBE, is a term more particularly used to denote a globe of metal, plaster, paper, pasteboard, &c., on the surface of which is drawn a map, or representation of either the heavens or the earth, with the several circles which are conceived upon them; the former being called the *terrestrial globe*, and the latter the *celestial globe*.

The *celestial globe* is an inverted representation of the heavens, on which the stars are marked according to their several situations. The diurnal motion of this globe is from east to west, to represent the apparent

diurnal motion of the sun and stars. The eye is supposed to be placed in the centre of this globe, but, in fact, it is beyond the stars.

The *terrestrial globe* is an artificial representation of the earth, exhibiting its great divisions. The diurnal motion of this globe is from west to east.—The axis of the earth is an imaginary line passing through its centre; and the wire on which the artificial globe turns represents this line. The poles of the earth are the extremities of this axis; that on the north is called the *arctic*, that on the south the *antarctic* pole. The celestial poles are imaginary points in the heavens, exactly above the terrestrial poles. The brazen meridian is the circle in which the artificial globe turns, divided into 360 degrees. Every circle is supposed to be divided into 360 equal parts, called *degrees*, each degree into 60 equal parts, called *minutes*, each minute into 60 equal parts, called *seconds*, &c.; a degree is therefore only a relative idea, and not an absolute quantity, except when applied to a great circle of the earth, as to the equator or to a meridian, in which cases it is 60 geographical miles, or 69½ English miles.

A degree of a great circle in the heavens is a space nearly equal to twice the apparent diameter of the sun; or to twice that of the moon, when considerably elevated above the horizon. Degrees are marked with a small cipher, minutes with one dash, seconds with two, thirds with three, &c.; thus, $25^\circ\ 14'\ 22''\ 35'''$ are 25 degrees, 14 minutes, 22 seconds, 35 thirds. In the upper semicircle of the brass meridian, these degrees are numbered 10, 20, &c., to 90, from the equator towards the poles, and are used for finding the latitudes of places. On the lower semicircle of the brass meridian, they are numbered 10, 20, &c., to 90, from the poles towards the equator, and are used in the elevation of the poles.

Great circles, as the equator, ecliptic, and the colures, divide the globe into two equal parts. Small circles, as the tropics, polar circles, parallels of latitude, &c., divide the globe into two unequal parts. Meridians, or lines of longitude, are semicircles, extending from the north to the south pole, and cutting the equator at right angles. Every place upon the globe is supposed to have a meridian passing through it, though there be only 24 drawn upon the terrestrial globe; the deficiency is supplied by the brass meridian. When the sun comes to the meridian of any place (not within the polar circles), it is noon or mid-day at that place. The first meridian is that from which geographers begin to reckon the longitudes of places. In English maps and globes, the first meridian is a semicircle, supposed to pass through London, or the Royal Observatory at Greenwich. The equator, a great circle of the earth, equidistant from the poles, divides the globe into two hemispheres, northern and southern. The latitudes of places are reckoned from the equator northward and southward, and the longitudes are reckoned upon it eastward and westward. The equator, when referred to the heavens, is called the *equinoctial*, because, when the sun appears in it, the days and nights are equal all over the world, viz. 12 hours each. The declination of the sun, stars, and planets, is counted from the equinoctial northward and southward; and their right ascensions are reckoned upon it eastward round the celestial globe, from 0 to 360 degrees.

The ecliptic is a great circle in which the sun makes his apparent annual progress among the fixed stars. It is the real path of the earth round the sun. The points at which the ecliptic intersects the equator, at an angle of $23^\circ\ 28'$, are called the *equinoctial points:* the ecliptic is situated in the middle of the zodiac. The apparent path of the sun is either in the equinoctial, or in lines nearly parallel to it, and his apparent annual path may be traced in the heavens, by observing what particular constellation in the zodiac is on the meridian at midnight; the opposite constellation will show, very nearly, the sun's place at noon on the same day. The zodiac on the celestial globe is a space which extends about 8° on either side of the ecliptic. Within this belt the motions of the planets are performed.

The ecliptic and zodiac are divided into 12 equal parts, called *signs*, each containing 30°; and the sun makes his apparent annual progress through the ecliptic, at the rate of nearly a degree in a day. The names of the signs, and the days on which the sun enters them, are given in the article ECLIPTIC. The colures, two great circles passing, one through the points Aries and Libra and the poles of the world, the other through Cancer and Capricorn and the poles of the world, have their uses in mechanical geography. That passing through Aries and Libra is called the *equinoctial* colure; that passing through Cancer and Capricorn, the *solstitial* colure. The tropics are two smaller circles, each $23^\circ\ 28'$ from the equator, with which they are parallel; the northern is called the *tropic of Cancer*, the southern the *tropic of Capricorn*. The tropics are the limits of the torrid zone, northward and southward; and within these boundaries alone is the sun ever seen vertical. The polar circles are two small circles, parallel to the equator (or equinoctial), at the distance of $66^\circ\ 32'$ from it, and $23^\circ\ 28'$ from the poles. The northern is called the *arctic*, the southern the *antarctic* circle. Parallels of latitude are small circles drawn through every ten degrees of latitude, on the terrestrial globe, parallel to the equator. Every place on the globe is supposed to have a parallel of latitude drawn through it, though there are generally only 16 parallels of latitude drawn on the terrestrial globe. The hour circle, on the artificial globe, is a small circle of brass, with an index or pointer fixed to the north pole. The hour circle is divided into 24 equal parts, corresponding to the hours of the day; and these are again subdivided into halves and quarters. The horizon is a great circle, which separates the visible half of the heavens from the invisible; the earth being considered as a point in the centre of the sphere of the fixed stars.

Horizon, when applied to the earth, is either sensible or rational. The sensible or visible horizon is the circle which bounds our view, where the sky appears to touch the earth or sea. The sensible horizon extends only a few miles; for example, if a man of six feet high were to stand on a large plane, or on the surface of the sea, the utmost extent of his view, upon the earth or the sea, would be only a very few miles. The rational or true horizon is an imaginary plane, passing through the centre of the earth, parallel to the sensible horizon. It determines the rising and setting of the sun, stars, and planets. The wooden horizon, circumscribing the artificial globe, represents the rational horizon on the earth. This horizon is divided into several concentric circles, arranged in the following order:—One contains the 32 points

of the compass, divided into half and quarter points. The degrees in each point are to be found in the amplitude circle. Another contains the 12 signs of the zodiac, with the figure and character of each sign; and another contains the days of the month, answering to each degree of the sun's place in the ecliptic, and the 12 calendar months.

The cardinal points of the horizon are east, west, north, and south. The cardinal points in the heavens are the zenith, the nadir, and the points where the sun rises and sets. The cardinal points of the ecliptic are the equinoctial and solstitial points, which mark out the four seasons of the year; and the cardinal signs are, ♈ Aries, ♋ Cancer, ♎ Libra, and ♑ Capricorn. The zenith is a point in the heavens exactly over head, and is the elevated pole of our horizon. The nadir is a point in the heavens exactly under our feet, being the depressed pole of our horizon, and the zenith or elevated pole, of the horizon of our antipodes. The pole of any circle is a point on the surface of the globe, 90° distant from every part of the circle. Thus the poles of the world are 90° from every part of the equator; the poles of the ecliptic (on the celestial globe) are 90° from every part of the ecliptic, and 23° 28′ from the poles of the equinoctial; consequently they are situated in the arctic and antarctic circles.

Every circle on the globe, whether real or imaginary, has two poles diametrically opposite to each other. The equinoctial points are Aries and Libra, where the ecliptic cuts the equinoctial. The point Aries is called the *vernal equinox*, and the point Libra the *autumnal equinox*. When the sun is in either of these points, the days and nights on every part of the globe are equal to each other. The solstitial points are Cancer and Capricorn. When the sun enters Cancer, it is the longest day to all the inhabitants on the north side of the equator, and the shortest day to those on the south side. When the sun enters Capricorn, it is the shortest day to those who live in north latitude, and the longest day to those who live in south latitude. A hemisphere is half the surface of the globe; for every great circle divides the globe into two hemispheres. The horizon divides the upper from the lower hemisphere in the heavens; the equator separates the northern from the southern on the earth; and the brass meridian, standing over any place on the terrestrial globe, divides the eastern from the western hemisphere. The latitude of a place, on the terrestrial globe, is its distance from the equator in degrees, minutes, or geographical miles, &c., and is reckoned on the brass meridian, from the equator towards the north or south pole.

The quadrant of altitude is a thin piece of brass, divided upwards from 0 to 90°, downward, from 0 to 18°; when used, it is generally screwed to the brass meridian. The upper divisions determine the distances of places on the earth, the distances of the celestial bodies, their latitudes, &c.; and the lower divisions are applied to finding the beginning, the end, and duration of twilight. The longitude of a place, on the terrestrial globe, is the distance of the meridian of that place from the first meridian, reckoned in degrees and parts of a degree, on the equator. Longitude is either eastward or westward according as a place is to the east or west of the first meridian. No place can have more than 180°, or half the circumference of the globe. (See LONGITUDE.)

Hour circles are the same as meridians. They are drawn through every 15° of the equator, each answering to an hour. The brass meridian and these circles always correspond. The crepusculum, or twilight, is that faint light which we perceive before the sun rises and after he sets. It is produced by the rays of light being refracted in their passage through the earth's atmosphere, and reflected from the different particles thereof. The twilight is supposed to end in the evening, when the sun is 18° below the horizon. The angle of position between two places on the terrestrial globe is an angle at the zenith of one of the places, formed by the meridian of that place, and a vertical circle passing through the other place, measured on the horizon, from the elevated pole towards the vertical circle. Rhumbs are the divisions of the horizon into 32 parts, called the *points of the compass*. We subjoin a few problems illustrative of the use of the globes.

Problem 1.—*To find the latitude of any place.*—Rule. Turn the globe till the place comes to the graduated edge of the brazen meridian, and the degree on the meridian with which the place corresponds is the latitude north or south, as it may be north or south of the equator.

Problem 2.—*To find the longitude of any place.*—Rule. Turn the globe till the place comes to the brazen meridian, and the degree on the equator, intersected by the brazen meridian, shows the longitude.

Problem 3.—*To find any place on the globe, having the latitude and longitude of that place given.*—Rule. Find the longitude of the given place on the equator, bring it to that part of the brass meridian which is numbered from the equator towards the poles; and then, under the given latitude, on the brass meridian, you will find the place required.

Problem 4.—*To find the difference of latitude of any two places.*—Rule. If the places are in the same hemisphere, bring each to the meridian, and subtract the latitude of the one from that of the other; if in different hemispheres, add the latitude of the one to that of the other, and the sum will show the difference of latitude.

Problem 5.—*To find the difference of longitude between any two places.*—Rule. Bring one of the places to the brazen meridian; mark its longitude; then bring the other place to the meridian, and the number of degrees between its longitude and that of the first mark is the difference of longitude. When this sum exceeds 180°, take it from 360°, and the remainder will be the difference of longitude.

Problem 6.—*To find the distance between two places.*—Rule. When the distance is less than 90°, lay the quadrant of altitude over both the places; so that the division marked O may be on one of the places; then the degree cut by the other place will show the distance in degrees. Multiply these degrees by 69½, and the product will be the distance in English miles. The distance between two places, with the angle of position, may be found, at the same time, in the following manner: Elevate the globe for one of the places, bring it to the meridian, screw the quadrant of altitude over it; then move the quadrant till it come over the other place, and observe what degree of it this last place cuts. Subtract this distance from 90°, and the remainder will be the distance in degrees. The quadrant of altitude, on the horizon, will now show the angle of position. When the distance is greater than 90°, find the antipodes of one of the places, and measure the distance between this and the

other place with the quadrant of altitude. Subtract this distance from 180, and the remainder will be the whole distance required. *When the angle of position is required*, this case may be performed thus: 1. Elevate the globe for the antipodes of one of the places, and, having fixed the quadrant over it, bring its edge over the other place, and add the degree cut by it to 90°, and the sum will be the distance required. 2. The quadrant will show the position; only, west must be read for east; east for west; north for south; and south for north.

Problem 7.—The hour being given at any place, to find what hour it is in any other part of the world.—Rule. Bring the place, at which the time is given, to the meridian; set the index to the given hour; then turn the globe till the other place comes to the meridian, and the index will show the time required.

The earth turns round on its axis from the west towards the east, and causes a different part of its surface to be successively presented to the sun. When the meridian of any place is directly opposite to the sun, it is then noon to all places on that meridian. Meridians towards the east come opposite to the sun sooner than those towards the west; and hence the people there have noon much sooner, and all the other hours of the day will be proportionably advanced. The earth takes 24 hours to turn on its axis, and the rate at which it turns every hour may be found, by dividing 360° by 24; the quotient, 15, is the number of degrees the earth turns in an hour. Hence it is that a place lying 15° to the east of another will have noon one hour sooner; if it is 30° or 45°, it will have noon two or three hours sooner than the other; and so on, in the same proportion, for all places farther removed. Places that are situate 15°, 30°, or 45°, to the west of that place at which it is noon, will have noon one, two, or three hours later; and so on, in the same proportion.

Problem 8.—To adjust the globe for the latitude, zenith, and sun's place.—Rule. For the *latitude:* elevate the pole above the horizon according to the latitude of the place, and the globe will be adjusted for the latitude. For the *zenith:* screw the quadrant of altitude on the meridian, at the given degree of latitude, counting from the equator towards the elevated pole, and the globe will be rectified for the zenith.—For the *sun's place:* find the sun's place on the horizon, and then bring the place which corresponds thereto, found on the ecliptic, to the meridian, and set the hour index to 12 at noon; then will the globe be adjusted for the sun's place.

Problem 9.—To find the sun's declination.—Rule. Bring the sun's place for the given day to the brass meridian, and the degree over it will be the declination sought; or bring the day of the month marked on the *analemma* to the brass meridian, and the degree over it will be the declination, as before. 1. The declination of the sun being its distance north or south from the equator, this problem is exactly the same as that for finding the latitude of a place. 2. The greatest north declination, 23° 28′, is when the sun enters Cancer, June 21st. The greatest south declination, 23° 28′, is when it enters Capricorn, December 21st.

Problem 10.—To find the sun's rising and setting for a given day at a given place.—Rule. Elevate the globe for the sun's declination; bring the given place to the meridian; set the index to 12, and turn the globe till the given place comes to the eastern edge of the horizon; then the index will show the time of the sun's rising. Next bring the given place to the western edge of the horizon, and the index will show the hour at which the sun sets. If the hour circle have a double row of figures, make use of that which increases towards the east; the sun's rising and setting may then be found at once, by bringing the place only to the eastern edge of the horizon; for the index will point on one row to the hour of rising, and on the other (that which increases towards the west) to the hour of setting. *By this problem may be found the length of the day and night.* Double the time of the sun's setting, and it will give the length of the day. Double the time of the sun's rising, and it will give the length of the night.

Problem 11.—To find all those places in the torrid zone to which the sun is vertical on a given day.—Rule. Find the sun's place for the given day, bring it to the meridian, mark the declination, and turn the globe round, when all those places which pass under that mark of the meridian, will have the sun vertical on the given day. By the analemma, bring the day of the month, marked upon the analemma, to the brazen meridian, and mark the declination; then the places will be found as above.

Problem 12.—The day, hour, and place being given, to find at what places of the earth the sun is then rising and setting, where it is noon, and where midnight.—Rule. Find the place to which the sun is vertical at the given hour, bring the same to the meridian, and adjust the globe to a latitude equal to the sun's declination. Then, to all places under the western side of the horizon, the sun is rising; to those above the eastern horizon, the sun is setting; to all those under the upper half of the brazen meridian, it is noon; and to all those under the lower half, it is midnight.

Problem 13.—To show, by the globe, the cause of day and night.—The sun shines upon the earth, and illuminates that half only which is turned towards him: the other half is in darkness. But, as the earth turns round on its axis from west to east once in 24 hours, every meridian upon the earth will, in that time, successively be presented to the sun, and be deprived of its light again. Rule. Elevate the globe for the sun's declination, so that the sun may be in the zenith, and the horizon will be the terminator, or boundary circle, of light and darkness: that half of the earth above the horizon enjoys light; that half below the horizon will be in darkness.—Put a patch upon a globe, to represent any place, turn the globe round from west to east, and, when the place comes to the western side of the horizon, the sun appears to the inhabitants of that place to be rising in the east; but it is more properly the inhabitants of that place rising in the west. Go on to turn the globe round, and the place will ascend higher towards the meridian in a contrary direction. When the place has arrived at the meridian, it will then be noon there, and the sun will be at his greatest altitude for that day. Continue to turn the globe, and the place will gradually recede from the meridian, and decline towards the eastern horizon, which will cause the appearance of the sun descending towards the west. When the place has arrived at the eastern horizon, as it is then going below the boundary of light and darkness, the sun will appear to be setting in the west. The place being now at a greater distance than 90° from that point where the sun is vertical is deprived of his light,

and continues in darkness till, by the revolution of the earth, it arrives again at the western horizon, when the sun will appear to rise as before. The sun is obviously rising at the same time to all places on the western side of the horizon, and setting at the same time to all places on the eastern side of the horizon.

Problem 14.—*To show, by the globe, the cause of the variety of the seasons.*—When the sun is in the equator, the horizon will represent the terminator, or boundary circle of light and darkness; and, the poles being made to coincide with it, we shall have a fair representation of the two seasons, spring and autumn; for, its rays then extending 90° every way from the vertical point, both poles will be illuminated. When the sun is in the tropic of Cancer, being 23½° farther to the north than before, his rays will extend 23½° beyond the north pole, on the opposite meridian: they will not, however, reach the south pole by 23½°; they will extend to the antarctic only, being 90° distant from the tropic of Cancer: hence, to make the horizon the terminator in this case, the north pole must be elevated 23½° above the horizon, and we shall have the summer season to Europeans.

When the sun is in the tropic of Capricorn, the reverse of this takes place; for the sun's rays then extend 23½° beyond the south pole, on the opposite meridian, and only as far north as the arctic circle: hence, to make the horizon the terminator in this case, the south pole must be elevated 23½° above the horizon, and we shall have the winter season to Europeans. The problems thus given are only to be considered as specimens of what may be performed. On the terrestrial globe, Butler describes 57; while, on the celestial sphere, the number and variety are still much greater. It is said that Anaximander of Miletus, a pupil of Thales, who flourished about the 50th Olympiad (580 B. C.), invented the terrestrial globe. That Ptolemy had an artificial globe, with the universal meridian, appears from his *Almagest*. The ancients likewise made celestial globes. Among the moderns, several have distinguished themselves in the construction of globes. The Venetian Coronelli (who died 1718) prepared, in 1683, with the assistance of Claudius Molinet and other Parisian artists, a terrestrial globe, for Louis XIV., twelve Parisian feet in diameter. The same artist made a celestial globe of the same size. Funk, in Leipsic, published in 1780 models in the form of cones (*coniglobia*), as substitutes for celestial globes. These cones may be made almost as serviceable as globes, and are incomparably cheaper. Some of the best modern globes are those made since 1790, at Nuremberg, after the direction of the famous observer Bode. Newton's globes are very good. Globes have been lately made in this country, for the use of learners, with nothing but the meridians and parallels of latitude drawn indelibly on them. They are covered with a substance on which drawings can be made with a slate pencil, and easily effaced. In the United States, white globes have been prepared, on which the pupil can draw with a black-lead pencil, and rub out the work at pleasure. Either sort must be highly useful in schools where geography is carefully studied.

Among the most remarkable globes in existence, that of Gottorp, in the Academy of Science of Petersburg, is worthy of notice. This is a large concave sphere, eleven feet in diameter, containing a table and seats for twelve persons, to whom the inside surface represents the visible phenomena of the heavens. The stars are distinguished by gilded nails, according to their respective magnitudes, and arranged in groups, as the different constellations require. The outside is a terrestrial globe, representing the land and water on the surface of the earth. It is called the *globe of Gottorp*, from being substituted for one originally made in that place, which, with inconceivable labour, was conducted upon rollers and sledges, over snow, and through forests, to Riga, and thence by sea to Petersburg. In 1751, it was consumed by fire, and from its iron plates and materials the present globe was made. But, large as these globes are, they become diminutive when compared with the sphere constructed by the late Doctor Long. This is eighteen feet in diameter; and it will enable thirty persons to sit within its concavity, without any inconvenience. The entrance is over the south pole, by six steps. This wonderful machine stands in Pembroke Hall, in the University of Cambridge. All the constellations and stars of the northern hemisphere, visible at Cambridge, are painted upon plates of iron, which, joined together, form one concave surface. Unfortunately, it is now very much damaged. There is a terrestrial globe exhibiting in Paris, sixty feet in diameter, admirably executed: it will contain 100 persons. It cost 5000*l.*

The Celestial Globe. The general definitions given of the terrestrial globe apply also to the celestial, the various circles of which are more aptly illustrated by the armillary sphere, which is well adapted to give youth just notions of those imaginary circles which astronomers have applied to what is vulgarly called the *concave sphere of the heavens;* but, by means of those circles, we investigate, with the nicest accuracy, the motions of the celestial bodies. There are six great circles of the sphere, which require particular attention, and on this account we may briefly recapitulate their general arrangement. They are the horizon, the meridian, the equator, the ecliptic, the equinoctial colure, and the solstitial colure. The sphere is contained in a frame, on the top of which is a broad circle, representing the meridian. It is suspended on two pins, at opposite points of the meridian. These pins are a continuation of the axis of the sphere both ways, and, as the sphere turns round upon them, they are considered as poles, north and south. The equator goes round the sphere, exactly in the middle, between the two poles. The ecliptic, the colures, the tropics, and polar circles, have been already defined, and are easily discovered.

The horizon is graduated, according to the division of the circle, into quadrants and degrees; and, to refer celestial objects to the horizon, we have also the points of the compass laid down. Hence the amplitude, or distance, of heavenly bodies, from the east and west points, and their azimuth, or distance from the meridian, are reckoned on the horizon of the armillary sphere. The graduation of the equator enables us to fix the right ascension of celestial, and the longitude of terrestrial objects. The graduation of the ecliptic serves to indicate, in the armillary sphere, the latitude and longitude of celestial bodies. The colures are, in a manner, the limits of the year, pointing out the seasons by the two opposite points of the ecliptic. The hour circle tells us in what time any motion of the earth, in the centre, is performed. In fine, many details of the science may be pleasingly and popularly illustrated by this contrivance.

By placing small patches of paper on the different circles, to represent stars, we perceive, that those which are farthest from the poles will describe the greatest circles; and that the greatest circles are described by those stars situated in the celestial equator. A star has acquired its greatest elevation when it comes to the upper semicircle of the meridian, and its greatest depression when it is at the lower circle of the meridian: the meridian bisects its arc of apparition. Some circles of revolution are wholly above, others entirely below, the horizon; therefore the patches on those circles show us which stars descend below, or which never ascend above the horizon.—And any object, whose circle of revolution is on the same side of the equator with the elevated pole, is longer visible than it is invisible; the contrary holds true if it be on the other side of the equator.

The following definitions are more immediately applicable to the celestial globe: The declination of the sun, of a star, or planet, is its distance from the equinoctial, northward or southward. When the sun is in the equinoctial, he has no declination, and enlightens half the globe, from pole to pole. As he increases in north declination, he gradually shines farther over the north pole, and leaves the south pole in darkness: in a similar manner, when he has a south declination, he shines over the south pole, and leaves the north pole in darkness. The greatest declination the sun can have is 23° 28′; the greatest declination a star can have is 90°, and that of a planet 30° 28′, north or south. The latitude of a star, or planet, is its distance from the ecliptic, north or south, reckoned towards the pole of the ecliptic, on the quadrant of altitude. Some stars, situate in and about the pole, have 90° of latitude; the planets have only 8°; and the sun, being always in the ecliptic, has no latitude. The longitude of a star, or planet, is reckoned by the degrees of the ecliptic, from the point Aries round the globe. On the celestial globe, the longitude of the sun corresponds with the sun's place on the terrestrial globe.

The right ascension of the sun, or a star, is that degree of the equinoctial which rises with the sun, or a star, in a right sphere, and is reckoned from the equinoctial point Aries eastward round the globe. Oblique ascension of the sun, or a star, is that degree of the equinoctial which rises with the sun, or a star, in an oblique sphere, and is likewise counted from the point Aries eastward round the globe. Oblique descension of the sun, or a star, is that degree of the equinoctial which sets with the sun, or a star, in an oblique sphere. The ascensional or descensional difference is the difference between the right and oblique ascension, or the difference between the right and oblique descension; and, with respect to the sun, it is the time he rises before six in the spring and summer, or sets before six in the autumn and winter. The angle of position of a star is an angle formed by two great circles intersecting each other in the place of the star, the one passing through the pole of the equinoctial, the other through the pole of the ecliptic.

The poetical rising and setting of the stars is so called because the ancient poets referred the rising and setting of the stars to the sun. When a star rose with the sun, or set when the sun rose, it was said to rise and set *cosmically*. When a star rose at sunsetting, or set with the sun, it was said to rise and set *achronically*. When a star first became visible in the morning, after having been so near the sun as to be hid by the splendour of his rays, it was said to rise *heliacally*; and when a star first became invisible in the evening, on account of its nearness to the sun, it was said to set *heliacally*. A constellation is an assemblage of stars, on the surface of the celestial globe, circumscribed by the outlines of some assumed figure, as a bull, a bear, a lion, &c. This division of the stars into constellations directs us to any part of the heavens where a particular star is situated. The zodiacal constellations are 12 in number; the northern constellations 41, and the southern 46, making in the whole 99. The largest stars are called *stars of the first magnitude*. Those of the sixth magnitude are the smallest that can be seen by the naked eye.

Sir John Byerley has recently introduced into England a globe of a new and important character, invented by M. Guesney, an advocate of Coutances in Normandy, and described by him in a work entitled, *Mouvement Heliaque*, Paris, 1825. Many of the more important phenomena of geology and physical geography have given birth to the wildest theories. M. G. being led to regard them as produced by the precession of the equinoxes (see PRECESSION), attempted their solution on scientific bases. Unfortunately, M. G. is a sworn enemy of the Newtonian system, and, while his whole theory is grounded on the precession of the equinoxes, he denies the cause of that precession, and affirms that the earth is perfectly spherical! His work abounds with errors quite as easy to refute, but he has the great and exclusive merit of having first had the idea of constructing a terrestrial globe in harmony with the celestial, by tracing the system of the ecliptic upon it, as upon the celestial globe.

We may here observe, that the whole of the appearances in the heavens are to be referred to the two motions of the earth. The polar star is not polar to any planet but our own; and the poles of the ecliptic in the folds of Draco and in the Dorado are only so in reference to the earth. The axes of the world, as they are called, or those of the ecliptic and the equator, are two lines crossing each other *in the centre of the earth*, at an angle of 23° 28′, and extending to the heavens; but, we repeat it, they do not pass through the centres of any other planets; and are, therefore, to be referred to the earth alone.

The points where these lines pass through the surface of the earth are the poles on which its motions are performed, the movement of rotation, or diurnal motion, on the poles of the equator, and the movement of translation, or annual motion, on the poles of the ecliptic. M. Guesney's great difficulty was, to fix the seat of the poles of the ecliptic on the terrestrial globe. In this he received no aid from astronomers, who declare the ecliptic to be a circle in the heavens, and to have no reference whatever to the earth, forgetting that, as the plane of the ecliptic passes through the centre of the earth, *it must cut its surface somewhere:* to determine those points, then, and consequently the poles of the terrestrial ecliptic, was the object of M. Guesney. He found that the magnetic needle and its dip were both directed to one point on the globe near the polar circle at the back of Iceland, precisely on the first meridian adopted by order of Louis XIII., passing through the island of Ferro. He found that, by supposing the seat of the pole of the ecliptic there, it gave a

satisfactory solution of many, hitherto inexplicable phenomena; he therefore fixed it there by approximation. Sir J. B. appears to be the only scientific person who has taken the trouble to sift the wheat from the chaff, and on this basis to erect a theory embracing the principal phenomena. Not, however, satisfied with approximation, where mathematical accuracy was evidently attainable, he endeavoured to ascertain precisely the poles of the terrestrial ecliptic, when, fortunately, he found that Laplace, pursuing another object, had already solved the problem.

To avoid the confusion of every maritime nation using a different first meridian, Laplace wished them to take that "of which the midnight corresponds with the instant when the great axis of the ecliptic is perpendicular to the right line of intersection of the equator and ecliptic, which meridian is 166° 46′ 12″ east of Paris," or 169° 6′ 27″ east of Greenwich Observatory.

On the authority, therefore, of the greatest astronomer of any age, Sir J. B. has had a terrestrial globe prepared by Mr. Newton, with the system of the ecliptic described on the poles as fixed by Laplace; the north pole of the ecliptic being in the polar circle, and the winter solstitial colure, or first meridian, 10° 53′ 35″ west of Greenwich. A circle drawn from this pole as a centre, on a radius of 23° 28′, will pass through the pole of the earth, and trace its line of motion round the pole of the ecliptic, in 25,920 years.

This revolution of the pole of the equator round that of the ecliptic is admitted by all astronomers to take place in the *heavens*, but not in the earth. They admit, too, that the axis of the ecliptic is fixed and immovable, the ecliptic being so; but they have not yet shown how a right line intersecting another fixed right line at a given angle shall move round the latter at its extremity, and not at a given distance from the point of intersection! Assuming, then, that the pole of the equator rovolves round the pole of the *terrestrial ecliptic*, it remains to show a few of the terrestrial effects of such motion.

By inspection of the globe, we find that the pole of the equator is now at nearly its greatest distance from western Europe; that it is advancing at the rate of about 394 yards annually on North America, and will pass through Lancaster Straits, Hudson Straits, over Resolution Isle, enter Europe at Cape Finisterre, pass over Bilbao and the northern frontier of Spain, through France over Toulouse, through Lombardy over Milan, through Germany over Vienna, and pass into Russia over Moscow, &c. &c. It is found that the solstitial colures are almost entirely in the ocean, cutting only a small portion of western Africa and a portion of Kamtschatka, and proceeding without interruption until they meet the lower part of New Zealand.

On inspecting the globe farther, we find that Kamtschatka was, at a given period, within the tropics, which accounts for tropical fossils being found in the polar regions; and that the Oural Mountains were formerly in the latitude of Mexico, which explains why the precious metals are found in such high latitudes, and why the same precious stones are found in Mexico and the Oural Mountains. We find also that the direction of the straits in the higher latitudes run from west to east, or in the direction of the waters of the pole. The debris of mountains are found in the same direction in England, France, Italy, Scandinavia, &c. The plains of Lombardy are covered with Alpine debris, and, in Scandinavia, masses of 50,000 tons have been transported (Dr. Buckland fancies on the back of an iceberg) by the immense force of the Polar Ocean.

The radius of the earth at the equator is about 65,000 feet greater than the polar radius, owing to the centrifugal force (which is as the radii of the parallels of latitude). And, as the pole moves through 46° 56′ of latitude in 12,960 years, in that lapse of time one part of the equator will be carried 46° 56′ into the southern hemisphere. At that period all western Europe will be buried under the waters of the pole (forming the period of a deluge), as it was at three distinct periods, at intervals of nearly 26,000 years; which ascertains the existence of the globe in its present state (which was probably its primitive) for 70,000 years. This change of the plane of the equator is probably the cause of all the great phenomena; it changes the latitude from polar to tropical regions, and thus renders a change in the action of the centrifugal force; and, from whatever part the pole is receding, the centrifugal force is increasing, which produces an alteration of surface; in whatever place it is advancing there is a consequent depression. There is thus a daily tendency to elevation in some parts, and to depression in others; and to this cause Sir J. B. attributes earthquakes and volcanic action. According to this theory, as the elevation and depression must be greatest in the direction of the motion of the pole, so ought the degree of volcanic action to be. On inspecting the globe, we find this to be the case, and that volcanic action is greatest on the meridians of South America and the Philippine Isles. Where no elements of combustion exist we have eruptions of mud, &c.

The difference between the earth's radius at the equator and at 45° is 5340 French toises, or about 33,000 English feet. Now, the equator changing its position nearly 47°, it follows that in the solstitial colure the present position of the equator will be depressed at least 33,000 feet. This will readily account for marine fossils being found in Chimborazo, 15,500 feet above the surface of the ocean.

The above is a brief outline of the system to which Sir John Byerley intends shortly to call the attention of the public. He courts inquiry; for, if the theory be well founded, it will entirely remodel the science of physical geography; and, on this account, we have requested Sir John to furnish us with the preceding abstract of his theory, which our confined limits must render naturally imperfect.

GLOTTIS (from γλωττα, the tongue); the superior opening of the larynx at the bottom of the tongue.

GLUCINE, or GLUCINA; the name of a very rare earth, found only in three rare minerals, beryl or emerald, euclase and chrysoberyl. It is usually procured from the beryl, in which it exists in the proportion of fourteen per cent., combined with silex and alumine. The process for obtaining it pure is as follows:—The mineral is reduced to an exceedingly fine powder, mingled with three times its weight of carbonate of potash, and exposed to a strong heat for half an hour. The fused mass is then dissolved in dilute muriatic acid, and the solution evaporated to perfect dryness, by which means the silex is rendered perfectly insoluble. The alumine and glucine are then redissolved in water, acidulated with muriatic

acid, and thrown down together by pure ammonia. The precipitate, after being well washed, is macerated with a large excess of carbonate of ammonia, by which glucine is dissolved; and, on boiling the filtered liquid, carbonate of glucine subsides, which, on being heated to redness, affords pure glucine. In this condition, it is white, tasteless, without odour, and quite insoluble in water. Specific gravity, 3. Vegetable colours are not affected by it. It is supposed, by analogy, to be the oxide of a metal, and its supposed metallic base is called *glucinum*. The salts which glucine forms with acids have a sweetish taste.

Carbonate of Glucine, obtained by double decomposition, is precipitated in a soft state, and is not easily dried, is insipid, insoluble in water, and is not rendered soluble by an excess of acid.

Nitrate of Glucine cannot be crystallized, but by evaporation forms a gelatinous mass, which is very deliquescent.

Sulphate of Glucine is difficultly crystallizable; its taste is saccharine and astringent; it is very soluble in water, its solution assuming by concentration the consistence of a syrup.

Phosphate of Glucine is in the form of a white powder, or of a viscous substance, insipid, and insoluble in water, but rendered soluble by an excess of acid.

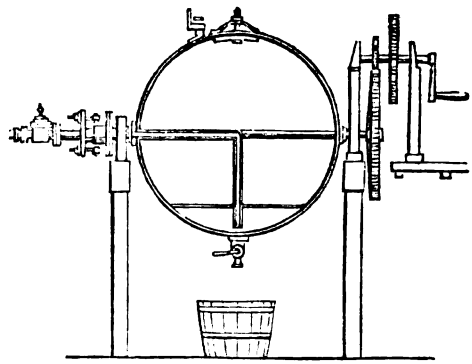
Muriate of Glucine is soluble in water, and by evaporation can be obtained in small crystals.

Fluate of Glucine is obtained by mixing fluate of potash and muriate of glucine: it is thrown down in the form of a gelatinous precipitate.

GLUE, among artificers; a tenacious, viscid matter, which serves as a cement. Glues are of different kinds, according to the various uses they are designed for, as the common glue, glove glue, parchment glue, isinglass glue, &c. The common or strong glue is made of the skins of animals, as oxen, cows, calves, sheep, &c.; and the older the animal is the better is the glue made of its hide. Indeed, whole skins are rarely used for this purpose, but only the shavings, parings, or scraps of them; or the feet, sinews, &c. Those who make glue of parings, first steep them two or three days in water, then wash them well out, boil them to the consistence of a thick jelly, which they pass, while hot, through osier baskets, to separate the impurities from it, and then let it stand some time, to purify it farther; when all the filth has settled to the bottom of the vessel, they melt and boil it a second time. They next pour it into flat frames or moulds, whence it is taken out pretty hard and solid, and cut into square pieces or cakes. They afterwards dry it in the wind, in a sort of coarse net; and at last string it, to finish its drying. The best glue is that which is oldest; and the surest way to try its goodness is, to lay a piece to steep three or four days, and if it swell considerably without melting, and when taken out resume its former dryness, it is excellent. In some large manufactories, it is now found advantageous to employ steam-pipes for heating the glue, which is by this means better, while all danger of fire is prevented.

A glue that will hold against fire and water, may be made thus:—Mix a handful of quick lime with four ounces of linseed oil, boil them to a good thickness, then spread the paste on tin plates in the shade, and it will become exceedingly hard, but may be dissolved over a fire as glue.

A patent has been obtained for the manufacture of glue from bones, which promises to be of considerable advantage. The apparatus is represented beneath.



The patentee employs steam at a high pressure, which is conveyed into the globular metallic vessel by the hollow axis. In this also is placed the bones from which the gelatine is to be extracted. It is afterwards evaporated, and dried on nets in the ordinary way. Motion is communicated to the globe by the wheel-work and winch.

Parchment glue is made by gently boiling shreds of parchment in water, in the proportion of one pound of the former to six quarts of the latter, till it is reduced to one quart: the fluid is then strained from the dregs, and afterwards boiled to the consistence of glue. Isinglass glue is made in the same way; but this is improved by dissolving the isinglass in alcohol, by means of a gentle heat.

GLUTEN; a vegetable compound, procured by repeatedly washing wheat flour in a large quantity of water, by which means the starch is dissolved, leaving the gluten behind in a very tenacious, ductile, somewhat elastic state, and possessed of a brownish-gray colour. It has scarcely any taste, and is insoluble in water, alcohol, and ether, but is taken up by acids and alkalies. The acid solution is precipitated by an alkali, and, reciprocally, the alkaline solution by an acid. Dried by a gentle heat, it contracts its volume, and becomes hard and brittle. Its products with fire, or nitric acid, are nearly the same as those of gum and sugar. Gluten is present in most kinds of grain, such as wheat, barley, rye, oats, peas, and beans; but the first contains it in far the largest proportion, which is the reason that wheaten bread is more nutritious than that made with other kinds of flour; for, of all vegetable substances, gluten appears to be the most nutritive. It is to the presence of gluten that wheat flour owes its property of forming a tenacious paste with water, to which cause is due the formation of light spongy bread. The carbonic acid, which is disengaged during the fermentation of the dough, being detained by the viscid gluten, distends the whole mass, and thus produces the rising of the bread. Good wheat flour contains from 8 to 10 per cent. of gluten.

Gluten consists of two distinct principles; to one of which has been applied the name of *gliadine*, gluten, and to the other that of *zymome*, a ferment. To obtain these principles, the gluten is boiled repeatedly in alcohol, which dissolves the gliadine, and leaves the zymome in a pure state. On mixing the powder of guaiacum with the latter substance, a beautiful blue colour instantly appears; and the

same phenomenon ensues, though less rapidly, when it is kneaded with gluten, or the flour of good wheat moistened with water. With bad flour, the gluten of which has suffered decomposition, the blue tint is scarcely visible. The intensity of the colour thus produced is entirely dependent on the relative quantity of zymome contained in the flour; and, since the quantity of zymome is proportional to the quantity of gluten, the proportion of the latter, and therefore the quality of the flour, is tested by the action of the guaiacum.

GNOMON, in *astronomy*, is an instrument or apparatus for measuring the altitudes, declinations, &c., of the sun and stars. The gnomon is usually a pillar, or column, or pyramid, erected upon level ground, or a pavement. For making the more considerable observations, both the ancients and moderns have made great use of it, especially the former; and many have preferred it to the smaller quadrants, both as more accurate, and more easily made and applied. The most ancient observation of this kind extant is that made by Pytheas, in the time of Alexander the Great, at Marseilles, where he found the height of the gnomon was, in proportion to the meridian shadow at the summer solstice, as 213½ to 600; just the same as Gassendi found it to be, by an observation made at the same place, almost 2000 years after, viz. in the year 1636. This method of observation, however, is by no means accurate, as is proved by the following deficiencies in the ancient observations made in this manner: 1. The astronomers did not take into account the sun's parallax, which makes his apparent altitude less than it would be if the gnomon were placed at the centre of the earth. 2. They neglected refraction, by which the apparent height of the sun is somewhat increased. 3. They made their calculations as if the shadows were terminated by a ray coming from the sun's centre; whereas it is bounded by one coming from the upper edge of his limb.—These errors, however, may be easily allowed for; and, when this has been done, the ancient observations are generally found to coincide nearly with those of the moderns.

GNOMON, in *dialling*, is the style-pin of a dial, the shadow of which points out the hours. This is always supposed to represent the axis of the world, to which it is therefore parallel, or coincident, the two ends of it pointing straight to the north and south poles of the world.

GOITRE. See WEN.

GOLD is the most precious metal employed in commerce. It is exceedingly soft and flexible, but its tenacity is sufficiently great to sustain, in a wire one-tenth of an inch in diameter, 500 lbs. weight without breaking. In hardness it is superior to lead and tin, but inferior to iron, copper, platina, and silver. Its lustre does not equal that of steel, platina, or silver, but it surpasses the other metals in this respect. It may be exposed for any length of time to the atmosphere, without suffering the least change. It is also unalterable in the common fire; but on being exposed to powerful burning mirrors, or to the heat of the oxy-hydrogen blowpipe, it not only melts, but even rises in vapour.

Gold is not readily oxidized or dissolved by any of the pure acids. Its best solvents are chlorine and nitro-muriatic acid; and, according to Sir H. Davy, the chlorine is the agent in both cases, since the nitro-muriatic acid does not dissolve gold, except when it gives rise to the formation of chlorine. It is to be inferred, therefore, that the chlorine unites directly with the gold, and that the compound formed is a chloride of gold. There is no inconvenience, however, in regarding it as a muriate, since re-agents act upon it as if it were such. The gold is precipitated from its solvent by a great number of substances. Lime and magnesia precipitate it in the form of a yellowish powder. Alkalies exhibit the same appearance; but an excess of alkali redissolves the precipitate. The precipitate of gold obtained by a fixed alkali appears to be a true oxide, and is soluble in the sulphuric, nitric, and muriatic acids; from which, however, it separates by standing. Gallic acid precipitates gold of a reddish colour, and very soluble in nitric acid, to which it communicates a fine blue colour. Ammonia precipitates the solution of gold much more readily than fixed alkalies. This precipitate, which is of a yellowish-brown colour, possesses the property of detonating with a very considerable noise, when greatly heated. It is known by the name of *fulminating gold*.

Most metallic substances precipitate gold from its solution in nitro-muriatic acid. Lead, iron, and silver precipitate it of a deep and dull purple colour; copper and iron throw it down in its metallic state. A plate of tin, immersed in a solution of gold, affords a purple powder, called the *purple powder of Cassius*, which is used to paint in enamel. Ether, naphtha, and essential oils take gold from its solvent, and form liquors, which have been called *potable gold*. The gold which is precipitated on the evaporation of these fluids, or by the addition of sulphate of iron to the solution of gold, is of the utmost purity. The principal use of gold, as is well known, is in coinage.—It has been with mankind, from time immemorial, the representative sign of every species of property. Even before the art of coining was invented, it passed for money in the condition in which it was found in the earth; and in this form it still enjoys a currency in many parts of Africa. It is rarely employed in a state of perfect purity, but is almost universally alloyed with copper, or with silver, in order to increase its hardness. The alloy of gold and silver is found already formed in nature, and is that most generally known. It is distinguishable from that of copper, by possessing a paler yellow than pure gold, while the copper alloy has a colour bordering upon reddish yellow. A variety of means are employed to judge of the quality of alloys, supposed to consist in part, or principally, of gold, without resorting to a regular analysis.

The art of gilding metals (see GILDING) depends upon the double property which mercury possesses, of amalgamating with gold, and of becoming volatile by heat, and thus quitting the gold, which adheres strongly to the metal upon which the mercurial amalgam has been spread. The composition of the amalgam generally used is eight parts of mercury to one of gold. The malleability and extreme divisibility of gold are the foundation of the art of *gold-beating;* and these two properties are so remarkable in this art, that natural philosophers are in the habit of quoting the results it furnishes, as examples of the divisibility of matter. Boyle has observed that a grain of gold, reduced to leaves, will cover a surface of 50 square inches; that each one of these square inches may be divided into 46,656 other little squares, and that, of course, the entire amount of surface de-

rived from one grain of gold is capable of being divided into 2,322,800 parts, each of which is visible to the naked eye.

In consequence of the wonderful extension which the gold-beater is enabled to give to this precious metal, it is employed for ornamental purposes to an extent which, from its comparative scarcity, would otherwise be impossible. Thus it is estimated that an equestrian statue, of the natural size, may be coated with a piece of gold not exceeding ten shillings and sixpence in value. The gilding of the dome of the *Hôtel des Invalids*, at Paris, cost about 5000*l*. And in India, where it is common to gild towers, bridges, gates, and colossal idols, it is known to be attended with still less expense.

The following is a short account of the ingenious art of *gold-beating*. The gold used is as pure as possible, and the operation is commenced with masses weighing about two ounces. These are beaten into plates six or eight inches long, by three-quarters of an inch wide. They are then passed between steel rollers, till they become long ribands, as thin as paper. Each one of these is now cut into 150 pieces, each of which is forged on an anvil, till it is about an inch square, after which they are well annealed. Each of the squares in this state weighs $6\frac{4}{10}$ grains, and in thickness is equal to $\frac{1}{768}$ of an inch. The 150 plates of gold thus produced from one mass are interlaid with pieces of very fine vellum, about four inches square, and about twenty vellum leaves are placed on the outsides; the whole is then put into a case of parchment, over which is drawn another similar case, so that the packet is kept close and tight on all sides. It is now laid on a smooth block of marble, or metal, of great weight, and the workman begins the beating with a round-faced hammer, weighing sixteen pounds; the packet is turned, occasionally, upside down, and beaten with strong but not acute strokes, till the gold is extended nearly to an equality with the vellum leaves. The packet is then taken to pieces, and each leaf of gold is divided into four with a steel knife. The 600 pieces thus produced are interlaid with pieces of animal membrane, from the intestines of the ox, of the same dimension and in the same manner as the vellum. The beating is continued, but with a lighter hammer, which weighs about twelve pounds, till the gold is brought to the same dimensions as the interposed membrane. It is now again divided into four, by means of a piece of cane, cut to an edge, the leaves being by this time so light that any accidental moisture, condensing on an iron blade, would cause them to adhere to it. The 2400 leaves hence resulting are parted into three packets, with interposed membrane as before, and beaten with the *finishing*, or *gold hammer*, weighing about ten pounds, till they acquire an extent equal to the former. The packets are now taken to pieces, and the gold leaves, by means of a cane instrument and the breath, are laid flat on a cushion of leather, and cut, one by one, to an even square, by a cane frame; they are lastly laid in books of twenty-five leaves each, the paper of which is previously smoothed, and rubbed with red bole, to prevent them from adhering.

Gold wire, as it is called, is, in fact, only silver wire gilt, and is prepared in the following manner. A solid cylinder of fine silver, weighing about 20lbs., is covered with thick leaves of gold, which are made to adhere inseparably to it by means of the burnisher: successive laminæ are thus applied, till the quantity of gold amounts to 100 grains for every pound troy of silver. This gilt silver rod is then drawn successively through holes made in a strong steel plate, till it is reduced to the size of a thick quill, care being taken to anneal it accurately after each operation. The succeeding process is similar to the former, except that a mixed metal, somewhat softer than steel, is employed for the drawing plates, in order to prevent the gilding from being stripped off; and no farther annealing is requisite after it is brought to be as slender as a crow-quill. When the wire is drawn as thin as is necessary, it is wound on a hollow copper bobbin, and carefully annealed by a very gentle heat: finally, it is passed through a flatting-mill, and the process is complete. According to Dr. Halley, 6 feet in length of the finest gilt-wire, before flatting, will counterpoise no more than a grain; and as the gold is not quite $\frac{1}{57}$ of the whole, a single grain of gold, thus extended, will be 345.6 feet long, and only the millionth part of an inch in thickness. (See METALLURGY.)

GOLDSMITH; an artist who makes vessels, utensils, and ornaments, in that metal. The work is either performed in the mould, or beaten out with the hammer, or other engine. All works that have raised figures are cast in a mould, and afterwards chased and finished: plates, or dishes, of silver or gold, are beaten out from thin flat plates, and tankards and other vessels of that kind are formed of plates soldered together, and their mouldings are beaten, not cast. The goldsmith makes his own moulds, and for that reason ought to be a good designer, and have a taste in sculpture: he also ought to know enough of metallurgy to be able to assay mixed metals, and to mix the alloy.

GONIOMETER; an instrument for measuring the angles of crystals.

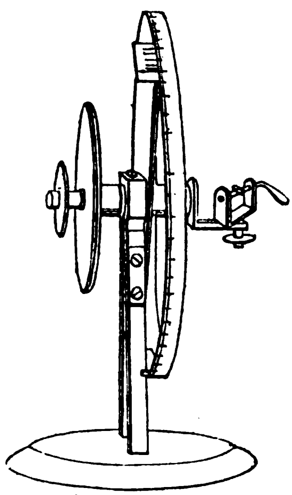
From the advances that have been made of late years in crystallography, a very large proportion of mineral substances may now be recognized, if we can ascertain the angular dimensions of their external forms, or the relative position of those surfaces that are exposed by fracture. But though the modifications of tetrahedrons, of cubes, and of those other regular solids, to which the adventitious aid of geometry could be correctly applied, was determined with the utmost precision; yet it was often a subject of regret, that our instruments for measuring the angles of crystals were not possessed of equal accuracy, and that in applying the goniometer to small crystals, where the radius in contact with the surface was necessarily very short, the measures, even when taken with a steady hand, would often deviate too much from the truth to determine the species to which a substance belonged.

A means of remedying this defect was suggested by Dr. Wollaston, by which in most cases the inclination of surfaces might be measured as exactly as could be wanted for common purposes; and, when the surfaces were sufficiently smooth to reflect a distinct image of distant objects, the position of faces only 1-50th of an inch in breadth might be determined with as much precision as those of any larger crystals.

For this purpose, the ray of light reflected from the surface is employed as radius, instead of the surface itself; and accordingly, for a radius of 1-50th of an inch, we may substitute either the distance of

the eye from the crystal, which would naturally be about twelve or fifteen inches; or, for greater accuracy, we may, by a second mode, substitute the distance of objects seen at a hundred or more yards from us.

The instrument consists of a circle graduated on its edge, and mounted on a horizontal axle, supported by an upright pillar. This axle, being perforated, admits the passage of a smaller axle through it, to which any crystal of moderate size may be attached by a piece of wax, with its edge, or intersection of the surfaces, horizontal and parallel to the axis of motion.



This position of the crystal is first adjusted, so that, by turning the smaller axle, each of the two surfaces whose inclination is to be measured will reflect the same light to the eye.

The circle is then set to zero, or 180°, by an index attached to the pillar that supports it.

The small axle is then turned till the farther surface reflects the light of a candle, or other definite object, to the eye; and, lastly (the eye being kept steadily in the same place), the circle is turned by its larger axle, till the second surface reflects the same light. This second surface is thus ascertained to be in the same position as the former surface had been. The angle through which the circle has moved is, in fact, the supplement to the inclination of the surfaces; but, as the graduations on its margin are numbered accordingly in an inverted order, the angle is correctly shown by the index, without the need of any computation.

It may here be observed that it is by no means necessary to have a clean uniform fracture for this application of the instrument to the structure of laminated substances; for, since all those small portions of a shattered surface that are parallel to one another (though not in the same plane) glisten at once with the same light, the angle of an irregular fracture may be determined nearly as well as when the reflecting fragments are actually in the same plane.

In this method of taking the measure of an angle, when the eye and candle are only ten or twelve inches distant, a small error may arise from parallax, if the intersection of the planes or edge of the crystal be not accurately in a line with the axis of motion: but such an error may be rendered insensible, even in that mode of using the instrument, by due care in placing the crystal; and, when the surfaces are sufficiently smooth to reflect a distinct image of objects, all error from the same source may be entirely obviated by another method of using it.

For this purpose, if the eye be brought within about an inch of the reflecting surface, the reflected image of some distant chimney may be seen inverted beneath its true place, and by turning the small axle may be brought to correspond apparently with the bottom of the house (or with some other distant horizontal line). In this position the surface accurately bisects the angle which the height of that house subtends at the eye (or rather at the reflecting surface); then, by turning the whole circle and crystal together, the other surface, however small, may be brought exactly into the same position; and the angle of the surfaces may thus be measured with a great degree of precision.

The inclination of the surfaces of a primitive crystal of carbonate of lime is stated, with great appearance of precision, to be 104° 28′ 40″; a result deduced from the supposed position of its axis at an angle of 45° with each of the surfaces, and from other erroneous circumstances of apparent harmony by simple ratios. But however strong the presumption might be that this angle, which by measurement approaches to 45°, is actually so, it must nevertheless be in fact about 45° 20′; for the inclination of the surfaces to each other is very nearly, if not accurately, 105°, as it was formerly determined to be by Huygens; and, since the measure of the superficial angle given by Sir Isaac Newton corresponds with this determination of Huygens, his evidence may be considered as a farther confirmation of the same result; for it may be presumed that he would not adopt the measures of others without a careful examination.

Gout, or Arthritis, a disease of adults, is sometimes regular, attended with the secretion of the superfluous earthy matter which is no longer necessary for the formation of the bones; sometimes irregular, when the vital powers are weakened, and the superfluous bony matter, instead of being carried off by the organs of secretion, is deposited beneath the skin, or accumulates internally, thus producing chalk-stones and various internal concretions. There are two principal causes of the gout—bad diet and suppression of perspiration. Frequent use of wine, in particular of acid wines, as well as the daily use of very nourishing, fat, and high-seasoned food, contributes chiefly to the production of the disease, both from the excess of nutritive and earthy matter, and from its exciting effects on the blood; since so great a quantity of nutritive matter is not required by the fully developed body, and is not assimilated by the weakened organs of digestion. The disease in these cases is called *podagra*, and returns at regular periods. (See Podagra.)

In spring, in autumn, and with many much oftener, violent pains are felt in or near the joint of the great toe; the part becomes inflamed, red, and swollen. A fever is usually connected with it, if the local inflammation re-acts upon the whole system of the blood. Among the poorer classes, the real gout is seldom met with; yet, even among these, overloading the stomach with poor and badly-cooked food, repeated exposure to cold, an accumulation of half-assimilated matter in the blood, and suppressed secretion, sometimes produce irregular gouty attacks, wandering pains, depositions of an extraordinary quantity of earthy matter in the limbs, and striking deformities. Gout and rheumatism are frequently confounded, but they are very different in their nature. Rheumatism attacks every age of life; gout only adults. Rheumatism is an inflammatory state of the system of muscles and tendons; in the gout, this inflammation is in the joints, the capsular ligaments,

and the bones. Accordingly, in the former the pain is rather seated in the muscles, spreads according to their course, and is more changeable in respect to place; in the latter, the pains are in the joints and along the bones. Rheumatism is not accompanied with those earthy tumours and accumulations which characterise the gout. In the latter disease, the sweat sometimes leaves a fine earthy dust upon the skin of the patient. Both diseases may, however, be present in the body at the same time, and be combined with each other. Rheumatism may also change, with time, into the gout, if, with the advancing age, the disease passes from the muscular system to the bones and joints. If nature is no longer vigorous enough to form a regular eruption of the gout—if the individual is old, or the disease is checked in its course, it often attacks the internal parts, the stomach, the lungs, the brain, and may thus prove fatal.

Respecting the treatment of gout, the diet which is to be observed, &c., many erroneous opinions still prevail. Some believe that, particularly in the podagra, no remedy ought to be taken; others trust entirely to purgatives; others seek a remedy in abstinence and drinking water; others, misled by the theory of Brown, who placed the podagra entirely in the class of asthenic diseases, seek for a remedy in strong liquors. There is, however, no specific against gout. The treatment of the disease must be regulated by the judgment of a cautious physician, who carefully observes the age and the bodily constitution of the patient, his habits, the condition of the vital powers, the state of his arterial system, and the peculiar nature of the case. With one arthritic patient, for instance, bleeding, drinking of water, and the use of cooling means, may be very necessary, which with another may become injurious, nay, fatal; as may be the case, on the other hand, with exciting, diaphoretic, and other means.

GOVERNOR; a contrivance for equalising the motion of mills and machinery. When any part of the machinery of a mill is suddenly stopped, or suddenly set a-going, and the moving power remains the same, an alteration in the velocity of the mill will take place; and it will move faster or slower. Every machine having a certain velocity at which it will work to more advantage than at any other, the change of velocity arising from the foregoing cause is in all cases a disadvantage, and in delicate operations exceedingly hurtful. In a cotton-mill, for instance, which is calculated to move the spindles at a certain rate, if from any cause the velocity is increased, a loss of work immediately takes place, and an increase of waste from the breaking of threads, &c.; on the other hand, there must be an evident loss from the machinery moving slower than is necessary. Various contrivances are used for remedying this evil. (See STEAM-ENGINE.)

GRAIN; the name of a small weight, the 20th part of a scruple in apothecaries' weight, and the 24th of a pennyweight Troy.

GRAMME; the unit of weight in France, which has taken the place of the *gros;* equal to 15.4441 grains Troy, or 5.6481 drams avoirdupois. All greater or less weights are formed from it by multiplication or division: for instance, the *decagramme*, a weight of 10 *grammes*, which is equal to 6 drams, 10.44 grains; the *hectogramme*, a weight of 100 *grammes* (3 oz. 4 dr. 8 gr.); the *kilogramme*, a weight of 1000 *grammes* (about 2 lbs. 8 oz.); the *myriagramme*, a weight of 10,000 *grammes* (about 26 lbs. 9 oz.). The *decigramme* is $\frac{1}{10}$th of a *gramme*, or 1 gr. $\frac{54}{100}$ths; the *centigramme* is a $\frac{1}{100}$th of a *gramme*, or .154 of a grain; the *millegramme* is $\frac{1}{1000}$th part of a *gramme*, or .0154 of a grain: it supplies the place of the *carat*.

GRANULATION, in *surgery*. The little, grain-like, fleshy bodies, which form on the surfaces of ulcers and suppurating wounds, and serve both for filling up the cavities and bringing nearer together and uniting their sides, are called *granulations*. Nature is active in bringing parts whose disposition, action, and structure have been altered by accident or disease, as nearly as possible to their original state; and, after having, in her operations for this purpose, formed pus, she immediately sets about forming a new matter upon surfaces in which there has been a breach of continuity. This process has received the name of *granulating* or *incarnation*. The colour of healthy granulations is a deep florid red. When livid, they are unhealthy, and have only a languid circulation. Healthy granulations on an exposed or flat surface rise nearly even with the surface of the surrounding skin, and often a little higher; but when they exceed this, and assume a glowing appearance, they are unhealthy, soft, spongy, and without any disposition to form skin. Healthy granulations are always prone to unite.

GRAPE-SHOT is a combination of small shot, put into a thick canvass bag, and corded strongly together, so as to form a kind of cylinder, the diameter of which is equal to that of the ball adapted to the cannon. The number of shot in grape varies according to the service or size of the guns.

GRAPHITE. See PLUMBAGO.

GRAPNEL, or GRAPLING; a sort of small anchor, fitted with four or five flukes or claws, and commonly used to fasten boats or other small vessels.

GRATE; a frame of iron bars, used for burning coal as fuel. Grates are commonly smaller than fireplaces intended for the consumption of wood, on account of the greater heat emitted by coal. Those used for burning anthracite should be made deeper and of a greater height than others, so as to present a comparatively small surface to the air; for, in very cold weather, the air conducts the heat from the surface faster than combustion renews it, so that, if the amount of surface exposed be large, the fire will go out. This kind of coal yields no visible smoke. The chimney, however, should be large enough to transmit smoke, otherwise some of the carbonic acid, which is formed during the combustion, will be sent into the room.—This gas is the suffocating vapour of burning charcoal.

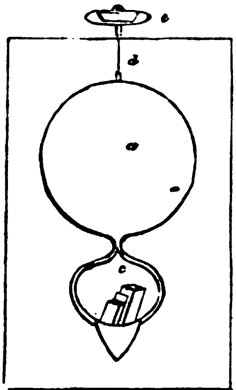
GRATINGS, in *ship-building;* a sort of open cover for the hatches, resembling lattice-work, serving to give light to the lower apartments, and to permit a circulation of air, both of which are particularly necessary, when, from the turbulence of the sea, the ports between decks are obliged to be shut.

GRAVE, in *music*, is applied to a sound which is of a low or deep tone. The thicker the cord or string, the more grave is the note or tone; and the smaller, the more acute. *Grave*, in the Italian music, denotes a very grave and slow motion, somewhat faster than *adagio*, and slower than *largo*.

GRAVER. See ENGRAVING.

GRAVIMETER. This is a very valuable instrument for determining the specific gravity of bodies. The

one represented beneath was invented by Nicholson. *a* is a hollow ball of brass or copper; *e* is a dish affixed to the ball by a short slender stem *d*; *c* is another dish affixed to the opposite side of the ball by a kind of stirrup. In the instrument actually made, the stem *c*, is of hardened steel, $\frac{1}{40}$ of an inch in diameter, and the dish *c* is so heavy as in all cases to keep the stem vertical, when the instrument is made to float in any liquid. The parts are so adjusted that the addition of 1000 grains, in the upper dish *e*, will just sink it in distilled water, at the temperature of 60° of Fahrenheit's thermometer, so that the surface shall intersect the middle of the stem *d*. Let it now be required to find the specific gravity of any fluid. Immerse the instrument therein, and by placing weights in the dish *e* cause it to float, so that the middle of the stem *d* shall be cut by the surface of the fluid. Then, as the known weight of the instrument added to 1000 grains is to the same known weight added to the weights used in producing the last equilibrium, so is the weight of a quantity of distilled water displaced by the floating instrument to the weight of an equal bulk of the fluid under consideration. And these weights give the ratio of the specific gravities. Again, let it be required to find the specific gravity of a solid body less than 1000 grains. Place the instrument in distilled water, and put the body in the dish *e*. Make the adjustment of sinking the instrument to the middle of the stem, by adding weights in the same dish. Take those weights from 1000 grains, and the remainder will be the weight of the body. Place now the body in the lower dish *c*, and add more weight in the upper dish *e*, till the adjustment is again obtained. The weight last added will be the loss the solid sustains by immersion, and is the weight of an equal bulk of water. Consequently the specific gravity of the solid, compared with water, is as its weight to the loss it sustains by immersion.



GRAVITY, in *physics*; the natural tendency or inclination of bodies towards a centre.

Terrestrial gravity is that force by which all bodies are continually urged towards the centre of the earth. It is in consequence of this force that bodies are accelerated in their fall, and, when at rest, that they press the body, or that part of the body, by which they are supported. As to the cause of gravity, or its nature, nothing is known; and it would be useless to detail the hypotheses advanced to account for this most important law of nature. All that can be said is, that it appears to be an essential property of matter, or, at least, of all matter that has hitherto become the object of human investigation, though it is by no means certain that matter may not exist which is not subject to its influence. This part of the subject appears to be beyond human comprehension. Instead, therefore, of wasting our time in useless speculation as to the cause, let us only attend to its effects, and content ourselves with examining more particularly the manner in which this principle operates on material bodies, and the laws by which it appears to be regulated; the principal of which, as deduced from experiment, or from the most unequivocal inferences, are as follows: 1. that gravitation takes place between the most minute particles of bodies; 2. that it is proportional to the masses of these bodies; 3. that it varies inversely as the square of the distance, in proceeding from the surface of the body outwards, or from its centre; 4. that it varies directly as the distance, in descending from the surface to the centre in uniform spherical bodies; 5, that it acts equally on bodies in a state of rest as on those in motion, and that its action in the latter case is always the same, whether that motion be to or from the centre of attraction, or in any other direction; 6. that it is transmitted instantaneously from one body to another.

Gravity, as relating to the science of mechanics, is divided into *absolute* and *relative*.

Absolute gravity is that by which a body descends freely and perpendicularly in a vacuum or non-resisting medium. *Relative gravity* is that by which a body descends, when the absolute gravity is constantly counteracted by a uniform, but inferior force, such as in the descent of bodies down inclined planes, or in resisting mediums. (See HYDROSTATICS, SPECIFIC GRAVITIES, and MECHANICS.)

GRENADE; a hollow sphere of iron, differing from a bomb by the smallness of its diameter. The smallest grenades, or those thrown by the hand, are called *hand-grenades*; they are from 2½ to 3½ inches in diameter. The fusee is calculated to burn from twelve to fifteen seconds, so that time is allowed for throwing them. The short distance to which they can be thrown, and the danger of accidents, have occasioned them to be disused. The small grenades are now employed only for what are called, in French, *perdreaux*, several of them being fastened to a board, and thrown from mortars. The grenades in general use are thrown from howitzers, and are of very different sizes, from two to twenty pounds' weight. They are chiefly calculated to act against cavalry and distant columns, where they may do great harm. In the battle of Wagram, one grenade killed and wounded forty men. As the utility of large grenades at sea is acknowledged, but objections exist to the use of howitzers of large calibre, the United States introduced the use of oval grenades in 1815, which may be fired from twelve and twenty-four pounders. In the British service the grenades are made with a spiral thread on the surface, that the opposition of the air may give them a rotatory motion, and thus more certainty of direction. Grenades are often thrown from cannons. During the siege of Gibraltar, they were thrown 3000 yards upon the Spanish works.

GRENADIER; originally a soldier destined to throw the hand-grenades. Soldiers of long service and acknowledged bravery were selected for this service, so that they soon formed a kind of *élite*. They were the first in the assaults. When hand-grenades went out of use, the name *grenadier* was preserved, and the troops so called generally formed one company of a regiment, distinguished by the height of the men and a particular dress, as, for instance, the high bear-skin cap. This continues to be the case in most armies. In the Russian and Prussian armies, the grenadiers form whole regiments belonging to *corps d'armée* of the guards. With the French, the grenadier com-

pany is (and was under Napoleon) the first of each battalion. The dragoons among them also had grenadier companies, which were afterwards united under the name of *grenadiers à cheval*, a kind of cavalry between cuirassiers and dragoons. Our own grenadiers have generally been found the most effective men in the service.

Groin, among builders, is the angular curve made by the intersection of two semi-cylinders or arches, and is either regular or irregular:—*regular*, as when the intersecting arches, whether semi-circular or semi-elliptical, are of the same diameters and heights; and *irregular*, when one of the arches is semi-circular, and the other semi-elliptical.

Groschen; a silver coin, so called from the Latin *grossus* (thick); thick coins, in opposition to thin lead coins. The oldest groschen known were struck in Treves, in 1104. The first Bohemian groschen were coined in 1296, at Kuttenburg. In 1525, the groschen was divided into twelve pfennige. In 1504, the small groschen, now in use, were first struck at the city of Gosslar. The Marien-groschen are valued at eight pfennige, and thirty modern groschen of Prussia are equal to a thaler.

Grosch is also the name of a Russian copper coin, worth two copecks.

Gross, in opposition to *net*, is applied to merchandise including that in which it is packed. It refers particularly to weight. Thus we say, "The bag of coffee weighs nine hundred weight *gross*," that is, including the weight of the bag.

Grotesque, in *painting*, is often confounded with *arabesque*. All ornaments compounded in a fantastical manner, of men, beasts, flowers, plants, &c., are called sometimes *arabesques*, and sometimes *grotesques*: but there is a distinction between them. Arabesques are flower-pieces, consisting of all kinds of leaves and flowers, real or imaginary. They are so called from the Arabians, who first used them, because they were not permitted to copy beasts and men. As they were also used by the Moors, they are sometimes called *moresques*. The Romans ornamented their saloons with paintings in which flowers, genii, men and beasts, buildings, &c., are mingled together according to the fancy of the artist. These ornaments are properly called *grotesques*, because they were found in the ruined buildings of the ancient Romans, and in subterranean chambers, which the Italians call *grottoes*.

The origin of these fantastic compositions is traced, by Bottiger, to the carpets of Persia and India, adorned with all the wonders of Oriental fable. In the baths of Titus and Livia, at Rome, in Adrian's villa at Tivoli, in the houses in Herculaneum and Pompeii, and many other places, such grotesques have been found; sometimes, indeed, showing an excess of ornament, but generally valuable for their arrangement and execution. Raphael was well aware of their beauty, and caused his pupils, particularly Giov. Nanni da Udine, to use them as patterns in painting the porticoes of the Vatican. He likewise used them, as the ancients did, for borders. The taste for grotesques has, in part, degenerated into the monstrous and unnatural; *grotesque* has therefore become a term of art to express a distorted figure, a strange monster, the offspring of an unrestrained imagination.

Grotto; a small artificial edifice made in a garden, in imitation of a natural grotto. The outsides of these grottoes are usually adorned with rustic architecture, and their inside with shell-work, coral, &c.

Grouping, in the *fine arts*, is that arrangement of objects by which their individual characteristics are severally resolved into the component parts of a whole, which is then called a group. A group may consist of as many parts or objects as the skill of the artist enables him to combine together, but cannot be formed with less than two. One object can never bear the name of a group; and even though there should be many objects introduced, unless they mutually assist each other in forming something more complete than either of them when separate and alone, they cannot be termed a group, for it is the essential principle of a group, that the parts should be so intimately combined and blended together, that they should lose their character as distinct objects and become an unalienable portion of a mass which should appear to be one—an undivided, indivisible whole. The parts should bear such a relation to each other, that if ever separated, as is the case sometimes in sculpture, they should lose much of their character, and should evidently show that they are but part of a group, and not complete in themselves.

Grouping is the first requisite of any work of art in which more objects than one are introduced, and may be divided into two classes, close and open, the former applicable to both masses and lines, the latter to lines only; or, to speak less technically, the close group may be formed of objects, some of which shall be broad and occupying a large space, as drapery, and others of a more slender nature, such as naked limbs, staves, &c.; in this case the character of the group will depend principally on the relation of quantities, but the direction of lines in such objects as naked limbs are still available materially to increase the effect, and the most perfect group must necessarily be of this class. The open group is rather tolerated as a skilful evitation of disadvantages, by a harmonious arrangement of slender objects, than held up to admiration for its intrinsic beauty. This species of group is by far the most difficult to achieve successfully, from the want of variety in the quantities; and its character will principally depend on the direction of the lines formed by the main objects. Lightness is generally the advantage proposed by this style of grouping, but disunion is too often the result; and it never can equal a skilful arrangement of lines, threading and overlaying well varied and properly combined masses.

From the above it would appear that, as grouping is dependent upon the relation of quantities and lines, it must be subject to mathematical rules, though they have never been strictly defined. What is termed the science of grouping, or composition, comprises merely a few vague and general principles, gleaned from the works of those who have been great in practice and experience. These differ in painting and sculpture, what is deemed right in the one being rejected in the other. From the different nature of the materials employed, and the different process of working them, inductions of principles widely differing have resulted. The pyramidal form of groups is, in sculpture, almost a matter of necessity, from the solidity required in the base to support the weight of the upper part. Unless worked in metal, lightness of composition is nearly proscribed to this branch of the arts. The example we have chosen of a group from the antique sculpture, the Toro Farnese (see Arts, Fine, *Plate* V.), is carried as far in the way of

lightness as the art will allow in so extensive a composition; but it will be seen that, to support the superincumbent weight, blocks or stems of trees have been introduced, which can be looked upon as no other than unavoidable defects. Many attempts have been made to avoid the use of these incumbrances; but we are not aware of any instance in which it has been so successfully done as in the noble group of the Archangel Michael and Satan, by our own Flaxman, in the possession of the Earl of Egremont, to which we shall presently have occasion again to refer on another ground. In this instance, the tail of Satan is so admirably entwined with the legs of the angel as to afford all the requisite support for the upper part of the figure, whilst it conceals nothing in the principal view of the group.

In sculpture, a group requires to be so composed as to display a harmonious arrangement of lines, and a due balance of masses, from more points of view than one—frequently from all points, which compels a more purely scientific arrangement than is absolutely necessary, and we may say usually adopted, in the sister art, which professes to afford but one point of view; and it may probably be concluded that the absence of due investigation on the part of the most numerous class of professors, those of painting, has left us decidedly without true principles either of grouping or judging of groups when executed. The sculptor, from the nature of his materials, can achieve all that is required of him by positive experiment. Experience, therefore, supplies the want of science with him, and man is apt to be too indolent to search for a principle to supply what he can with facility obtain by practice. The painter, on the other hand, has not such ready means of experiment; to alter is with him to re-execute: but he has an all-powerful veil in chiaro-scuro to hide the errors he was not sufficiently skilful or industrious to avoid. Most of the artists have a kind of bed of Procrustes to which they reduce all their subjects; and by the application of the few vague rules, gathered from the practice of their predecessors, whom they strictly imitate, they produce what, with the aid of colour and chiaro-scuro, pass current for scientific works, from the want of some true standard or principle to judge by.

The few principles established may be comprised within the following rules:—

1. The principal objects should occupy the largest spaces, and form the largest masses of the group, and should be set off and contrasted by smaller parts of different character.

2. The two sides should be varied both in quantity and character.

3. The general form or outline of the group should be free from harsh, angular projections, or vacuities of any decided shape, and the ground-plan as varied as the nature of the objects will allow.

These rules, amplified with such necessary consequences as setting off projecting parts with receding ones, convex forms with concave or flat, upright with diagonal or horizontal, straight with curved lines, are all that are at present agreed upon. The arts have progressed rather by strong feeling or genius than any decided principle, which at once explains the inequality found in the works of all the great masters, and the utter incapability of their pupils to preserve the acquirements of what is from hence evidently falsely termed science. Frequently the eye has acquired correctness and taste, and the hand great facility; but the exercise of the mind has had so little to do with it that though the artist could perceive errors, and point out their remedy, he was unable to explain the principle on which his decision was formed.

The pyramidal form is one of the most approved for the general shape of a group, as conventionally settled to be the most universally agreeable, and, perhaps we may add, to the artist most useful, most easily managed, and, under any circumstances, most readily come at. But, unless to produce a peculiar effect, which will be treated of under the head of ILLUSTRATION, it will be the better if the apex of the pyramid be removed a space from the centre, for the sake of obtaining more variety and inequality in the two sides. The principal differences in groups will be found to exist in the ground-plans, on which various theories have been adopted. Raffaelle has given us a specimen of an oval or circular arrangement of figures in his cartoon of the Death of Ananias. Titian took a bunch of grapes for his system, which gave a central convexity with retreating ends. Others have adopted the opposite scheme, making their groups on a concave ground-plan. But these are incidental applications of the foregoing rules to particular cases, and perhaps too evidently systematic to bear much repetition. One of the most powerful engines in grouping is the arrangement of the lines formed by the objects, so as to secure a sweep or convolution, as the group is intended to be of a graceful or an energetic character.

Long and flowing lines have always an agreeable effect in a composition of numerous parts, as they give the appearance of connection and union, which we have already shown to be the essential principle of grouping. Some remarkable effects may be found produced by this means, of which one of the most striking instances exists in Fuseli's stupendous Lazar House. The long line formed by the principal figure, with his drapery blended into that of the female about his knees, is carried on to the other figures behind so judiciously, that it would be impossible to detach any portion, however slight, without breaking a link of the mighty chain with which those horrors are bound together. Another instance, of a more graceful and agreeable character, will be found in the Paolo and Francesca, in the Whirlwind, from Dante, by the same artist. Here the flowing lines of two exquisitely drawn figures are so intimately and beautifully blended, so naturally and yet so ingeniously lengthened, by making one figure considerably higher than the other, that, as a composition of two figures, it is perhaps without its equal in the world. The same principle pervades Flaxman's celebrated group of the Archangel Michael and Satan. Being in sculpture, and to be viewed from different points, it was constructed, almost of necessity, with a view to agreeable variety and play of line alone. In it you have a long flowing line, twisted into a kind of knot at the base, in the figure of Satan, and thereby affording a solidity which supports, and at the same time contrasts, the lightness and tenuity of the angel above. But there would be no end to instances of the application of the rules already laid down: all the finest works of art are constructed according to them, with variations in manner and style, which form the peculiarities, merits or demerits, distinguishing each school.

It is advisable to avoid too sudden and violent contrasts near the principal figure or object, if there be more than two components to the group. A kind of echo of the actions has sometimes a beautiful effect, as giving strength and preponderance to what is intended to be a leading feature; but these delicacies in grouping require considerable practice, before success can be ensured. Some remarkable instances of unity have been produced by these means, but more frequently sameness and want of variety are the result. In the Witches, from Macbeth, poetical expression allows of great similarity, and the character of the objects almost preclude much difference of attitude: here the pyramid reigns in full force; and this is one of the instances in which the equality of the two sides might have been admitted; but, upon a principle belonging to *illustration* rather than grouping, Mr. Frank Howard has preferred an arrangement by which his "Weird Sisters" become an admirable specimen for the present subject, without being in any way deficient in poetical character. To obtain originality, he has made one of the side figures principal, and occupying the largest space, and contrasted the broad and simple folds of her drapery by the narrow and diverging folds of the dress of the centre figure. The third assimilates to both her sisters, having some parts of her vestment in ample folds, and some more close and contracted. There is no violent contrast: the lines formed by the drapery and staves on which the witches rest, are gradually raised from each other, until the two sides are inclined in opposite directions; the group is solid; and the external form without decided angles or vacuities, will not bear the removal of a line. The similarity of the attitudes of the figures ensures that union which is the first requisite of a group.

We find few groups among the relics of antiquity, and those, with one or two exceptions, constructed on the most simple plan. But, celebrated as some of these are, they do not reach the perfection of the single figures. It must be allowed that, having little more than sculpture remaining, we have not so good an opportunity of judging as could be wished; but the fame of the most admired pictures has come down to us, and we do not find the Venus of Apelles, or that of Praxiteles, rivalled by a group. The most extensive and elaborate composition in sculpture which has been preserved is that already referred to as our exemplar (see ARTS, FINE, *plate* V.), the Toro Farnese, more remarkable as a scarce specimen, than for any particular merit as a group. The bull, from which it takes its name, occupies the apex of the pyramidal form to which it generally tends; and the avenging sons, Zethus and Amphion, one pushing and the other pulling the infuriated animal, are skilfully varied without any violent contrast, both aiding to complete the general form by leaning forward. But from hence the skill declines. Dirce, seated upon the rock on which Zethus, Amphion, and the bull are standing, seems rather in the character of a support to the animal than a principal of the composition. Antiope, in a quiet attitude on the other side, fills up an unpleasant opening between the bull and one of her sons, and serves by her calmness to give vigour to the group, but to which, strictly speaking, she can hardly be said to belong. The unfortunate Lycus is likewise detached, and serves to ornament the rocky base as an adjunct rather than a component part of the group. Altogether, it does not display science in arrangement commensurate with the exquisite execution of individual parts, for which the antique sculpture is so remarkable, and in which we are taught to consider the remains unrivalled at present, and impossible to be surpassed at any time. The ancients do not seem to have held grouping in equal esteem with individual character of form and fine proportion. This love of simplicity, in opposition to complexity and combination, is also apparent in another art, that of music, in which their prejudices were so strong as to induce the memorable infliction of punishment for adding a few notes to their scale, and affording greater capabilities for the display of any power they might possess: an act more worthy of nations deemed by them barbarians. But the same feeling predominating in all the relics of their works of art, whether of painting or sculpture, we are compelled to search for its actuating principle in want of skill to combine, or appreciation to admire the combination of beauties of different characters.

The earliest grouping of any extent is to be found in the works of the Florentine school: the Campo Santo of Pisa, and the gates of Ghiberti, so admired by Michael Angelo, who afterwards carried grouping to a perfection that has never yet been excelled. And, if the ancients are alone in the representation of single and simple figures, Michael Angelo must be considered alone in the combination of extensive and energetic groups.

Grouping has, since his time, been an object of unceasing study, and is now considered one of the most essential requisites in a work of art, and one of the highest objects of attainment. Still the science has been neglected for practical facility, and we cannot but think that the arts decline in consequence. One great mind arises, and from an intuitive perception of the relations of quantities and lines, or from some strong impression produced by accidental circumstances, originates a splendid work, of a different character from any of his predecessors. If really scientifically constructed, it seldom happens that the artist is able or willing to explain the principles on which he acted; his pupils, therefore, merely imbibe some portion of their master's feeling, and, parrot-like, imitate his style, which soon degenerates into mannerism, because attempted without a knowledge of the originating principle, and without the same perception of the qualities of mass and line.

The fewer the objects the more difficult to group, which gave Fuselli occasion to say that "to invent a good single figure was a very difficult thing, that to compose two was not very easy, but that three figures would compose themselves." The slightest attention to diversifying the quantities and lines of two figures on either side of a third in the centre, so completely ensures an agreeable general form, and a due balance of parts, as almost to justify this quaint remark. Thus, in the celebrated group of Laöcoon and his two sons, the attitudes of the latter are combined with that of the principal figure, so as to produce a pyramidal form, varied on each side in shape and quantity; and the vacuities formed by the extended action of the father are filled up, by the limbs of the sons, in such a simple and natural manner as to appear almost the necessary consequence of the materials. But suppose the abstraction of one of the children, and the difficulties of the grouping are immensely increased. Had the remaining child been on either side, the due balance of parts could hardly have been

Drawn by Felix Blunt. Engraved by J. Dey

preserved The disproportion of size between the figures would have created too great a contrast to allow of harmony, and the preponderance of the one side would have given a tottering character to the group, that would have excited an apprehension of more danger to the son from the overwhelming weight of his father than from the bite of the serpent.

Mr. Ottley remarks that the Florentine and Roman schools arranged their groups of figures so as to make complete compositions without the intervention of drapery, and that they clothed their figures in such a manner as not to interfere with the first arrangement; but, in the schools which followed, the drapery became an essential part of the composition, which style prevails strongly in the present day, having derived a charm from being peculiarly adapted to splendour of colour and chiaro-scuro.

GUIDES; in some armies, persons particularly acquainted with the ground, who serve in the staff, to give the necessary information, and point out the best route for an army. As it is, however, impossible always to have officers of this kind, some armies have geographical engineers attached to the staff, whose particular studies are geography and topography. Napoleon gave the name of *guides* to his first body of guards, formed after he had been on the point of being surprised and taken prisoner in a castle on the Mincio.

GUILD, in *commerce;* a society, fraternity, or company, associated for carrying on commerce or some particular trade. The merchant guilds of our ancestors answer to our modern corporations. The societies of tradesmen, exclusively authorized to practise their art, and governed by the laws of their constitution, played a very important part in the middle ages. Few institutions show the progress of civilization in a stronger light than that of guilds, from the first rude mixture of all kinds of labour, its division, the establishment of corporations, the corruption of these by privileges which are in some cases highly absurd, down to their total abolition, and the restoration of liberty to human industry. Though the division of labour is comparatively of recent date, yet the division of the people by occupations is one of the oldest and rudest political institutions of which history makes mention. These divisions by occupations or castes generally took their rise, however, from a difference of national origin, as with the Egyptians, Indians, &c. The Romans had various mechanical fraternities, which might be compared to modern guilds, as they had the right to enact by-laws. In the later times of the republic, these societies not unfrequently appeared as political parties; and, on this account, their influence was restrained, and they were partly abolished after the establishment of the monarchy. In Italy, the cradle of the class of free citizens in the middle ages, and particularly in the Lombard cities, those connecting links between the ancient and modern civilization, some remains of these Roman institutions, or recollections of them, probably contributed to revive the guilds, which naturally presented themselves as an excellent means of supporting the citizens against the nobility, by uniting them into powerful bodies.

With the increasing importance of the cities, which became the seats of industry, and with the establishment of their constitutions, begins also the extension of guilds. The chief reason that mechanical industry was freely developed in the middle ages, at the same time with agricultural, which had been exclusively cultivated by the Greeks and Romans, was the independence which the mechanics acquired with the growth of municipal and civil liberty. Mechanical industry has always been essentially of a democratic character, and would never have flourished under the feudal system. It is not possible now to give the exact date of the origin of these societies in Upper Italy. Traces of them are found in the 10th century. Thus, in Milan, we find the mechanics united under the name *credentia*. It is certain that small societies of mechanics existed as early as the 12th century, which appear, in the following century to have been in the possession of important political privileges. We even meet with abuses in these bodies as early as this period; and, several centuries later, the guilds became the subject of bitter and just complaint, particularly those in Germany.

When the advantages of these associations became known and felt, they rapidly increased; and, in the struggles of the citizens and the nobility, the principal resistance against the latter was made by the corporations. As soon as the citizens acquired an influence on the administration, the guilds became the basis of the municipal constitutions, and every one who wished to participate in the municipal government was obliged to become the member of a guild. Hence we often find distinguished people belonging to a class of mechanics, of whose occupation they probably did not know any thing. This mixture of social and political character, as well as the insignificance of the individual, considered merely as such, is a natural consequence of the rudeness of the period. Just principles are the work of time. It is only by slow degrees that the true is separated from the false, the essential from the unessential. Political, like religious and scientific principles, are at first always vague and incoherent. Men must have long experience of the concrete before they form just notions of the abstract. Thus it is a characteristic of the middle ages, that political rights were considered as arising from special privileges. All that men enjoyed was looked upon as a gift from the lord paramount. In fact, the idea of the rights of man, as an individual, has been developed only in very recent times. Even the ancient republics had no just conception of it.

In Germany, the establishment of guilds was also intimately connected with that of the constitutions of the cities. The latter were different according as the ancient Roman or the old German organization of the community prevailed; the relations among the mechanics were also very different. The mechanical arts were at first practised chiefly by the villeins; and, even in the time of Charlemagne, they appear to have been pursued on the estates of the feudal lords, by the bondsmen, as is still the case on the great possessions of Russian noblemen. Commerce on any very extended scale could not, however, be carried on by bondsmen. Although there early existed free mechanics, yet they were also under the protection and jurisdiction of the feudal lord, before the privileges of the cities were acknowledged, except in cities of Roman origin. These privileges early secured to them, as a distinct class of vassals, a sort of organization under the direction of the masters of each trade, as appears from the oldest law of the city of Strasburg, which seems to belong to the 15th

century; and out of this the guilds in Germany may have originated. The full developement of the guilds in Germany occurred in the last half of the 12th century, and the oldest examples are those of the cloth-shearers and retailers in Hamburg (1152), the drapers (1153) and shoemakers in Magdeburg (1157). But they possessed no political importance in Germany before the 13th century, when a struggle arose between them (the labouring classes) and the citizens belonging to ancient families, the civic aristocracy. The guilds were victorious, and became so powerful, that even persons of "free occupations" joined these associations, as the allodial possessors of land sometimes placed themselves under feudal lords. The corporations of merchants and mechanics became more and more confirmed in their privileges and monopolies, whilst the country people suffered by being made, in many respects, the slaves of the guilds. Particular branches of industry were often subject to restrictions in favour of the guilds, which were sometimes of a most offensive nature. The guilds became insupportable aristocracies, sometimes allowing only a certain number of master mechanics in the place, and seldom admitting any one into their associations except favourites of the masters. The examinations for the admission of a journeyman to the rank of a master were used as means of extorting money, and were often combined with the most absurd humiliations.

The guilds are now abolished in a considerable portion of Germany; and yet many persons wish to restore the ancient order of things, as a support of aristocratical distinctions, and as tending to repress that free exercise of industry which is so favourable to the growth of the democratic spirit. Attempts were made to check the insolence of the guilds by the laws of the empire, in 1731, but without success. In France, the guilds also originated with the increasing importance of cities, and became general in the reign of Louis IX.; but they were subject to abuses, as in Germany, and were abolished at the time of the revolution. In this country, the societies of mechanics are important principally in a political respect, on account of their connection with the democratic element of our constitution.

GUILLOTINE. This instrument has been erroneously considered the invention of Guillotin, a physician of Paris, during the French revolution. A similar instrument, called *mannaia*, was used in Italy for beheading criminals of noble birth. The *maiden*, formerly used in Scotland, was also constructed on the same principle. The Convention having determined, on the proposition of Guillotin, to substitute decapitation for hanging, as being less ignominious for the family of the person executed, the guillotine was adopted, also on his proposition, as being the least painful mode of inflicting the punishment. It was erected in the *Place de Grève*, and the first criminal suffered by it April 25, 1792. Portable guillotines, made of iron, were afterwards constructed. They were carried from place to place, for the purpose of executing legislative enactments. This machine consists of two upright pillars, in the grooves of which a mass of iron, sharpened at the lower extremity, is made to move by cords. Being raised to a certain height, it falls, and at once severs the head of the criminal (who is laid upon a horizontal scaffolding) from his body. It is much surer than the sword or axe, which is sometimes used for decapitation, and of which we read, in many instances, that several blows have been necessary to put an end to the life of the sufferer. In the reign of terror, it was called by the most violent political fanatics *notre très Sainte-Guillotine*. It is still the common instrument of capital punishment in France.

GUINEA; an English gold coin, legally worth twenty-one shillings sterling. Guineas were first coined in the reign of Charles II. (1662), of gold which the English procured from Guinea, and hence the name. Till 1718, they were of the value of twenty shillings sterling.

GUINEA CLOTH. Mariners give the name of Guinea to a much greater extent of the African coast than is recognized by geography; and, in commerce, several articles made for the African trade are called by this name. Guinea cloth is a kind of calico, calculated for the African market, where it is an important article of barter. There are also Guinea knives, &c.

GUM; one of the proximate principles of vegetables, distinguished by the following properties:—It is an insipid, inodorous, uncrystallizable solid, more or less transparent, the various colours which the different kinds possess being derived from mixture with colouring principles, while exuding in a fluid state. It is insoluble in alcohol, and extremely soluble in water, in which properties it is the reverse of resin. It differs from mucilage only in being deprived of the water which rendered it fluid; and, of course, when water is added, it again becomes mucilage. This mucilage is apparently not susceptible of fermentation, and may be kept for a long time, as it is less disposed to spontaneous changes than almost any vegetable product. Its chemical composition so nearly approaches sugar, that it may be converted into it by means of nitric acid. Gum, as above defined, is identical in all vegetables, and the different kinds vary only in the quantity and quality of the substances united with them. It exists naturally almost pure in gum-Arabic and gum-Senegal, and, more or less mixed, in the gum which exudes from the plum, cherry, and other fruit-trees, as also in the mucilage of flax-seed, slippery elm, &c. Various resins and gum-resins are commonly confounded under this appellation.

GUM-ARABIC is the product of the *mimosa nilotica* and some other species of the same genus, inhabiting the sandy parts of Arabia, Egypt, Senegal, and Central Africa. It exudes spontaneously, in a fluid state, and remains attached to the branches after it has concreted and become solid. This exudation takes place continually, during the whole of the dry season, from October to June, but more copiously immediately after the rains. December and March are the two months in which this gum is collected by the Arabs, with whom it is an important aliment, those tribes that are continually wandering in the desert often making it their principal article of food during a great part of the year.

Gum-Arabic is obtained in rounded masses, transparent, or of a light yellow colour, capable of being easily reduced to a powder, insipid to the taste, or possessing a slight acidity, which, however, is perceptible only by those who use it habitually. It is easily soluble in water, and the solution has the property of conveying pulverised solids through a filter, which would separate them were they suspended merely in water: thus it is impossible, by

this means, to separate powdered charcoal from gum-water. In pharmacy, gum-Arabic is employed to suspend in water substances which otherwise could not be kept equally diffused, as balsams, fixed oils, resins, &c.; but its principal consumption is in manufactures, forming the basis of crayons and cakes of water-colours, as well as of writing-ink, and several liquid colours, serving to increase the consistency of these colours, and to prevent their spreading in calico-printing, affording a clear cement for joining light substances, which may be prepared in a moment, giving a lustre to ribands, silks, &c., which, however, is destroyed by the application of water. It is, besides, used for a great variety of purposes. In medicine, it is frequently employed, especially in dysenteries, as a demulcent, and enters into the composition of a variety of emollient preparations. Gum-Senegal, as it is called, has the same chemical character with gum-Arabic: indeed, the chief part of the gum-Arabic of commerce is brought from Senegal, and constitutes the most important article of trade with that country.

Gum Resins apparently combine the properties of gums and resins, being partly soluble in water, partly in alcohol; but they are evidently compound substances, formed of two or more vegetable principles, which, indeed, are often in a state of mere mechanical mixture. Aloes, assafœtida, galbanum, gamboge, olibanum, scammony, and a great variety of concrete juices, are referred to this head. (See Resin.)

Gun; a fire-arm, or weapon of offence, which forcibly discharges a ball, shot, or other offensive matter, through a cylindrical barrel, by means of gunpowder. *Gun* is a general name, under which are included divers, or even most species of fire-arms. They may be divided into great and small. Great guns, called also by the general name *cannons*, make what we also call *ordnance*, or *artillery*, under which come the several sorts of cannon. Great guns of all sorts, cannons, carronades, &c., whether of iron or brass, are cast in sand, and afterwards bored. Small guns, muskets, fowling-pieces, &c., are forged from bars of malleable iron, hammered to a proper width, and then turned over a mandril, or cylindrical rod, so as to form a tube with a bore smaller than that of the intended piece. The edges overlap about half an inch, and are firmly welded together. The tube is then hammered, in semicircular grooves, on an anvil hollowed for the purpose. It is afterwards bored with several instruments, of different sizes, in succession, till the hollow is sufficiently large and smooth. A plug is firmly screwed into the breech, so as to make it perfectly close. The projecting parts of the barrel, the sight, the loops which fasten it to the stock, &c., are soldered on.

Gunnery signifies the science of using artillery against an enemy judiciously, and to the greatest effect. Besides an accurate acquaintance with the management of ordnance of all kinds, the military engineer should understand the range, the charge, and direction necessary for different distances, their materials, with the manner of making and of preserving them. He should also know the component parts, the fabrication, the effect of gunpowder, and the method of preserving it, with the manner of preparing and managing every thing that appertains to ammunition. The artillerist must be able to instruct his men in their exercises, both on horseback and on foot; he must be well acquainted with the management of the horses that are used to transport the cannon and to mount the flying artillery; he must know how to harness them to the cannon, how to move and manœuvre with them on ground of every kind, how to repair, at the moment, any sudden damage, and must be thoroughly acquainted with tactics, especially with the peculiarities of the ground, and with the art of availing himself of them most judiciously in the disposition of his artillery. He must, finally, be able to attack or defend any position; he must have an accurate acquaintance with the science of fortification; but especially he must be practically skilled in throwing up batteries and other field-works, so that he may be able, by disposing his artillery before or within a strong place, to assist the engineer most effectually in its attack or defence. Besides, the artillerist has often the regulation of the lights, and other signals, in time of war, of the fire-works in peace, &c. All this must be learned by experience, and by the study of auxiliary sciences. Mathematics (particularly the doctrine of curves, to calculate the path of the balls), physics, and chemistry, are also very necessary, in order to understand the effect of powder, and the manufacturing of ammunition, as well as that of all kinds of fire-works.

Gunpowder is a mixture of saltpetre, sulphur, and charcoal. If we may believe the relations of the missionaries, and the reports of the Chinese historians, the Chinese were first acquainted with the application of gunpowder. Perhaps it proceeded from them to the Arabs; for, in 1331, the Moors used it in their operations before Alicant, and certainly in 1342 at Algesiras. Among the Europeans, the traces of this invention are still more ancient; for the Greek fire, which was first employed in 668, must have, at least, contained saltpetre mixed with pitch, naphtha, &c., since it was customary, by means of it, to hurl stones from metallic tubes. The first information of the knowledge of the Europeans with regard to the chemical mixture of powder is found in the ninth century, in a book composed by Marcus Gracchus, preserved in the University of Oxford, which also accurately explains its composition. Roger Bacon (who died in 1294) was likewise acquainted with the power which saltpetre has, when set on fire, of burning vividly.

The discoverer of the power of powder, when confined and set on fire, of propelling heavy bodies, was, according to common report, Berthold Schwartz, a monk, who is said to have lived at Mayence, between 1290 and 1320. He, in some of his experiments in alchemy, had put the mixture into a mortar, and, having accidentally dropped into it a spark of fire, to his astonishment saw the pestle fly off into the air. In 1356, powder is mentioned in the accounts of the treasury of Nuremberg; in 1360 the House of Assembly at Lübeck was burned by the imprudence of the powder manufacturers; and, in 1365, the Margrave of Misnia had pieces of artillery in his possession. In the course of a few years afterwards, it was known through Europe. Thus the first traces of this invention would appear to be found in Germany; other nations, however, have put in their claims to this honour.

The proportion of the ingredients in the composition of gunpowder is different in different countries: in the Prussian powder-mills, 75 parts of saltpetre, 11 parts of sulphur, and 13½ parts of charcoal, are

used but in the French mills, 75 parts of saltpetre, 12½ of coal, and 12½ of sulphur. In the manufacture of this article, which is carried on in very different ways, much depends upon the goodness of the ingredients. The crude saltpetre is broken up, moistened, and exposed to the action of a slow fire, continually skimmed and violently agitated, till all the moisture evaporates, and the saltpetre remains in the form of a fine powder. The sulphur is pulverized after having been well purified. The charcoal is that derived from the alder, or any other soft wood or bushes, as, for example, hemp-stalks, which are burned with great care in a confined room, and reduced to a fine powder.

These three ingredients are moistened, and brought under a stamping, or more commonly a rolling-mill, where two metallic, or, which are better, marble cylinders, turn round a fixed vertical wooden pillar, and crush to pieces the mixture, which lies upon a round smooth surface of the same material. Other mills effect this bruising operation by several large iron runners, revolving upon a metallic plate, similar to a painter's grinding-stone, or by a rapid revolution of the mixture in casks containing metallic balls. After the mixture, in some one of these ways, has been acted on in the mills for the space of six or eight hours, and when the ingredients are united, and form one homogeneous mass, it is pressed, while yet wet, by means of cylindric rollers of wood, through a perforated sieve, by which the powder is formed into grains. In other mills, this process of forming it into grains takes place after the powder has been pressed between two boards into a solid cake, and then submitted twice to the operation of a grooved roller of wood or copper.

The powder, after it has been grained, is spread upon boards in the drying houses, and exposed to the strong heat of an oven for two days. In order to prevent its taking fire, the oven is well lined with clay and copper. Of late years, this process of drying has been generally effected by means of steam. Finally, the powder is sorted by being passed through several sieves. In the first, or coarsest, remains what is entirely useless; through the second passes the second-sized, or cannon powder; and through the third and last the finest, or musket powder. The powder, thus prepared, is packed in oaken casks.

Gunpowder should be of a slate colour, with a round and pure grain, and also have a uniform colour on being broken up; nor should it leave behind it, either on the hand or on paper, any black spots. When set on fire, it should burn at once, without crackling, or leaving upon paper any appearances of its combustion. When applied to the tongue, the taste should be extremely cooling. In order to prove its strength, let any person apply an accurately fitting ball to a small mortar, and the distance to which the ball is thrown will prove the strength of the powder. The French government *eprouvette* is a mortar seven French inches in diameter, and three ounces of powder must throw a copper globe, of 60 pounds weight, 300 feet; otherwise the powder is not admissible. Another method is, to suspend a small cannon as a pendulum, and to judge of the strength of the powder by the force of the recoil, which will describe a greater or less arc of a circle. In the preservation of powder, fire and water must both be carefully guarded against.

Powder destined for military purposes should be deposited in an airy building, removed at least 1000 paces from any habitation, provided with lightning rods, and surrounded with walls, ditches, and palisadoes; there should be a guard constantly set, to prevent the introduction of fire, and to hinder all persons from entering who have things about them that will produce fire. These buildings should contain openings for the free passage of the air; the casks should stand upon a platform of wood, at a distance from the wall, and the powder itself should be sunned and dried every one or two years. If the powder is to be kept in damp places, as, for example, in the casemates (arched passages under ground) of fortresses, the walls should be internally covered with lead, and a vessel filled with unslaked lime placed in the middle of the apartment, so that the moisture of the atmosphere may be attracted by the lime.

In the transportation of gunpowder, dust, which is liable to penetrate the cracks and joints of the casks, should be carefully guarded against, as the friction may produce explosion. It is also necessary for its good preservation, that the carriages and vessels in which it is transported should be water-tight. We may effectually preserve it from moisture, by dipping the cask and the sackcloth covering into melted pitch. Vessels prepared in this way, and containing powder, may be immersed in the water for weeks, without having their contents in the least injured. The effects of this substance, when set on fire, are truly wonderful. When powder is heaped up in the open air, and then inflamed, it detonates without report or effect. A small quantity of powder left free in a room, and fired, merely blows out the windows; but the same quantity, when confined in a bomb within the same chamber, and inflamed, tears in pieces and sets on fire the whole house. Count Rumford loaded a mortar with one-twentieth of an ounce of powder, and placed upon it a 24-pound cannon, weighing 8081 lbs.; he then closed up every opening as completely as possible, and fired the charge, which burst the mortar with a tremendous explosion, and raised up this immense weight.

GUNTER'S LINE; a logarithmic line, usually graduated upon scales, sectors, &c. It is called the *line of lines*, and *line of numbers*, being only the logarithms graduated upon a ruler, which therefore serves to solve problems instrumentally, in the same manner as logarithms do it arithmetically. It is usually divided into a hundred parts, every tenth of which is numbered, beginning with 1, and ending with 10, so that, if the first great division, marked 1, stand for one-tenth of any integer, the next division, marked 2, will stand for two-tenths, 3, three-tenths, and so on; and the intermediate division will, in like manner, represent one-hundredth parts of an integer. If each of the great divisions represent ten integers, then will the lesser divisions stand for integers; and if the great divisions be supposed each 100, the subdivisions will be each 10.

Use of Gunter's Line:—1. *To find the product of two numbers.* From 1 extend the compass to the multiplier; and the same extent, applied the same way from the multiplicand, will reach to the product. Thus, if the product of 4 by 8 be required, extend the compasses from 1 to 4, and that extent, laid from 8 the same way, will reach to 32, their product.

2. *To divide one number by another.* The extent

from the divisor to unity will reach from the dividend to the quotient; thus, to divide 36 by 4, extend the compasses from 4 to 1, and the same extent will reach from 36 to 9, the quotient sought.

3. *To find a fourth proportional to three given numbers.* Suppose the numbers 6, 8, 9: extend the compasses from 6 to 8; and this extent, laid from 9 the same way, will reach to 12, the fourth proportional required.

4. *To find a mean proportional between any two given numbers.* Suppose 8 and 32: extend the compasses from 8, in the left-hand part of the line, to 32 in the right; then bisecting this distance, its half will reach from 8 forward, or from 32 backward, to 16, the mean proportional sought.

5. *To extract the square root of a number.* Suppose 25: bisect the distance between 1 on the scale and the point representing 25; then half of this distance, set off from 1, will give the point representing the root 5. In the same manner, the cube root, or that of any higher power, may be found by dividing the distance on the line, between 1 and the given number, into as many equal parts as the index of the power expresses; then one of those parts, set from 1, will find the point representing the root required.

Gunter's Quadrant is a quadrant made of wood, brass, or some other substance, being a kind of stereographic projection on the plane of the equinoctial, the eye being supposed in one of the poles, so that the tropic, ecliptic, and horizon form the arches of circles; but the hour circles are other curves, drawn by means of several altitudes of the sun for some particular latitude every year. This instrument is used to find the hour of the day, the sun's azimuth, &c., and other common problems of the sphere or globe; as also to take the altitude of an object in degrees.

Gunter's Scale, usually called by seamen the *gunter*, is a large plain scale, having various lines upon it, of great use in working the cases or questions in navigation. This scale is usually two feet long, and about an inch and a half broad, with various lines upon it, both natural and logarithmic, relating to trigonometry, navigation, &c. On the one side are the natural lines, and on the other the artificial or logarithmic ones. The former side is first divided into inches and tenths, and numbered from 1 to 24 inches, running the whole length, near one edge. One half of the length of this side consists of two plane diagonal scales, for taking off dimensions for three places of figures. On the other half of this side are contained various lines relating to trigonometry, as performed by natural numbers, and marked thus, viz. *Rhumb*, the rhumbs or points of the compass; *Chord*, the line of chords; *Sine*, the line of sines; *Tang.*; the tangents; *S. T.*, the semi-tangents; and at the other end of this half are *Leag.*, leagues or equal parts; *Rhumb*, another line of rhumbs; *M. L.*, miles of longitude; *Chor.*, another line of chords. Also in the middle of this foot are *L.* and *P.*, two other lines of equal parts: and all these lines on this side of the scale serve for drawing or laying down the figures to the cases in trigonometry and navigation. On the other side of the scale are the following artificial or logarithmic lines, which serve for working or resolving those cases, viz. *S. R.*, the sine rhumbs; *T. R.*, the tangent rhumbs; *Numb.*, line of numbers; *Sine*, sines; *V. S.*, the versed sines; *Tang.*, the tangents; *Meri.*, meridional parts; *E. P.*, equal parts.

Gunwale, or Gunnel, of a Ship, is that piece of timber which reaches, on either side of the ship, from the half-deck to the forecastle, being the uppermost bend, which finishes the upper works of the hull in that part, and wherein they put the stanchions which support the waist-trees. This is called the *gunwale*, whether there be guns in the ship or not.

The lower part of any port, where any ordnance is, is also termed the *gunwale*.

Guy; a rope used to keep steady any weighty body from bearing or falling against the ship's side while it is hoisting or lowering, particularly when the ship is shaken by a tempestuous sea.

Guy is also the name of a tackle used to confine a boom forward when a vessel is going large, and to prevent the sail from shifting by any accidental change of the wind or course, which would endanger the springing of the boom, or perhaps the upsetting of the vessel.

Guy is likewise a large slack rope, extending from the head of the main-mast to the head of the fore-mast, and having two or three large blocks fastened to it. It is used to sustain a tackle to load or unload a ship with, and is accordingly removed as soon as that operation is finished.

Gymnastics, if we understand by this word all bodily exercises, may be most conveniently divided into—1. Military exercises; 2. Exercises systematically adapted to develope the physical powers, and preserve them in perfection, which constitutes the *art of gymnastics*, properly so called; 3. Exercises for the sick, a most important branch, which has been very little attended to. The ancients divided their gymnastics into *gymnastica militaria, gymnastica medica* (including under this head our second and third divisions), and *gymnastica athletica*, or, as Galen calls them, *vitiosa*, which were practised by professional athletæ at the gymnastic games, and were in bad repute with reflecting men, even in those times, on account of their injurious effects on the health and morals. The class of gymnastics which we have enumerated under the second head have their origin in the exercises of war and the chase. The preparation of youth for those occupations leads to the introduction of gymnastics; and the chase itself has been considered by many nations as a preparation for war; the Spartans and American Indians are instances. The ancients do not inform us precisely of the origin of gymnastics, considered as a branch of education. We first find them in a systematic form among the Greeks.

The first gymnasium is said to have been established in Sparta. In Athens, always disposed to mingle the element of the beautiful in whatever she undertook, gymnastics were refined, from the rude military character which they bore among the Spartans, into an art; and the gymnasia became temples of the graces. In each, there was a place called *palæstra*, in which wrestling, boxing, running, leaping, throwing the discus, and other exercises of this kind, were taught. Gymnastics were afterwards divided into two principal branches—the palæstric, taking its name from the *palæstra*, and the orchestric. The former embraced the whole class of athletic exercises; the latter, dancing and the art of gesticulation. It is not known, with accuracy, what particular exercises were usually practised in the gymnasia. The enthusiasm for athletic sports among the Greeks, their love of the beautiful, which was gratified in the gymna-

sia by the sight of the finest human forms in the prime of youth, and by the halls and colonnades adorned with statues and pictures and occupied by teachers of wisdom and philosophy, rendered these places the favourite resort of the old and young. Gymnastics even formed an essential part of the celebration of all the great festivals.

After a time, however, the character of the competitors at the Olympian, Isthmian, Nemæan, and other great games of Greece, degenerated, as they became more and more a separate class, exercising, at least in many cases, in buildings exclusively devoted to them. Euripides calls them useless and injurious members of the state. It is not precisely known to what extent their exercises were practised in the gymnasia. The Greeks, as well as the Romans, set a very high value upon the art of swimming. In Sparta, even the young women swam in the Eurotas; and a common phrase of contempt was, "he can neither swim nor write."

Running was also much esteemed, and the Olympiads were, for a long time, named from the victors in the race. Riding on horseback was deemed a liberal exercise. Dancing (by which we are not to understand the modern dancing of the two sexes intermingled, but the art of graceful motion, including oratorical gesture, together with certain formal dances performed at festivals) was likewise indispensable to an accomplished man. Wrestling was also much valued.

There are not many materials remaining, to enable us to judge of the exercises practised by the Grecian women. In later and corrupt times, they took part in the public games with men. With the decline of Greece, the gymnastic art naturally degenerated, and became gradually reduced to the exercises of professional athletæ, which survived for a long time the ruin of the land of their birth. The Olympic games continued to be celebrated several centuries after Christ. Some late travellers have thought that they could find traces of the ancient games remaining even in our day. "You have the Pyrrhic dance as yet," says Byron. The Romans, under the emperors, imitated the gymnasia, as they did every thing Grecian; but their establishments were little better than places of vicious gratification. The thermæ, or baths, in Italy, took the place of the gymnasia in Greece. Among the Romans, gymnastics never became national, as they may be said to have been among the Greeks. There are some indications, indeed, of early gymnastic games,—we mean the *consualia;* but with this stern, martial, and practical nation, gymnastics took altogether a more military character. They were considered merely as preparatory to the military service, or, when they constituted a part of the exhibitions at festivals, were practised only by a particular class, trained for brutal entertainments, at which large bets were laid among the spectators, as is still the custom on our own race-course.

Vegetius gives us information concerning the exercises in which the young soldiers were trained, and they were of a very useful character. When all the acquisitions of the human intellect were lost in the utter corruption of the latter ages of the Roman empire, and the eruptions of wandering barbarians, the gymnastic art perished.

We may date its revival from the commencement of tournaments, the first of which were held in the ninth and tenth centuries in France, and may have had their origin in the military games of the Romans, aided by the martial spirit of the descendants of the German conquerors of France. They received, however, their full perfection from the spirit of chivalry. The first tournaments were fought with blunt weapons, which were called *armes gracieuses.* At a later period, sharp weapons were introduced, and many fatal encounters happened before the eyes of the ladies. About the year 1066, Godefroy de Preuelly collected the rules and customs of tournaments into a code, which was afterwards generally adopted. At a later period, the character of these celebrations degenerated so much, that they were finally prohibited by the pope and the emperor, as the Roman *ludi* had several times been by the emperors. With the superiority which, in the course of time, infantry began to acquire over cavalry, as it always does with the advance of civilization and scientific tactics, and the invention of gunpowder, the institutions of chivalry declined. The heavy steel coats were done away, and the art of skilful fencing began to be introduced.

The first treatises upon this subject appeared in the sixteenth century. The Italians were the first teachers, and three different schools, the Italian, French, and German, were soon formed. We speak here of fencing with the small-sword; but the Germans also practised the art of fencing with a straight broad-sword, perhaps owing to their neighbourhood to the Sclavonian nations, who all prefer the cut to the thrust. The weapon of the Sclavonians, however, is the crooked sabre. At the same time, vaulting began to be much practised. The Roman *desultores,* indeed, lead us to suppose that the Romans knew something of this art; and it was no doubt also practised by the knights of the middle ages; but the present art of vaulting is modern in its character, and carried to the greatest perfection in France. Fighting with a dagger, and even with a knife, was taught, as useful, in this turbulent age, and much skill was attained in Holland, in defence, by the weapon last mentioned. Wrestling, as an art, was also revived, and many treaties were written on it in the sixteenth and seventeenth centuries, from which we learn that it was often practised in connection with boxing, forming the same compound as the ancient *pancratium.* The famous painter, Albert Durer, wrote *Armorum tractandorum Meditatio* (in 1412). It still exists in manuscript at Breslau. Modern horsemanship had its origin in Italy, and the first riding-school was established at Naples. In the reign of Henry VIII. it was introduced into England. Running, shooting, hurling, leaping, were not taught systematically; yet much importance was attached to proficiency in them, in many parts of Europe, on account of the numerous popular meetings, like those which still exist in Switzerland. Swimming, at this period, was not taught as an art. Where there were convenient places for bathing, children naturally learned it. Elsewhere little pains were taken to instruct them in this useful branch of gymnastics; though in many parts of Europe there were races on and in the water.

The Greeks had, besides the combat with the *cæstus,* a contest of boxing termed *sphæromachia,* because the combatants had balls in their hands. Boxing, taught with caution, is an invigorating exercise, and the skilful boxer is always furnished with natural arms. The art of cudgel-playing is a useful exercise,

as practised in France, where it is different from that which is practised in England. In the last century, when men broke loose from the yoke of authority, and thinking and thoughtless heads began to speculate deeply or frivolously on the existing order of things, education began to receive its share of attention, and the better sort of teachers saw that gymnastics must soon be introduced among the other branches of instruction. Salzmann, a German clergyman, was the first instructor of youth at whose institution in Thuringia bodily exercises were taught, in the latter part of the last century. These were principally running, leaping, swimming, climbing, and balancing. Guts-Muths wrote a very respectable treatise upon modern gymnastics, which, as the first, deserves much praise. He afterwards wrote a more enlarged work on the same subject.

A German of the name of Volker established the first gymnasium in London. At the same time, Captain Clias, a Swiss, established a gymnasium at Chelsea, in the Royal Military Asylum. He soon after published his work on gymnastics, the chief merit of which is its brevity and clearness. Dr. Jahn and his pupil Eiselen published, soon after the peace of Paris, a work on modern gymnastics, which is excellent in many respects, though it is sometimes too minute and pedantic.

Gymnasia have since been opened in various parts of Germany, but they are now strictly confined to bodily exercises. In 1825, Doctor Beck, a German, and pupil of Doctor Jahn, established the first gymnasium in the United States of America. Others have been subsequently established in different parts of the country. It generally happens, that the pupils of a gymnasium after a while lose their interest in the exercises. This was observed even in Germany, where patriotic feelings were mingled with the exercises. The reason of this appears to be, that little or no difference is made in the exercises of different ages, and it is natural that an exercise repeated for years should become wearisome. Gymnastics therefore, when they are taught as a regular branch of education, ought to be divided into two courses. In the first course we would include walking and pedestrian excursions; elementary exercises of various sorts; running, 1. quick, 2. long continued; leaping in height, length, and depth; leaping with a pole, in length and height; vaulting; balancing; exercises on the single and parallel bars; climbing; throwing; dragging; pushing; lifting; carrying; wrestling; jumping, 1. with the hoop, 2. with the rope; exercises with the dumb-bells; various gymnastic games; skating; dancing; some military exercises; swimming, which we include in the first course, because it can be easily taught to children. Some of these exercises, of course, are not suitable for very young children, and they should be distributed in a regular gradation, which caution and experience will teach.

Gymnastics, properly so called, may be begun by a boy from six to eight years old. The second course consists of repetitions of some of the former exercises of vaulting, both on the wooden and the living horse, either standing or running in a circle; boxing, driving, riding on horseback, and fencing with the broad-sword and the small-sword. Fencing with the small-sword is one of the noblest of gymnastic exercises. No other is so well entitled to the name of an art; no other calls the powers into such active exercise; no other requires such quickness of limb, of mind, and of eye, together with so much self-possession; no other developes so completely the whole frame. It is a noble art. Riding, indeed, deserves likewise the name of an art, in which a man may make continual improvement. It cannot, however, be called so pure a gymnastic exercise as fencing, and, in its nature, it is more mechanical. Many excellent horsemen are men of very inactive or limited minds; but all good fencers whom we have known were men of quick apprehension and lively intellect. This accounts for the circumstance that the artists of the middle ages valued fencing so highly. Almost all the great masters and distinguished poets of those times were skilful swordsmen, and some of them, as Leonardo da Vinci and Bacculio, wrote treatises on the use of their favourite weapon. Boxing, riding, and the various exercises on the living horse, should not be commenced much before the sixteenth year.

Gypsum, sulphate of lime, or common plaster of Paris, is found in a great variety of forms. It is either in regular crystals, in which form it is sometimes called *selenite*, or in large crystalline plates and masses, which is perfectly transparent, and as pure as the finest plate-glass; or it occurs in fascicular or radiated masses, which are also crystallized; it is sometimes found in snow-white, scaly flakes, like foam or snow; it is at other times semi-transparent, like horn; and, lastly, it is met with most commonly in large, fine or cross-grained compact masses, forming rocks, and constituting large and extensive strata. In this form, it exhibits a great variety of colours—white, red, brown, bluish-white, &c. The variety of gypsum last described constitutes all the hills and beds of this mineral, which are so frequent among secondary rocks, and in what are called the *salt* and *coal formations*. It occurs rarely, if ever, among the primitive rocks, and not often among those of the transition class. It is almost always found associated with the rock salt, whereon salt-springs are found. It contains but few vegetable or animal remains; those that occur are chiefly bones of quadrupeds, amphibia, fresh-water shells, and vegetable remains. Caves are of frequent occurrence in gypsum.

The purer semi-transparent specimens of gypsum are used for ornamental works, in vases, urns, &c., and for statuary; for which purposes its softness makes it very useful, and easy to work; but this also renders it difficult to polish. In this last form, it is the alabaster of the arts. It constitutes the material used in making the fine plastering for the internal finishing of costly edifices, and gives the walls a most beautiful whiteness. It is also used, after being burned, for the composition of stucco-work of all sorts. But the great and important use of gypsum, or *plaster*, as it is usually called, is for manuring grass and grain lands; in which cases it is truly invaluable. And it is inconceivable how great an additional quantity of grass will be obtained, by the sprinkling a peck of ground plaster upon the acre of land. It is certainly the cheapest and best manure for grass or grain when it can be readily procured.

HAIL appears to be a species of snow, or snowy rain, which has undergone several congelations and superficial meltings, in its passage through different zones of the atmosphere, some temperate and others frozen. It is generally formed in sudden alternations of variable weather. Hail-stones are often of con-

siderable dimensions. They sometimes fall with a velocity of 70 feet a second, or about 50 miles an hour. Their great momentum, arising from this velocity, renders them very destructive, particularly in hot climates. They not only beat down the crops, and strip trees of their leaves, fruits, and branches, but sometimes kill even large beasts and men. The phenomena attending the formation and fall of hail are not well understood. But it is certain that they are connected with electricity. This fact we find noticed by Moses, who relates that "the Lord sent thunder and hail, and the fire ran along upon the ground" (*Gen.* ix. 23). This has been supposed to account for the great variations of temperature to which the hail has been subjected, in its passage through the different strata of the atmosphere. Artificial hail can be produced by an electrical apparatus, and volcanic eruptions are often followed by a fall of hail-stones of great size. Hail-rods have been erected at the suggestion of Volta, in countries much exposed to the ravages of hail storms, on the same principle as lightning-rods. They consist of lofty poles, tipped with metallic points, and having metallic wires communicating with the earth. By thus subtracting the superabundant electricity from clouds, he imagined that the formation of hail might be prevented. These rods are used in Germany and Switzerland, but their success is not proportionate to the expectations entertained of them. The violence with which hail is discharged upon the earth, under an oblique angle, and independently of the wind, would be explained by Volta's supposition, that two electrical clouds are drawn towards each other in a vertical direction, and by their shock produce hail, which, by the law of the composition of forces, would be projected in the diagonal of its gravity, and of the result of the direction of the clouds. In Germany, there are companies which insure against damage by hail.

HAIR; the fine, threadlike, more or less elastic substance, of various form and colour, which constitutes the covering of the skin, particularly of the class of mammalia. It is of a vegetative nature, and appears also in animals of the lower orders, and indeed in all animals which have a distinct epidermis; therefore in insects. In the crustaceous animals, it sometimes appears in particular places, as the feet, on the margins of the shell, on the outside of the jaws, and grows in tufts. Hair is most distinctly developed in those insects—as caterpillars, spiders, bees, &c., which have a soft skin; in this case, it even appears of a feathery form; and butterflies are covered all over with a coat of woolly hair, of the most variegated and beautiful colours. The same variety and brilliancy is displayed in the feathers of birds, which may be considered as analogous to hair, whilst the two other classes of animals—fishes and reptiles—have no hair whatever. No species of mammalia is without hair in an adult state, not even the *cetacea*. In quadrupeds, it is of the most various conformation, from the finest wool to the quills of a porcupine or the bristles of the hog. The hair which is spread over almost the whole of the skin is comparatively short and soft. On particular parts, a longer, thicker, and stronger kind is found; as, for instance, the mane, fetlocks, and tail of the horse, the lion's mane, the covering of man's occiput, his beard, the beard of goats, &c.

The colour of the hair generally affords an external characteristic of the species or variety; but climate, food, and age produce great changes in it. The human body is naturally covered with long hair only in a few parts; yet the parts which we should generally describe as destitute of it produce a fine, short, colourless, sometimes hardly perceptible hair. The only places entirely free from it are the palms of the hands and the soles of the feet; but the body of the male often produces hair like that of the head, on the breast, shoulders, arms, &c. Each hair originates in the cellular membrane of the skin, from a small cylindrical root, which is surrounded by a covering or capsule, furnished with vessels and nerves, called the *bulb*. The root is tubular, and contains a clear gelatinous fluid. The pulp on which the hair is formed, passes through the bottom of the bulb, in order to enter the tube of the hair, into which it penetrates for a short distance, never, in common hairs, reaching as far as the external surface of the skin.—According to Vauquelin, black hair consists of, 1. an animal matter, which constitutes the greater part; 2. a white concrete oil, in small quantity; 3. another oil, of a grayish-green colour, more abundant than the former; 4. iron, the state of which in the hair is uncertain; 5. a few particles of oxide of manganese; 6. phospate of lime; 7. carbonate of lime, in very small quantity; 8. silex, in a conspicuous quantity; 9. lastly, a considerable quantity of sulphur.

The same experiments show that red hair differs from black only in containing a red oil, instead of a blackish-green oil; and that white hair differs from both these only in the oil being nearly colourless, and in containing phosphate of magnesia, which is not found in them. The human hair varies according to age, sex, country, and other circumstances. With the seventh month, the first traces of hair on the head are visible in the embryo. At birth, an infant generally has light hair: it always grows darker and stiffer with age. The same is the case with the eyelashes and eyebrows. At a later period, it begins gradually to lose its moisture and pliability, and finally turns gray, or falls out. These effects are produced by the scanty supply of the moisture above mentioned, and a mortification of the root. But age is not the only cause of this change; dissipation, grief, anxiety, sometimes turn the hair gray in a very short time. It begins to fall off on the top of the head. The hair of men is stronger and stiffer; that of females longer (even in a state of nature), thicker, and not so liable to be shed.

Blumenbach adopts the following national differences of hair:—1. brown or chestnut, sometimes approaching yellow, sometimes black, soft, full, waving; this is the hair of most nations of central Europe; 2. black, stiff, straight, and thin, the hair of the Mongolian and native American races; 3. black, soft, curly, thick, and full hair; most of the inhabitants of the South Sea Islands have it; 4. black, curly wool, belonging to the negro race. The hair, with the nails, hoofs, horns, &c., is one of the lower productions of animal life. Hence, in a healthy state, it is insensible, and the pain which we feel when hairs are pulled out arises from the nerves which surround the root. It grows again after being cut, and, like plants, grows the more rapidly if the nutritive matter is drawn to the skin by cutting; yet, in a diseased state, and particularly in the disease called the *plica polonica*, it becomes sensitive and inflamed to a certain degree, bleeds, and is clotted by a secretion of lymph, which coagulates into large lumps. Hair not only serves as a cover or ornament

to the body, but exercises an important influence on absorption and perspiration; where the hair is thick, the perspiration is more free. If the root is destroyed, there is no means of reproducing the hair; but if it falls out without the root being destroyed, as is often the case after nervous fevers, the hair grows out again of itself. Though hair, in a healthy state, grows only on the external parts of the body, cases are not unfrequent in which it is formed inside of the body in diseased parts.

How much the hair differs in its character from the other parts of the body (being, as we have said, of a vegetable nature), is strikingly shown from the circumstance that it continues to grow after death. As the hair is a very conspicuous object, and capable of much alteration, the arrangement of it has always been one of the most important duties of the toilet.

HAIR'S BREADTH; a measure of length, being the 48th part of an inch.

HALBERT, in *the art of war*, a well-known weapon carried by the sergeants of foot, is a sort of spear, the shaft of which is about six feet long. Its head is armed with a steel point, edged on both sides; but, besides this sharp point, which is in a line with the shaft, there is a cross piece of steel, flat, and pointed at both ends, but generally with a cutting edge at one extremity, and a bent sharp point at the other.

HALF-MOON, in *fortification;* an out-work composed of two faces, forming a salient angle, whose gorge is in the form of a half-moon.

HALF-PIKE; a defensive weapon, composed of an iron spike, fixed on an ashen staff. Its use is to repel the assault of boarders in a manner similar to the defence of the charged bayonet among infantry; hence it is frequently termed a *boarding pike*. It takes the epithet of *half* from its having a much shorter staff than the whole pike.

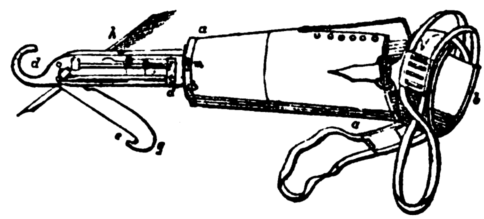
HALO is an extensive luminous ring, including a circular area, in the centre of which the sun or moon appears, whose light, passing through an intervening cloud, gives rise to the phenomenon: those about the moon are most common. When the sun or moon is seen through a thin cloud, a portion of the cloud round the sun or moon appears lighter than the rest, and this luminous disc is called a *corona*. Coronas are of various sizes, but they seldom exceed 10° in diameter; they are generally faintly coloured at their edges. Frequently, when a halo encircles the moon, a corona surrounds it. *Parhelia*, or mock suns, vary considerably in general appearance: sometimes the sun is encircled by a large halo, in the circumference of which the mock suns usually appear, which have often small halos round them.—(See METEOR.)

HAMMER; a well-known tool used by mechanics, of which there are various sorts; but they all consist of an iron head fixed crosswise to a handle of wood. Among blacksmiths there are the hand-hammer, the uphand-sledge, the about-sledge (which is swung overhead with both arms), &c.

HAMMOCK, in *naval affairs;* a piece of hempen cloth, six feet long and three feet wide, gathered together at the two ends by means of a clew, and slung horizontally under the deck, forming a receptacle for a bed. There are about from 14 to 20 inches in breadth allowed between the decks for every hammock in a ship of war. In preparing for battle, the hammocks, with their contents, are all firmly corded, taken upon deck, and fixed in various nettings, so as to form a barricade against small shot.

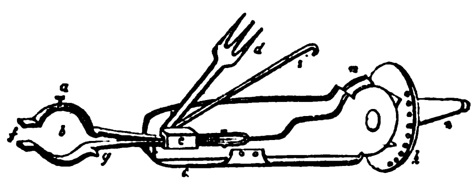
HAND; a very useful part of the human body, which we particularly notice, to call attention to a very ingenious substitute for it, contrived by Mr. Morison.

The inventor of the implements described in this article had the misfortune to lose both his hands, and was from necessity induced to contrive such instruments as might supply the deficiency as far as possible. He made, by the use of his instruments, several neat drawings (now in the possession of the Society for the Encouragement of Arts, &c.) to explain the construction of a great variety of instruments which he had invented at various times, and from among which those now to be referred to were selected, as being some of the most ingenious and useful in their application.



a is a tube or socket, formed of a strong leather, to receive the stump of the arm; it is open at one side next the open end, and has several holes to lace it on tight; but, to prevent any danger of its coming off, it is connected with a band, *b*, encompassing the arm above the elbow by two rings, one of which is marked *a;* the band is fastened by two double straps with a clasp. At the other end of the tube a piece of wood is fitted in, and faced with a circular iron plate; in the centre of this is a socket to receive various implements, one of which, *d*, is represented as affixed to the tube; it terminates in an iron hook, *d*, useful for lifting any article, as a chair, &c., or drawing on boots. The other part of the instrument is made hollow, to receive a button-hook, *e g*, and pen or pencil-holder, F, either of which can be turned out for use; they are retained in the positions of either shut or open by springs similar to that of a knife; behind these, a knife is placed, which can be opened out in a line with the instrument for use, or shut up within the instrument; there is also a hook to open the knife by. The dotted lines, *h*, show the manner in which a pen, or any similar instrument, can be held, the springs of the button-hook and pen-holder being sufficiently strong to hold such articles.

This instrument is adapted to the right arm; the left is provided with a similar leather socket, into which the instrument shown beneath is fitted; it



contains the button-hook *i*, and the fork *d*, either of which can be opened out for use; *c* is the spring by which they are held; *b* is a pair of spring-tongs,

which slide through a socket, and are by that closed up; they have two pair of jaws, one at the end *f*, the other by the side at *g*; *i* is a small hook, by which the tongs can be opened by the button-hook of the other hand. The whole of the instrument bends at a joint *h*, just where it joins the stump, and the end of the spring *e* catches in notches in the joint to hold it sufficiently firm at any particular point where it is set, by pressing the instrument on the knee, a table, or other fixture.

m is the pin which enters the stump; it has a notch all round it at the end, into which a wedge in the stump is received to hold it in; this wedge comes to the outside of the leather in the upper figure, and has a hook by which it can be pulled by the button-hook of the other hand, so as to release the instrument. This wedge does not, however, prevent the whole instrument from turning round in the stump; but by means of holes in the circular plate *h*, and a spring-catch at *m*, which enters any of them, the instrument can be fixed in any position; the catch *m* is relieved by pressing it upon the table, &c.; the instrument can then be turned round, but becomes fixed when the catch is at liberty.

Hand; a measure of four inches. In *painting* and *sculpture*, it signifies also the style of the artist.

Hands, in *heraldry*, are borne in coats of armour, right and left, expanded or open; and a bloody hand, in the centre of an escutcheon, is the badge of a baronet of Great Britain.

Handcuffs; instruments formed of two circular pieces of iron, each fixed on a hinge at the ends of a very short iron bar, which, being locked over the wrists of a malefactor, prevents his using his hands.

Hard-a-Lee; an order to the helmsman to put the helm close to the lee-side of a ship.

Hard-a-Port; an order to put the helm close to the larboard.

Hard-a-Starboard; an order to put the helm close to the right side of the ship.

Hardness, in *physics;* the resistance opposed by a body to impression, or to the separation of its particles. This property depends on the force of cohesion, or on that which chemists call *affinity*, joined to the arrangement of the particles, to their figure, and other circumstances. A body, says M. Hauy, is considered more hard in proportion as it presents greater resistance to the friction of another hard body, such as a steel file; or as it is more capable of wearing or working into such other body, to which it may be applied by friction. Lapidaries judge of the hardness of fine stones, &c., from the difficulty with which they are worn down, or polished.

Harelip is a single or double fissure of the upper lip, by which it is divided into two or three parts, and is thus made to resemble the lip of the hare. Children are not unfrequently born with this deformity. The fissure is sometimes confined to the lip, but more commonly extends to the gums and palate, which it divides into two parts. It produces great difficulty in speech, and besides keeping the mouth open, and thus suffering the saliva to escape, is a dreadful deformity in appearance. It is very common, but, fortunately, is easily curable, so that it seldom goes long unremedied, unless from choice or timidity. The operations for removing this most unfortunate deformity, in its worst forms, are among the merits which have given celebrity to the name of Dessault.

Harmony; the agreement or consonance of two or more united sounds. *Harmony* is either natural or artificial. *Natural harmony*, properly so called, consists of the harmonic triad, or common chord. *Artificial harmony* is a mixture of concords and discords, bearing relation to the harmonic triad of the fundamental note. The word *harmony* being originally a proper name, it is not easy to determine the exact sense in which it was used by the Greeks; but, from the treatises they have left us on the subject, we have great reason to conclude that they limited its signification to that agreeable succession of sounds which we call *air*, or *melody*. The moderns, however, do not dignify a mere succession of single sounds with the appellation of *harmony:* for the formation of *harmony* they require a union of melodies, a succession of combined sounds, composed of consonant intervals, and moving according to the stated laws of modulation.

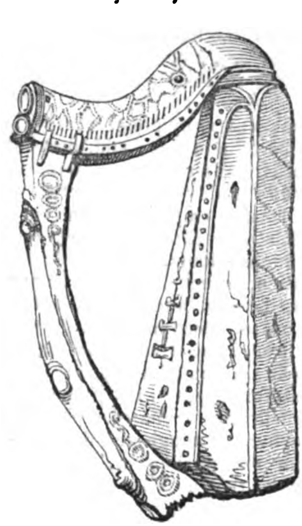
Harmony, Figured, in *music*, is that in which, for the purpose of melody, one or more of the parts of a composition move, during the continuance of a chord, through certain notes which do not form any of the constituent parts of that chord. These intermediate notes not being reckoned in the harmony, considerable judgment and skill are necessary so to dispose them that, while the ear is gratified with their succession, it may not be offended at their dissonance with respect to the harmonic notes.

Harmony, in *painting;* a term used in speaking both of ordonnance and composition, as well as the colours of a picture. In the ordonnance it signifies the union or connection of the figures with respect to the subject of the piece.

Harp; a stringed instrument, consisting of a triangular frame, and the chords of which are distended in parallel directions from the upper part to one of its sides. Its scale extends through the common compass, and the strings are tuned by semitonic intervals. It stands erect, and, when used, is placed at the feet of the performer, who produces its tones by the action of the thumb and fingers of both hands on the strings. The ancients had a triangular instrument, called *trigonum*, corresponding somewhat to our harp. Some authors say that this instrument came originally from the Syrians, from whom the Greeks borrowed it. The ancient *sambuca* is believed by some to correspond to the harp.

Some writers say that the harp came to us from the nations of the north of Europe, in whose languages they trace its etymology. Papias and Du Cange assert that the harp derives its name from the *Arpi*, a people of Italy, who invented it; but Galileo maintains that the Italians received it from the Irish. Whatever may have been its origin, its invention is very ancient. It was known to the Egyptians, as appears from the travels of Bruce and Denon. The four harps of which the latter traveller has given drawings are almost the same in shape as ours. The first two have twenty-one strings, the third eighteen, and the fourth only four. The designs are from the paintings found in the tombs of the kings in the mountains west of Thebes. The Hebrews, the Greeks, and the Romans appear to have made particular use of this instrument. The ivory harp, with seven strings, belonged to the Greeks, who, however, neglected it. The Romans preserved the use of it a long time in sacrifices. The Anglo-Saxons excelled in playing on the harp, which they generally accom-

panied with the violin and the cornicinus. The ancient Irish, Scotch, and Welsh also made much use of this instrument, and the harp figures conspicuously in the arms of Ireland. The Anglo-Normans also were skilful performers on this instrument. Strutt in his *England, Ancient and Modern*, has given engravings of the harps used by the people of the North, about the 9th century. They are triangular, like ours, but have only 12 strings. In the 13th century, the harp had only 17 strings, as appears from a manuscript of the time, cited and analyzed by Lebeuf. No instrument has received greater improvement from modern artists than this. In its present state, while it forms one of the most elegant objects to the eye, it produces some of the most agreeable effects to the ear of any instrument in practice.



We have carefully copied the figure of an ancient harp from a sculptured bas-relief; and it will be seen that in point of picturesque appearance it is not at all behind those which are employed in the present day.

HARPOON. The harpoon is an instrument of iron, of about three feet in length. It consists of three conjoined parts, called the *socket*, *shank*, and *mouth*, the last of which includes the *barbs*, or *withers*. This instrument, if we except a small addition to the barbs, and some enlargement of dimensions, maintains nearly the same form in which it was used in the fishery two centuries ago. At that time, the mouth, or barbed extremity, was of a triangular shape, united to the shank in the middle of one of the sides, and this, being scooped out on each side of the shank, formed two simple flat barbs. In the course of the last century an improvement was made, by adding another small barb, resembling the beard of a fish-hook, within each of the former withers, in a reverse position. The two principal withers, in the present improved harpoon, measure about eight inches in length, and six in breadth; the shank is from eighteen inches to two feet in length, and $\frac{6}{10}$ths of an inch in diameter; and the socket, which is hollow, swells from the size of the shank to nearly two inches in diameter, and is about six inches in length. To this weapon is fastened a long cord, called the *whale-line*, which lies carefully coiled in the boat, in such a manner as to run out without being interrupted or entangled. As soon as the boat has been rowed within a competent distance of the whale, the harpooner launches his instrument; and the fish, being wounded, immediately descends under the water with amazing rapidity, carrying the harpoon along with him, and a considerable length of the line, which is purposely let down, to give him room to dive. Being soon exhausted with the fatigue and loss of blood, he re-ascends in order to breathe, when he presently expires, and floats upon the surface of the water, when the whalers approach the carcass by drawing in the whale-line. The line is from 60 to 70 fathoms long, and made of the finest and softest hemp, that it may slip the easier; if not well watered, by its friction against the boat it would soon be set on fire; and, if not sufficiently long, the boat would be soon overset, as it frequently is. With the harpoon, other large fish, as sturgeons, &c., are also caught.

When the harpoon is forced, by a blow, into the fat of the whale, and the line is held tight, the principal withers seize the strong ligamentous fibres of the blubber, and prevent it from being withdrawn; and, in the event of its being pulled out so far as to remain entangled by one wither only, which is frequently the case, then the little reverse barb, or *stop-wither*, as it is called, collecting a number of the same reticulated sinewy fibres, which are very numerous near the skin, prevents the harpoon from being shaken out by the ordinary motions of the whale. The point and exterior edges of the barbs of the harpoon are sharpened to a rough edge by means of a file. This part of the harpoon is not formed of steel, as it is frequently represented, but of common soft iron, so that, when blunted, it can be readily sharpened by a file, or even by scraping it with a knife. The most important part in the construction of this instrument is the shank. As this part is liable to be forcibly and suddenly extended, twisted, and bent, it requires to be made of the softest and most pliable iron.

Harpoon Gun. The harpoon gun is well calculated to facilitate the capture of whales, under particular circumstances, especially in calm weather, when the fish are apt to take the alarm at the approach of boats within fifteen or twenty yards of them. The harpoon gun was invented in the year 1731, and used by some individuals with success. Being found somewhat difficult and dangerous in its application, it was laid aside for many years. It has, however, subsequently been highly improved, and rendered capable of throwing a harpoon nearly forty yards with effect; yet, on account of the address which is requisite for the proper management of it, and the loss of fish which, in unskilful hands, it has been the means of occasioning, together with some accidents which have resulted from its use, it has not been so generally adopted as might have been expected.

In its present improved form, the harpoon gun consists of a kind of swivel, having a barrel of wrought iron, from twenty-four to twenty-six inches in length, of three inches exterior diameter, and $1\frac{3}{4}$ inches bore. It is furnished with two locks, which act simultaneously, for the purpose of diminishing the liability of the gun missing fire. The shank of the harpoon fired from it is double, terminating in a cylindrical knob, fitting the bore of the gun. Between the two parts of the shank a wire ring slides freely, to which is attached the line. When the harpoon is introduced into the barrel of the gun, the ring with the attached line slides up, and remains on the outside, near the mouth of the harpoon; but the instant that it is fired, the ring, of course, flies back against the cylindrical knob. Some harpoons have been lately made with a single shank, similar to the common hand harpoon, but swell at the end to the thickness of the bore of the gun. The line, closely spliced round the shank, is slipped towards the mouth of the

harpoon, when it is placed in the gun, and, when fired, is prevented from disengaging itself by the size of the knob at the end.

HARPSICHORD; a stringed instrument, consisting of a case, framed of mahogany or walnut-tree wood, and containing the belly, or sounding-board, over which the wires are distended, supported by bridges. In the front the keys are disposed, the long ones of which are the naturals, and the short ones the sharps and flats. These keys being pressed by the fingers, their enclosed extremities raise little upright oblong slips of wood, called *jacks*, furnished with crow-quill plectrums, which strike the wires. The great advantage of the harpsichord beyond most other stringed instruments consists in its capacity of sounding many notes at once, and forming those combinations, and performing those evolutions of harmony, which a single instrument cannot command. This instrument, called by the Italians *clavicembalo*, by the French *clavecin*, and in Latin *grave cymbalum*, is an improvement upon the clavichord, which was borrowed from the harp, and was for more than a century in the highest esteem throughout Europe; but, since the invention of that fine instrument the grand piano-forte, the use of it has considerably diminished.

HARQUEBUSS (in the ancient statutes called also *arquebus*, *haquebut*, or *hagbut*) is a hand-gun, or fire-arm, of a portable length, usually borne on the arm. The word is formed of the French *arquebuse*, and that from the Italian *archibuso*, or *arco a buso* (of *arco*, a bow, and *buio*, a hole), on account of the touch-hole, in which powder is put to prime it, and the circumstance of its having succeeded to the bows of the ancients. The harquebuss is, properly, a fire-arm of the ordinary length of a musket or fowling-piece, cocked, usually with a wheel. Hanzelet describes its legitimate length to be forty calibres, and the weight of its ball one ounce seven-eighths; its charge of powder as much. There is also a larger kind, called *arquebuse à croc*, much of the nature of our blunderbusses. This was used, in time of war, to defend places, being usually rested on something when discharged. The first time these instruments were seen was in the imperial army which drove Bonnivet out of the state of Milan. They were so heavy that two men were employed to carry them.

HARTSHORN; the horns of the common male deer, to which many very extraordinary medicinal virtues were attributed; but the experience of late years gives no countenance to them. The horns are of nearly the same nature as bones, and the preparations from them by heat are similar to those from solid animal substances in general; so that the articles denominated *spirit of hartshorn* and *salt of hartshorn*, though formerly obtained only from the horns of different species of deer, are now chiefly prepared from bones. The former of these, which is a volatile alkali of a very penetrating nature, is an efficacious remedy in nervous complaints and fainting-fits; and the latter has been successfully prescribed in fevers. The scrapings or raspings of the horns, under the name of *hartshorn shavings*, are variously employed in medicine. Boiled in water, the horns of deer give out an emollient jelly, which is said to be remarkably nutritive. Burnt hartshorn is employed in medicine. The horns of the stag are used, by cutlers and other mechanics, for the handles of knives and cutting instruments of different kinds.

HAUTELISSE, and BASSELISSE; French words applied to tapestry. *Hautelisse carpets* are those which are worked with a perpendicular warp, and *Basselisse carpets* those with a horizontal warp. The latter are preferred in modern times, because they are easier to be made, and yet possess equal beauty. In the Netherlands, Brussels and Doornik furnish the best works of this kind; and, in France, the manufactory at Gobelins.

HAZEL; a small shrub or tree very common in most parts of England and America. Both the hazel and filbert are much esteemed, but particularly the latter, the flavour of its kernels being very delicious. They are, however, difficult of digestion, and, when eaten in large quantities, sometimes produce very unpleasant effects. The oil which is obtained from hazel-nuts, by pressure, is little inferior in flavour to that of almonds; and, under the name of *nut-oil*, is often preferred, by painters, on account of its drying more readily than any other of the same quality.—Chemists employ it as the basis of fragrant oils artificially prepared, because it easily combines with and retains odours. This oil is found serviceable in obstinate coughs. If nuts be put into earthen pots and well closed, and afterwards buried eighteen inches or two feet deep in the earth, they may be kept sound through the winter. In many parts of England, hazels are planted in coppices and hedge-rows for several useful purposes, but particularly to be cut down, periodically, for charcoal, poles, fishing-rods, &c. Being extremely tough and flexible, the branches are used for making hurdles, crates, and springles to fasten down thatch. They are also formed into spars, handles for implements of husbandry, and, when split, are bent into hoops for casks. The roots are used by cabinet-makers for veneering; and, in Italy, the chips of hazel are sometimes put into turbid wine, for the purpose of fining it.

HEAD; the part of the animal body which contains the brain and the higher organs of sense. In many animals, it is connected with the trunk by the neck, and is more or less movable; in some animals, however, it is immovable, and is merely a prolongation of the trunk. The head in animals is more distinct in proportion as the brain is more fully developed as the centre of the nervous system. It is entirely wanting in the lowest classes of animals, which, therefore, from the intestinal worms downward, form a third class, in the system of Latreille, under the name of *acephala* (headless animals); while those provided with heads are divided into two classes, the *vertebral animals*, having distinct and proper heads, and the *cephalidia*, having small and less distinctly formed heads. In this part the mouth (see MOUTH), as the opening of the œsophagus, is always situated.

In the second class of animals, in which the head is less distinct, that part of the body which is provided with the mouth may be called the *head end*. In the vertebral animals (mammalia, birds, reptiles, and fish), the head has a bony basis (cartilaginous only in the cartilaginous fishes). In fishes, the bones of the head are not united with each other; and the formation of the separate bones is various. In cartilaginous fishes the head is more or less oblong and angular; in osseous fishes, it is less flattened, and composed of a considerable number of bones connected in various ways; in all fishes, the cavity of the brain is very small and oblong. Equally various

is the formation of the head in the different classes of reptiles. In general, the head is composed of few bones, and more rounded in proportion as the brain is more developed. In birds, the bones of the head are more closely formed into one whole, constituting a skull more or less round, which contains the brain, and to the fore part of which the beak is attached. But the head is most perfect in the mammalia, and resembles the human head more nearly as the animal approaches more nearly to man.

In general, the human head may be considered as the standard, which may be traced, with gradual deviations, through the different classes, until it entirely ceases in the lower orders of animals. Nowhere is its proper office (to serve for the reception of the nervous system) s distinct as in the human head; the cavity of the skull containing the principal organ of sensitive life—the brain; as the great cavities of the trunk contain the chest, the organs of irritable life (the heart and lungs), and the abdominal cavity contains the organs of reproductive life (the organs of digestion and generation). The superiority of the head over the other two parts just mentioned appears, also, from these circumstances, that, whilst it is pre-eminently the seat of the nervous system, it also contains organs essential for functions of the irritable and reproductive system; as the inspiration and expiration of the air are effected through the nostrils and mouth, and the entrance of food into the abdominal cavity, as well as the preparation of it for digestion by mastication and the production of saliva, is effected by the mouth; and these organs appear more prominent in the heads of animals, as their sensitive system sinks lower in the scale.

It must not be forgotten that the head also contains the tongue, an organ not only important in respect to nourishment, but also communicating the desires and thoughts, until it becomes in man the organ of oral intercourse, of language, and of the finest of all music—the human voice in singing. The human head, and, more or less, the head of other animals, is divided into two chief parts, the skull (see SKULL) and the face. The importance of the head, as the noblest part of the animal system, has occasioned it to be used metaphorically, in all languages, to denote that which is chief.

HEART; a hollow, muscular organ, the function of which is to maintain the circulation of the blood, and which is of different formations in different animals. The organs of circulation are the heart, the arteries, the veins, and the capillary vessels. The blood is divided into the arterial blood and the venous blood. The object of the circulation is to carry the venous blood, which has returned from the body, into the lungs, where, by the influence of the air, it is converted into arterial blood, which is then again sent out into the system, to nourish it and repair its losses. The heart in men, quadrupeds, and birds, is composed of four cavities, two auricles and two ventricles (thence called *double*). It is enveloped in a membrane called the *pericardium*, situated towards the left of the cavity of the chest, between the lungs, and resting on the diaphragm. Its form is that of a cone flattened on its inferior and superior faces, the latter formed principally by the right, the former by the left auricle and ventricle.

The right auricle communicates with the right ventricle, besides which there are in it three openings, that of the *vena cava inferior*, that of the *vena cava superior*, and that of the coronary vein. The communication between this auricle and ventricle is closed by a valve when the heart contracts. The right or pulmonary ventricle communicates with the pulmonary artery, which is provided with three valves. When these valves are brought together, they interrupt the communication between the ventricle and the artery.

The left auricle communicates with the left ventricle, and contains also the orifices of the four pulmonary veins. The left ventricle, besides the communication with the left auricle, contains the orifice of the aorta. The ventricles are divided from each other by a fleshy wall, called the *septum cordis*. The valves at the openings of the arteries are called *semilunar;* that at the orifice of the right auricle, *tricuspid;* that at the orifice of the left auricle, *mitral;* and that at the orifice of the *vena cava inferior*, the *Eustachian* valve.

The heart, which with its immediate appendages of veins and arteries, is shown in the accompanying engraving, is formed of a firm, thick, muscular tissue, composed of fibres, interlacing with each other. It is also composed of nerves, membranes, and vessels. The coronary arteries arise from the aorta, and are distributed in the heart. The coronary veins return the blood of the heart into the right auricle. The arteries are the vessels which serve to carry the blood from the heart to all parts of the body. They terminate in the capillary vessels, a series of extremely minute tubes, which pass over into the veins.

The veins are the channels by which the blood passes back from the body into the auricles of the heart. The blood which is returned from the veins is black, and is called *venous;* that which leaves the heart is red, and is called *arterial*. The red blood, possessing nourishing and vital properties, rises in the capillary system of the lungs, flows into the pulmonary veins, thence is received into the left cavities of the heart, from which it passes into the aorta, and is transmitted to all parts of the body, to the capillary system. It there loses two degrees of temperature, and undergoes other changes, by the loss of some of its elements in the important functions of nutrition, calorification, and the secretions. It is now become black, passes through the veins, from the extremities of the body towards the heart, receives the chyle and the lymph, and is emptied into the right cavities of that organ, which returns it, through the pulmonary artery, to the capillary vessels of the lungs, where it is subjected to the influence of the air, resumes the qualities of red or arterial blood, and is ready for a new course.

Having thus described the route of the blood through the different parts of the system, we will now explain the mechanism of the sanguineous system. The blood contained in the two *venæ cavæ* is poured into the right auricle, which contracts, and

thus forces the fluid to escape; but the *vena cava superior* opposes to its passage the column of blood which it contains, the other veins are closed by valves, and it must therefore pass into the right ventricle. The ventricle then contracts, and, the tricuspid valve closing the passage through which the liquid entered, it is forced forward into the pulmonary artery, which contracts, and, its orifice being closed by the semi-lunar valve, propels the blood still forward into the capillary system of the lungs, whence it passes into the pulmonary veins, which pour it into the left auricle by their four orifices. The contraction of the auricle impels it into the left ventricle, by which it is, in the same manner, driven forward into the aorta (the mitral valve preventing its return into the auricle), and thence into the general circulation as above described. The two auricles contract and dilate simultaneously with each other, as do also the two ventricles. The dilatation is called *diastole;* the contraction, *systole*. It is difficult to determine what quantity of blood the heart projects at each systole. It is generally estimated at two ounces. The causes of the alternate contraction and dilatation of the heart are not less difficult to decide. They are entirely involuntary and dependent on the nervous system. The force of its contractions is likewise unknown. The systole of the ventricles is the cause of the motion of the blood in the arteries, which also dilate with each wave driven into them by the motion of the heart.

By what means the blood is made to penetrate the thousand windings of the capillary system, and what causes impel it to flow back through the veins, are yet subjects of dispute among physiologists. The time in which a drop of blood completes its circle of motion has been differently estimated, at from twenty-four hours to a few minutes. Among the lower orders of animals, the organization of the circulating system is very different. The infusoria, polypi, and intestinal worms have no distinct vessels, much less a heart; the echinodermata have distinct organs of circulation, but no part resembling a heart. Insects have a small cylindrical vessel, running along the back, which is rather the rudiment of a vascular system than of a heart. The first traces of a heart are found in some worms, in which some expansions are perceptible in a part of the vessel which runs the whole length of the body. In the spiders, lateral vessels are given off from the main vessel, and a pulsation is perceptible. The crustacea have a heart composed of one fleshy ventricle. In the mollusca, the heart appears completely formed; some of them have three cavities. The four classes of vertebral animals have red blood; but fishes and reptiles have only what is called a *single heart,* that is, composed of one auricle and one ventricle.

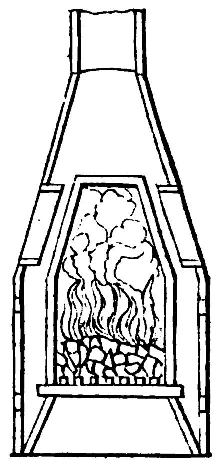
HEAT. See CALORIC and TEMPERATURE.

HEATING BUILDINGS. The subject of heat and cold, as applied to domestic purposes, has already been discussed under a variety of heads in this work. The theory of *specific heat* will be found under the article TEMPERATURE, and the radiation and reflection of heat may properly be discussed under those heads. The heating of buildings by artificial means is, however, so important as to require a distinct notice.

It is admitted on all hands that open fire-places are of all others the least fitted for heating buildings. On this account, through the whole of the north of Europe, iron or earthenware grates, similar to what we call German stoves, are generally adopted.

The principal objection to the German stove is that, even with the most careful management, it produces a strong and unwholesome effluvia. The atmosphere in its neighbourhood speedily acquires the smell of "burnt air," and the ordinary deposit of dust on the surface of the iron adds to the annoyance. To prevent this inconvenience in the heating of a large building, the heating surface of the stove should be much larger than it is in those generally employed.

If there be space beneath the building, the stove shown in the accompanying engraving will be found both economical and effective. It consists of a large central iron box, surrounded by another box of the same material. Between the two boxes is placed a series of flat plates, through which the air rushes from the outside of the building; and by the rapidity with which it passes prevents the burning, and consequently the empyreumatic odour exhaled from the common stove. The hot air is conveyed by a tube passing from the outer case, and the smoke is carried off by a chimney placed behind.



In some cases *steam* has been found very advantageous, and, though somewhat less economical, is more agreeable, and produces a more equable temperature. The steam-pipes employed for the purpose are usually of large dimensions, and, after it is deprived of its heat, the condensed water returns to the boiler for a new supply.

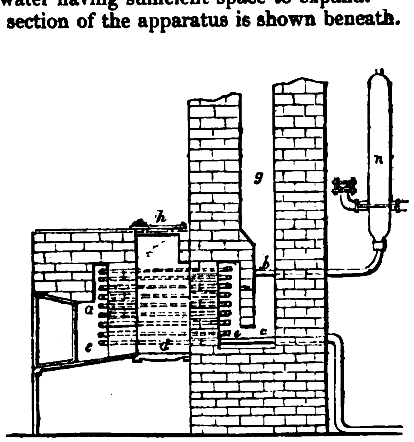
The employment of *hot water* is, in some respects, more valuable. It depends on an arrangement very similar to the circulation of the blood in the human frame. The water in the first instance has its temperature raised in a boiler of the ordinary kind, and, rising to the upper strata, is conveyed away by a pipe at the surface. It will thus pass through many hundred feet of pipe, and ultimately return to the bottom of the boiler, where it remains till its specific gravity is so far diminished as to cause it again to traverse through the same circuit. In this arrangement a temperature much below the boiling point may be advantageously employed.

Mr. Perkins has obtained a patent for some important novelties in the apparatus for heating buildings by the circulation of hot water. These improvements are designed to increase the temperature of the water; and the apparatus is described as applicable also to "a variety of purposes which require the heating medium to be higher than that of boiling water."

The patentee states that his "improvements consist in circulating water in tubes or pipes, which are closed in all parts, allowing a sufficient space for the expansion of the water which is contained within the apparatus, by which means the water will at all times be kept in contact with the metal, however high the degree of heat such apparatus may be submitted to, and yet at the same time there will be no

danger of bursting the apparatus, in consequence of the water having sufficient space to expand."

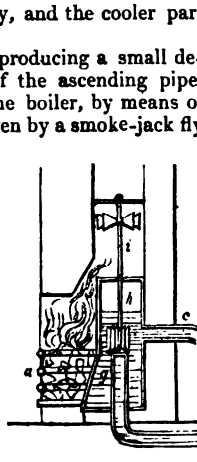
A section of the apparatus is shown beneath.



In this figure, *a* is a coil of tubing, which is placed within the furnace, as shown in the figure; *b* is a tube by which the water passes from the coil *a*, when in a heated state, and *c* is the tube by which the water is returned to the coil, after having given off the heat, to effect the object to which the apparatus is applied, whether for heating the air in buildings, evaporating fluids, heating metal, or other domestic purposes. The furnace consists of two compartments, *d* and *e;* the compartment *d* is that in which the fuel is burned, and the compartment *e* surrounds it, and is a sort of hot chamber, in which the coil of tubes, *a*, is placed, and the water therein becomes heated by the fire in the compartment *d*, the smoke and heated air passing from the ignited fuel into the compartment *e*, and thence into the chimney, *g*. The fuel is supplied at *h*.

There is another patent contrivance that must now be noticed, the particular feature of which is, that the hottest part of the current of water by this improvement is made to descend from the boiler, and the cooler water to rise up into the boiler, which is contrary to the natural course of fluids, where the heated portion ascends by its levity, and the cooler part descends by its gravity.

The contrivance consists in producing a small degree of vacuum over the top of the ascending pipe, which brings the water into the boiler, by means of a rapidly revolving beater, driven by a smoke-jack fly in the chimney. The inventor of this arrangement (Mr. Busby, of Brighton) has suggested a variety of modifications of his apparatus; but its general form will be best understood by a reference to the accompanying diagram. A common fire-grate is shown at *a*, at the back of which is placed the boiler, *g*. The revolving wheel, or beater, is shown at *h*, the smoke-jack fly being above, at *i*. The colder fluid, being thus raised by the vacuum, the hotter is allowed to pass down the pipe *c*, at the reverse end of the range, and hence a continued current of hot water is kept flowing from a boiler placed in any upper part of the building.



Heaven, in a physical sense, is the azure vault which spreads above us like a hollow hemisphere, and appears to rest on the limits of the horizon.—Modern astronomy has taught us that this blue vault is, in fact, the immeasurable space in which our earth, the sun, and all the planets, with the countless host of fixed stars, revolve. The blue colour of the heavens is, according to Nollet, an effect of the light of the sun and stars. According to this explanation, the boundless fields of unillumined space must, like all things else in the absence of light, appear black; but the light of the celestial bodies, which is reflected by the earth to the air, and thence again to the earth, occasions the blue colour. Saussure derives the blue colour, indeed, from the reflected light, but attributes the reflection not to the air, but to the vapours which it contains. He supports his opinion by observing that, if this were owing to the reflection of light from the air, glaciers and mountains covered with snow, seen at a distance of from seventy to ninety miles, would appear blue. That the rays of light are, in fact, reflected by the vapours in the atmosphere appears also from this circumstance, that the heavens, seen from a high mountain, appear of a much darker blue than when seen from a plain; and, even from the latter situation, the blue is very different at different times, and appears dark in proportion to the purity of the atmosphere. Saussure, on the basis of these observations, has invented an apparatus, called a *cyanometer*, in order to determine the quantity of vapour in the atmosphere, from the degree of blueness in the colour of the sky.

Heaven, in the ancient astronomy, denoted an orb or circular region of the ethereal heaven. The ancient astronomers assumed as many different heavens as they observed different celestial motions. These they supposed to be all solid, thinking they could not otherwise sustain the bodies fixed in them; and spherical, that being the most proper form for motion. Thus they have seven heavens for the seven planets, the Moon, Mercury, Venus, the Sun, Mars, Jupiter, and Saturn. The eighth was that of the fixed stars, which was particularly denominated the *firmament*. Ptolemy adds a ninth heaven, which he calls the *primum mobile*. After him, two crystalline heavens were added by Alphonso, king of Castile, to account for some irregularities in the motions of the other heavens; and, lastly, an empyrean heaven was drawn over the whole, for the residence of the Deity; which made, in all, twelve heavens. But others admitted many more heavens, according as their different views and hypotheses required.

Heights, Measurement of. A knowledge of the elevation of a country enables us to determine its climate, to lay out roads and aqueducts properly, and to guard against inundations. The geologist must, in the chart of the country which he wishes to describe, make divisions, according to the most prominent points; but, in order to do this, he must first have a knowledge of the measurement of altitudes. The military man, unless he is acquainted with the altitude of the points upon the chart before him, cannot form an accurate idea of the ground on which he is to execute his plan of operations. The topographer who wishes to represent a country in plaster of Paris, clay, &c., must also be acquainted with all its elevations and depressions. It was, therefore, very im-

portant to invent a method for quickly and accurately determining heights, by a knowledge of the atmosphere, and by the use of instruments, particularly of the barometer and thermometer.

As soon as it was discovered that the air which surrounds our globe was possessed of gravity and elasticity, the operation of which had been perceived on the barometer, it was inferred that its effects on the barometer would be different at different heights in the atmosphere, and that these variations must follow a certain law. Efforts were made to discover this law by experiment. The barometer and thermometer were carried to known heights, observations were there made, and from these observations rules were derived for finding the elevation of a place above the level of the sea. The celebrated Pascal, upon the 19th of September, 1648, on the Puy de Dome, near Clermont, made the first experiment, the result of which he had already anticipated. It appeared that the barometer stood at the height of twenty-six French inches three lines and a half, in the garden of the monastery at Clermont, but at only twenty-three inches two lines upon the summit of the above-mentioned mountain. It followed, as a necessary consequence, that the height of the column of mercury was diminished in the same proportion as the mass of the atmosphere which supported it in the barometer; and Pascal concluded that, by this process, we could determine whether two places were at the same height, or which of them was the higher, even though they were at a great distance from each other.

Succeeding philosophers followed this idea; but the little success which they met with at first shows how many difficulties the subject presented, although it now appears so simple. They had the scales, but were unacquainted with the value of the weights. Barometrical admeasurements first acquired precision and accuracy with Deluc (1754). This philosopher distinguished the effects produced by heat, on the air and on mercury, from those which depend upon their weight; and the improvements which he made form an epoch in the history of the barometer. This history has been written by Pictet, who himself played an honourable part in it. Biot also published inquiries made for the purpose of perfecting the theory of barometrical measurements, and some tables to facilitate the calculations.

Since Deluc's observations the remarkable formula proposed by the author of the *Mécanique céleste* is the most distinguished discovery on this subject. He reduced to a certain point, in a more natural and simple manner, all the corrections which are to be made on account of the influence of temperature, of moisture, and gravity, on the mercury and the air. He rested his theory on the most accurate data; but the co-efficient which he had assumed, in order to represent the relation between the weight of the atmosphere and that of the mercury, appeared to have too little foundation: the formula was to be proved; the length of the columns to be substituted for their weight; many causes of errors remained to be ascertained; the co-efficient was to be improved, or, rather, a new one was to be determined. Ramond has done all this. By a comparison between barometrical observations and actual measurements of the heights where the observations were taken, he has determined the co-efficient, which is contained in Laplace's last formula. Ramond and many other observers have shown, by experiment, that this formula is not only adapted to small as well as great heights, but is also useful in taking measurements under the surface of the earth.

Barometrical observations may attain great accuracy, when they are made with good instruments, by good observers, and under favourable circumstances. In order to ascertain the relative height of two points, two barometers and four thermometers are requisite; two of the thermometers being attached to the barometers, and two of them being free. These instruments must be as simple as is consistent with convenience and accuracy; and they must agree perfectly. The observers must be well acquainted with their instruments, in order to be able to use them; and it is particularly necessary that they should know on what the observations depend. If two or more observers undertake to ascertain the elevation of a place or country by barometrical measurement, they must attend especially to the following particulars:—*a*, that the instruments hang perpendicularly, protected from the sun, and that the free thermometer be raised, at least, nine feet from the ground, and from any objects which might have an influence on their temperature; *b*, the barometers should be accurately regulated, and the degree at which the mercury stands in the barometer and thermometer should be carefully noted; and, *c*, after the instruments are made to correspond, the observations should be made contemporaneously: finally, the observer must be particularly careful to note the state of the atmosphere. Observations should not be taken in stormy weather, or when the quicksilver in the barometer is liable to sudden variations; moderate weather, when the atmosphere is calm, being clear or cloudy, or when there is a light wind, is the most suitable time for making observations. The instruments should not be at too great a distance from each other. The greatest intervening space should not exceed ten miles.

If these general rules for measuring heights by the barometer are attended to, it is far preferable to every other instrument, to ascertain, expeditiously, the height of a mountain, the descent of a river, &c., for a certain space; the relative height of different points, the depth of a cavity, and the thickness of the strata of a mountain. We cannot, indeed, ascertain the fall of a river to an inch by barometrical measurement; but, by careful observations, we may come very near the truth. Tables, founded on Laplace's formula, give great facility in calculating these observations. Among many others, *Tables Hypsométriques* (Paris, 1809) are particularly good, on account of their correctness and adaptation for use. The labours of the distinguished natural philosopher and mineralogist D'Aubuisson (1809), the progress and result of which are detailed in a memoir read before the mathematico-physical class of the institute, at Paris, March 26 and April 9, 1810, are particularly worthy of notice. (See Air, Barometer, and Mountains.)

Heliacal, as applied to the rising of a star, planet, &c., denotes its emerging out of the sun's rays, in which it was before hid. When applied to the setting of the star, it denotes the entering or immerging into the sun's rays, and thus becoming lost in the lustre of his beans. A star rises heliacally when, after it has been in conjunction with the sun and on that account invisible, it gets at such a distance from the

sun as to be seen in the morning before the rising of that luminary.

Heliocentric Place of a Planet is that place in the ecliptic in which the planet would appear if viewed from the centre of the sun; and consequently the heliocentric place coincides with the longitude of a planet, as viewed from the same centre.

Heliometer; an instrument for measuring small distances on the sky, particularly the apparent diameters of the sun and of the moon, more conveniently than can be done with the micrometer. There are different ways of constructing it. The heliometer of Bouguer is an astronomical telescope, provided with two object-glasses, one of which is moveable, and which form two distinct images of the same object, visible through the same eye-glass. If, in contemplating a celestial body, the object-glasses are placed so as to bring the images to touch each other, the distance of the centres of the glasses gives the diameter of the image. In this manner, the instrument gives, for instance, the difference of the diameter of the sun in the perigee and apogee.

Helioscope is a telescope behind which the image of the sun is received upon a plane surface. An astronomical telescope is drawn out a little farther than is necessary for common use, and directed towards the sun. The image which is formed is received in a dark place. For this purpose, a dark chamber is employed, or the telescope is placed in a dark funnel-shaped enclosure, the bottom of which is covered with oiled paper, or closed with ground glass, on which the sun's image is formed. Upon this paper or glass a circle is described equal to the image, and divided, by five concentric circles, into twelve digits. With this instrument the spots on the sun, eclipses, &c., may be observed without injuring the eyes. For greater exactness, however, it is better to observe the sun through a telescope the glasses of which are smoked or coloured. Astronomical telescopes are commonly provided with coloured plane glasses, which may be screwed on when the sun is to be observed.

Hellebore; a plant formerly much used in medicine, and still employed in many species of disease. It has a bitter and acrid taste: the acrimony being felt on the tip of the tongue and then spreading itself immediately to the middle, without being much perceived in the intermediate part. On chewing the root for a few minutes, the tongue seems benumbed, and affected with a kind of paralytic stupor, as when burnt by eating any thing too hot. Black hellebore root, which is a strong cathartic, has been celebrated for the cure of maniacal and other disorders proceeding from what the ancients called *atra-bilis*, in which cases medicines of this kind are doubtless occasionally of use, though they are by no means possessed of any specific virtue. Our black hellebore does not however act with so much violence as that of the ancients, whence many have supposed it to be a different species of plant: and indeed the descriptions which the ancients have left us of their hellebore do not agree with those of any of the sorts usually taken notice of by modern botanists. Vauquelin ascribes its acrimony to a peculiar oil, which he separated from the infusion in alcohol, by distilling off the latter.

Helm; a long and flat piece of timber, or an assemblage of several pieces, suspended down the hind part of a ship's stern-post, where it turns upon a species of hinge to the right or left, serving to direct the course of a vessel, as the tail of a fish guides the body. The helm is usually composed of three parts, viz. the rudder, the tiller, and the wheel, except in small vessels, where the wheel is unnecessary. The rudder becomes gradually broader in proportion to its distance from the top, or its depth under water. The back or inner part of it, which joins the stern-post, is diminished into the form of a wedge throughout its whole length, so that it may be more easily turned from one side to the other, when it makes an obtuse angle with the keel. The length and thickness of the rudder is nearly equal to that of the stern-post. The tiller is a long bar of timber, fixed horizontally in the upper end of the rudder, within the vessel. The movements of the tiller to the right and left accordingly direct the efforts of the rudder to the government of the ship's course as she advances, which is called *steering*.

The operations of the tiller are guided and assisted by a tackle, communicating with the ship's side, called the *tiller-rope*, which is usually composed of untarred rope-yarns, for the purpose of traversing more readily through the blocks or pulleys. In order to facilitate the management of the helm, the tiller-rope, in all large vessels, is wound about a wheel, which acts upon it with the powers of a windlass. The rope employed in this service, being conveyed from the fore-end of the tiller to a single block on each side of the ship, forms a communication with the wheel by means of two blocks, fixed near the mizzen-mast, and two holes immediately above, leading up to the wheel, which is fixed upon an axis on the quarter-deck, almost perpendicularly over the fore-end of the tiller. Five turns of the rope are usually wound about the barrel of the wheel, and, when the helm is a-midship, the middle turn is nailed to the top of the barrel with a mark, by which the helmsman readily discovers the situation of the helm. The spokes of the wheel generally reach about eight inches beyond the rim or circumference, serving as handles to the person who steers the vessel. As the effect of a lever increases in proportion to the length of its arm, it is evident that the power of the helmsman to turn the wheel will be increased according to the length of the spokes beyond the circumference of the barrel; so that, if the helmsman employ a force of 30 lbs., it will produce an effect of from 90 to 120 lbs. upon the tiller (the barrel being one-fourth or one-fifth of the radius of the spokes), which again forming the long end of a lever 10 or 15 times the length of its shorter arm, the force of the rudder will, by consequence, be from 10 times 90 to 15 times 120, or from 900 to 1800 lbs. When the helm operates by itself, the centre of rotation of the ship and her movements are determined by estimating the force of the rudder by the square of the ship's velocity. When the helm, instead of lying in a right line with the keel, is turned to one side or the other, it receives an immediate shock from the water, which glides along the ship's bottom in running *aft*, on the side towards which the helm is turned, and pushes it towards the opposite side, whilst it is retained in this position; so that the stern, to which the rudder is confined, receives the same impression, and accordingly turns in one direction, whilst the head of the ship moves in the opposite. The more the velocity of a ship increases, the more powerful will be the effect of the rudder, because

the water will act against it with a force which increases as the square of the swiftness of the fluid, whether the ship advances or retreats. The direction given in the two cases will of course be contrary. By a late improvement, suggested by Captain Basil Hall, the helmsman is placed in the bow of the vessel, instead of the stern; and this arrangement has been found peculiarly advantageous in steam-vessels.

HELMET; a defensive armour, for the protection of the head, composed of skins of animals, or of metals. Some of Homer's heroes are represented as wearing brazen helmets, with towering crests, adorned with plumes of the tails or manes of horses. Among the Romans, the *cassis* was a metallic helmet; the *galea*, a leathern one.

HELMINTHAGOGA; medicines against worms.

HELMINTHIASIS; the disease which proceeds from intestinal worms.

HEMORRHAGE; a flux of blood from the vessels which contain it, whether proceeding from a rupture of the blood-vessels or any other cause. Hemorrhages produced by mechanical causes belong to surgery; those produced by internal causes, to medicine. The cutaneous system is rarely, and the cellular and serous systems are never the seats of hemorrhages; that of the mucous membranes is the most subject to them. The symptoms of the disease are not less various than its causes and its seats, and the treatment must of course be adapted to all these different circumstances. A hemorrhage from the lungs is called *hemoptysis;* from the urinary organs, *hematuria;* from the stomach, *hematemesis;* from the nose, *epistaxis.*

HEMORRHOIDS, literally, a flow or flux of blood. Until the time of Hippocrates, this word was used, conformably to its etymology, as synonymous with *hemorrhage.* It was afterwards used in a narrower sense, to indicate the flux of blood at the extremity of the rectum, and in some other cases which were considered analogous to it; thus we hear it applied to the flow of blood from the nostrils, the mouth, the bladder, and the matrix. It is at present used to signify a particular affection of the rectum, although the disease is not always attended with a flux; in this sense it is called *piles.* Certain general causes may produce a predisposition to this disease; in some cases, it appears to be the effect of an hereditary disposition; in general, it manifests itself between the period of puberty and old age, although infants and aged people are not entirely exempt from its attacks. The bilious temperament seems to be more exposed to it than any other. Men are oftener affected with it than women, in whom it is sometimes produced by local causes. It often shows itself in persons who pass suddenly from an active to a sedentary life, or from leanness to corpulency. Any circumstance which produces a tendency to stagnation of the blood at the extremity of the rectum is to be reckoned among the local causes. The accumulation of fecal matter in the intestines, the pressure produced by polypi, the obstruction of any of the viscera, especially of the liver, worms, the frequent use of hot bathing, of drastic purges, and particularly of aloes, long continuance in a sitting posture, riding on horseback, the accumulation of water by ascites,—such are some of the ordinary causes of hemorrhoids.

They are distinguished into several sorts, as external, when apparent at the anus; internal, when concealed within the orifice, blind or open, regular or irregular, active or passive, periodical or anomalous, &c. There is also a great difference in the quantity of blood discharged; it is usually inconsiderable, but in some cases is so great as to threaten the life of the subject. The quality, colour, &c., of the blood, also differ in different cases. The number, seat, and form of the hemorrhoidal tumours likewise present a great variety of appearances.

When the disease is purely local, we may attempt its cure; but, in the greatest number of cases, it is connected with some other affection, or with the constitution of the subject. In these cases, if the tumours are not troublesome on account of their size, or if the quantity of blood discharged is not very considerable, the cure may be attended with bad consequences. The best mode of treatment is, then, to recur to hygietic rather than medicinal influences. The subject should avoid violent exercises; but moderate exercise will be found beneficial; the food should not be too stimulating or nutritious. Travelling, or an active life, should succeed to sedentary habits. The constipation, with which the subjects of this disease are liable to be affected, should be remedied by laxatives or gentle purgatives. If bathing is used, it should be in lukewarm or cold water. Any thing which may be productive of a local heat should be avoided; as warm seats, soft beds, too much sleep. If the pain be considerable, recourse should be had to sedatives, gentle bleeding, leeches. If the disease appear under a more severe form, more violent remedies will become necessary. If the sanguineous fluxion become excessive, particular care must be paid to regulate it. If the tumours acquire a considerable volume, surgical operations may become necessary. If any bad consequences result from the suppression of the hemorrhoids, care must be taken to give the blood the salutary direction which it had previously; this may be effected by the use of laxative baths and emollient fomentations.

HEMP. This plant possesses a strong odour, with intoxicating and narcotic properties, on which account it is usual, in India and other Eastern countries, to mix the leaves with tobacco for smoking. It is a native of India and Persia, and was transported into Europe, where it is now cultivated successfully. The seeds do not preserve their vegetative properties beyond one season, on account of the quantity of oil they contain. Their goodness may also be determined by the taste. If an acrid or rancid flavour be present, the seeds have lost the power of germination; all that have a white or pale-greenish colour should likewise be rejected. A strong, heavily-manured soil, is the most suitable for its cultivation, on which account it succeeds so well on newly cleared lands. It should be sown more or less densely, according to the use for which it is intended; if very thick, the fibres are finer, have a better lustre, are more easily bleached, and of course more suitable for the finer kinds of cloth; if scattered sparingly, the plants attain a greater elevation, produce a stronger, coarser, and longer fibre, better adapted for cordage. Care should be taken not to cover the seed too deeply with earth, and, when a few inches high, it should be thinned and cleared of weeds; once is sufficient, for the hemp soon acquires such an ascendency as entirely to prevent the growth of other plants. The harvest is at two distinct periods. Soon after flowering, the male plants should be

pulled up without disturbing the roots of the females, which are to remain some weeks longer, in order to bring the seed to perfection. With unscientific people, however, these terms are transposed, the *males* are called *females* and *vice versâ*. The males should be tied immediately in bundles, the roots cut off while fresh, the upper leaves also beaten off; and it is the most eligible practice to immerse them in water without delay, for rotting. The females, which are three times more numerous than the males, should be pulled very carefully, without shaking or inclining the summits, and the flail should not be used, as it bruises the seed. The seed, when separated, should be spread out, turned at intervals, and exposed to a current of air, otherwise there will be danger of fermentation.

The process of rotting consists in the decomposition of the substance which envelopes and unites the fibres, and takes place much more rapidly in stagnant pools than in running water or extensive lakes—in warm weather than in the reverse. The time requisite varies from five to fifteen days, even in stagnant water. The water in which hemp has been rotted acquires an excessively disagreeable odour and taste, proving fatal to fishes, and should be at a distance from any inhabited place, lest it engender pestilential diseases; neither should it be permitted to corrupt those sources which are used for drink by man or beast. When water is not at hand, hemp may be rotted in the open air, by spreading it at night upon the green-sward, and heaping it together in the morning before the sun's rays have much power. In wet weather, it may be left upon the ground during the whole day, and, should the nights be very dry, it is better to water it. This process is called *dew-rotting*, and is very tedious, requiring three, six, or even eight weeks. Another method, again, is by placing it in a pit, and covering it with about a foot of earth, after having watered it abundantly a single time; but even this method requires double the time of water. After being rotted and rapidly dried, the hemp is ready for combing, beating, &c.; but these subsequent manipulations are found by experience to be very unhealthy, probably on account of the fine, penetrating dust which is created; wherefore, in this instance, at least, the employment of some of the various machines which have been invented is supported on the plea of humanity.

HENBANE possesses a heavy, disagreeable odour, and dangerous narcotic properties. Cases of poisoning, from eating this plant through mistake, have been frequent in Europe. This plant was originally imported from the eastern continent, but has now become naturalized in this country: it occurs in waste places, along road-sides, and in most places where a weed will thrive. From its narcotic qualities, it is occasionally employed in medicine. Twelve species of *hyascyamus* are known, all of them natives of the eastern continent.

HENNA PLANT. This plant grows in moist situations throughout the north of Africa, Arabia, Persia, and the East Indies, and has acquired celebrity from being used by the inhabitants of those countries to dye the nails of their fingers, and the manes, hoofs, &c., of their horses. For this purpose the leaves are dried, powdered, and made into a paste with hot water, which, when applied to the above-mentioned parts, leaves a yellow colour, requiring to be renewed about every three or four weeks. The Egyptian mummies have their nails stained yellow, probably by the use of the henna, though the circumstance is by some referred to the various drugs used in the process of embalming. Henna is cultivated extensively in Egypt, and the powdered leaves form a large article of export to Persia and the Turkish possessions. The colouring matter of this plant is very abundant, and it may be advantageously used for dyeing woollens, not only yellow, but brown of various shades, provided that alum and sulphate of iron be employed.

HERALD. This office is as old as that of the priesthood. Heralds are found among all nations, the *parlementaires* of the moderns being the same as the *heralds* of the ancients. Their persons were inviolable, otherwise they could not have accomplished the object of their institution. The Romans had three sorts of heralds—the *caduceatores, feciales* (heralds of war and peace), and *præcones* (criers or messengers of the superior magistrates). The *caduceator* carried certain plants, as myrtle, olive-branches, rosemary, &c., in his hand, as a symbol of his office, and for his security. Among the Grecians he carried a wand of laurel or olive (*caduceus*). The Athenian herald carried a wand bound round with wool, and ornamented with various kinds of fruits. He often united other employments with his office of herald, as that of cook and cup-bearer. The Spartan heralds must have been derived from *Talthybius*, the herald of Agamemnon, who was worshipped in a temple in Sparta. The *feciales*, forming a college of twenty members, established by Numa, had also a diplomatic character, as their department embraced every thing connected with the declaration of war and the making of treaties. If war was determined upon, they solemnly proclaimed it. If Rome considered herself injured, a *fecialis* demanded satisfaction. If this demand was not complied with within thirty-three days, the *fecialis* went again to the hostile frontiers, threw a bloody spear, and declared war by a solemn formula.

As the frontiers of the Roman territory extended farther and farther from the capital, this ceremony was performed upon a field without the city. The *feciales* wore the sacred *verbena* as a wreath round their temples; and, if they were sent to conclude a treaty, they carried a flint. The *præcones* were employed to proclaim matters of public interest to the people, at religious ceremonies, in the *comitia*, at public sales, judicial trials, in the senate, on the publication of the laws (which they read), at funerals, at games, in the army (if a general wished to address his men), at executions, and at all public meetings. In the middle ages, indigent knights, grown old in battle, were appointed heralds. Their duty was to be arbiters at the tournaments, to pass judgment on coats of arms and the right of knighthood. The study of armouries was therefore indispensable to them; hence the name *heraldry*. They were also the chroniclers of those times, and were present on all occasions of public ceremony.

In France, the first herald (*roi-d'armes*) was crowned and consecrated with religious ceremonies. There were thirty heralds of the realm; the second in rank was called *Montjoye St. Denis*, from the war-cry of King Dagobert. The heralds were united in associations, and their duties formed a branch of science which was communicated only to the members. If

any person pretended to the character of a herald, who, on examination, was found not to belong to the corporation, he was driven away with insults, and sometimes treated with violence. Most of the European orders have their heralds, who are masters of ceremonies. There are three kings at arms in England. The highest is the garter king at arms; the second for the southern provinces; the third for the northern provinces. These three kings at arms, with six subordinate heralds and four pursuivants, form, under the presidency of the Earl Marshal, Duke of Norfolk, the herald's college, or herald's office, established in 1340.

HERALDRY. Arms may belong to individuals, to families, or to countries. Badges and emblems on shields and helms occurred in the earliest times. In Numbers (chap. i. 52), the children of Israel are enjoined to pitch their tents, "every man by his own camp, and every man by his own standard," with the ensigns of his father's house. The poets of the Greeks and Romans speak of paintings and devices on shields and helmets. These symbols were, moreover, hereditary. Thus Xenophon relates that the kings of the Medes bore a golden eagle on their shields. Suetonius asserts that Domitian had a golden beard for his coat of arms; and Tacitus says of the ancient Germans that they marked their shields with brilliant colours, and that certain standards were borne before them in battle. Notwithstanding these traces of armorial bearings in the ancient world, our heraldry is no older than the tournaments. That armoury first became common and regulated by certain rules at these solemn festivals is corroborated by the following reasons:—In the first place, we find no tomb, or monument, with escutcheons, older than the eleventh century. The most ancient monument of this kind is said to be the bearings of Valmond, Count of Vasserburg, in the church of St. Emmeran, at Ratisbon. The shield is *coupé* of argent and sable; over it is a lion, with the words "*Anno Domini MX.*" On most of the other tombs, even of the eleventh century, no arms are found; and the use of them seems to have first become common in the twelfth century.

The first pope who can be proved to have had a coat of arms is Boniface VIII., who filled the papal see from 1294 to 1303. All the earlier papal arms are the fanciful inventions of later historians. On coins, also, no armorial ensigns are found till the thirteenth century. A second proof of our assumed origin of coats of arms is the word *blason*, which denotes the science of heraldry in French, English, Italian, and Spanish. This word has most probably its origin in the German word *blasen* (to blow the horn); for, whenever a new knight appeared at a tournament, the herald had to sound the trumpet, and, because all appeared with close visors, to proclaim and explain the bearing of the shield or coat of arms belonging to each. Because this was performed by the herald, this knowledge was called *heraldry*; and because, in doing so, he blew the trumpet, it was called *blazoning the arms*. That this was a prevailing practice at tournaments may be proved from the poetry of the Troubadours of the twelfth and thirteenth centuries. From the Germans, this custom was transmitted to the French; for there is no doubt that tournaments were usual in Germany much earlier than in France. But the French carried to far greater perfection the tournament, and the blazon or heraldry connected with it, as they did the whole system of chivalry. And, as the French language prevailed at the court of the Norman kings in England, pure French expressions have been preserved in British heraldry. Thus the green tincture (colour) in a coat of arms is termed *vert* (though in French *sinople*), which originally denoted a *reddish brown;* bright red is termed *gules*, probably with an allusion to the bloody revenge of wild animals, which play so conspicuous a part in heraldry. In a *coat of arms*, the helm is placed upon the shield, and the latter is surrounded by the wreath. At a tournament, the mantle of the knight, with the helm and shield, was suspended in the lists. The colours or tinctures of the shields had their foundation in the custom of the most ancient Germans of giving their shields various colours—a custom which received a tender meaning in the tournaments of the middle ages, the knight, bound to defend the honour of dames, and devote himself to their protection, wearing their colours on his shield. By degrees, the partitions or sections on shields came into use; for when, as often occurred, a knight was the champion of several ladies, he bore several colours on his shield, which had therefore to be divided into fields.

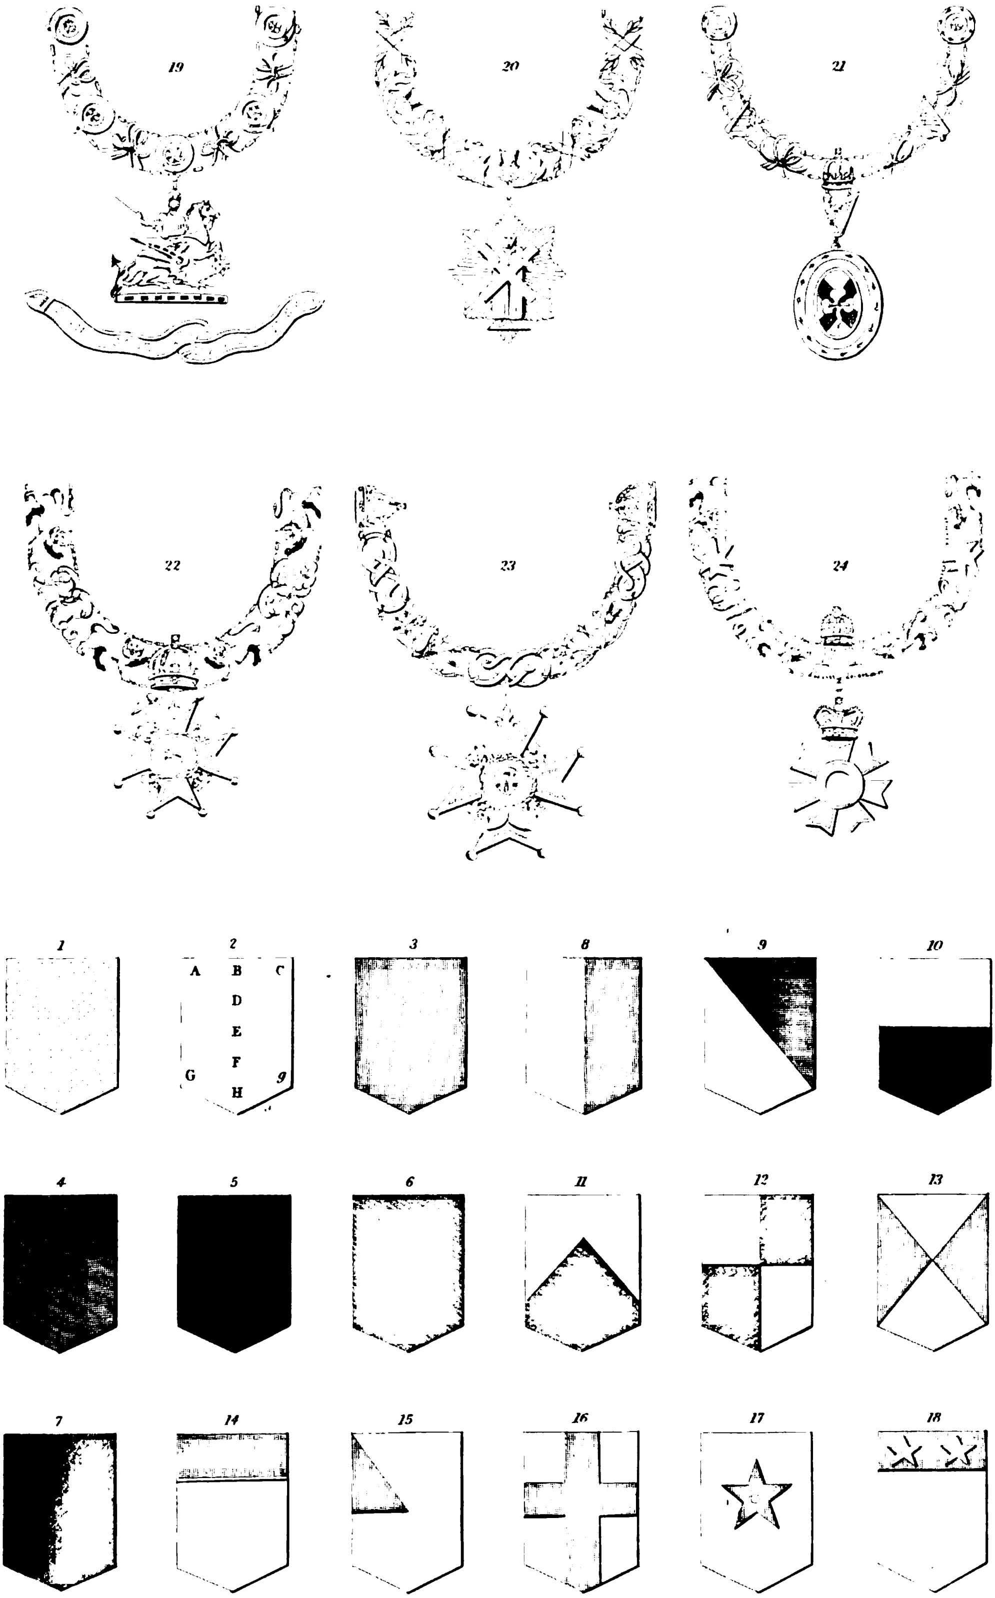
The *escutcheon*, or shield, in arms, means the original shield used in war, and on which arms were originally borne; the surface of the escutcheon is termed the *field*, because it contains such honourable marks as anciently were acquired in the field, &c.

Points of the escutcheon mean certain points or locations, in which the figures or charges of the field happen to be particularly placed. The shield is shown in *plate* I. HERALDRY, *fig.* 2. A signifies that part to be the *dexter chief;* B, the precise *middle chief;* C, the *sinister chief;* D, the collar, or *honour point;* as knights of the garter, thistle, &c., wear their badges of honour about their necks; in like manner is E called the heart, or *fess point*, as being the exact middle of the shield; F, the *nombril*, or navel *point;* G, H, I, the *dexter, middle*, and *sinister* points.

The *colours* used in the science of heraldry are generally *red, blue, black, green, purple;* termed in this science *gules, azure, sable, vert*, and *purpure*. *Yellow* and *white*, termed *or* and *argent*, are metals:

Names.	Colours.
Or	Yellow.
Argent	White.
Gules	Red.
Azure	Blue.
Sable	Black.
Vert	Green.
Purpure	Purple.

Colours and metals, when engraved, are known by points and hatched lines; as *or*, the metal gold, is known in engraving by small dots or points; *argent*, a metal that is white, and signifies silver, is always left plain; *gules*, this colour is expressed by lines perpendicular from top to bottom; *azure*, a colour known by horizontal lines from side to side; *sable*, a colour expressed by horizontal and perpendicular lines crossing each other; *vert*, a colour described by hatched lines from right to left diagonally; *purpure*, a colour known by hatched lines from the sinister chief to the dexter base, diagonally. The colours marked as already described are shown in *plate* I. HERALDRY, *fig.* 1 *to* 7.



Drawn by Charles Blunt. London Published by William Orr Paternoster Row Sept.r 1833 Engraved by J. Dower

Furs are not only used for the linings of robes and of dresses of state, the linings of the mantle, and other ornaments of the shield, but also in the coat-armours themselves: viz. *ermine, ermines, erminois, erminites, pean, vair, vair-en-point, counter-vair, potent-counter-potent.*

Ermine is represented by black spots on a white field; *ermines* is a field black with white spots; *erminois* is a field gold with black spots; *vair* is white and blue, represented by figures of small escutcheons, ranged in a line, so that the *base argent* is opposite to the *base azure; counter-vair* is when the bells or cups of the same colour are placed *base* against *base*, and *point* against *point; potent-counter-potent* is a field covered with figures like crutch-head, termed potents *counter placed*.

Partition lines are such as *party per pale, party per bend, party per fess, party per chevron, party per cross, party per saltire,* by which is understood a shield divided or cut through by a line or lines, either perpendicular, diagonal, transverse, &c., agreeably to the form of the ordinaries. The crooked lines, such as the engrailed, wavy, &c., are used in heraldry to form a difference between bearings which would be otherwise the same; for an escutcheon charged with a chief engrailed differs from a chief wavy as much as if the one bore a cross and the other a saltire.

Party per pale is the field divided by a perpendicular line, as *fig.* 8. Party signifies parted or divided, and is applied to all divisions of the field or charges. Party per bend is a field divided by a diagonal line from the dexter chief to the sinister base, as shown at *fig.* 9. *Party per bend, or, and vert,* name Hawly. Party per fess is a field equally divided by a horizontal line, as at *fig.* 10. Party per chevron is a field divided by such a line as helps to make the chevron, as at *fig.* 11. *Party per chevron, sable and argent,* name Aston. Party per cross, *or quarterly,* is a field divided by two lines, the one perpendicular and the other horizontal, crossing each other in the centre of the field, as at *fig.* 12. *Party per cross, argent and gules,* name Sir Henry Cock, of Hertfordshire. Party per saltire is a field divided by two diagonal lines, dexter and sinister, crossing each other in the centre of the field, as at *fig.* 13.

The crooked lines of partition are the *engrailed, inverted, wavy, nebule, imbattled, raguly, dancette, indented,* and *dove-tail.*

Ordinaries are those figures which, by their ordinary and frequent use, are become most essential to the science, viz: The chief, pale, bend, bend sinister, fess, bar, chevron, cross, and saltire; these have their diminutives.

We may take for an example the *chief,* which is formed by a horizontal line, and contains in depth the third of the field, as shown at *fig.* 14.

The *pale* consists of two perpendicular lines, drawn from the top to the base of the shield.

The pale has two diminutives—the half of the pale is called a *pallet;* and the half of the pallet is called an *endorse.*

The *bend* is formed by two parallel lines drawn from the dexter chief to the sinister base. The bend has four diminutives, the *bendlet,* the *garter,* the *cost,* and *riband.*

The *bend sinister* passes diagonally from the sinister chief to the dexter base of the shield. The bend sinister has two diminutives, the *scarp,* which is half the bend, and the *baton,* which is half of the scarp.

The *fess* is formed by two horizontal lines across the shield, and contains the third part of the field, and is always confined to the centre.

The *bar* is formed by two horizontal lines, and contains the fifth part of the field. The bar is never borne single; the bar has two diminutives, the *closet,* which is half the bar, and the *barrulet,* which is half the closet.

The *chevron* is formed by two lines placed pyramidically, like two rafters of a house, joined together in chief, and descending in form of a pair of compasses to the extremities of the shield. The chevron has two diminutives, the *chevronel,* which is half the chevron; and the *couple-close,* which is half the chevronel.

The *cross.* The cross is formed by the meeting of two perpendicular with two horizontal lines near the fess point, where they make four right angles; the lines are not drawn throughout, but discontinued the breadth of the cross.

The *saltire* is formed by the bend-dexter and bend-sinister crossing each other in right angles.

The *pile* is composed of two lines which form a long wedge.

The *quarter* is formed of two lines, one perpendicular, the other horizontal, taking up one-fourth of the field, and is always placed in the chief.

The *canton* is a square figure like the *quarter,* possessing only the third part of the chief.

A *gyron* is of a triangular figure, composed of two lines, one diagonally from the dexter chief angle to the centre of the shield; the other is drawn horizontal from the dexter side of the shield, meeting the other line in the centre of the field, as shown at *fig.* 15.

Flanches are formed by two circular lines, and are always borne double.

The *orle* is an inner border of the same shape as the escutcheon.

The *tressure* is a diminutive of the orle half in breadth, and is generally borne flory and counter-flory.

The *frett* is composed of six pieces, two of which form a saltire, and the other four a *mascle,* which is placed in the centre.

A *border* is a bearing that goes all round and parallel to the boundary of the shield in form of a hem, and contains the fifth part of the field.

A *border engrailed.* This border is bounded by two small semicircles, the points of which enter the field.

A *border indented* is the same in shape as the partition line indented.

A *border quarterly* is a border divided into four equal parts by a perpendicular and horizontal line.

The *cross* is one of the most important ordinaries. It is borne *indented, engrailed,* &c., as well as plain; but when *plain,* as in the example *fig.* 16, you only mention a *cross,* which is understood to be plain.

A *cross moline* signifies a cross which turns round both ways at the extremities.

A *cross potent.* This cross terminates like the head of a crutch, which anciently was called a potent.

A *cross pattée* is proper for a cross that is small in the centre, and so goes on widening to the ends, which are very broad.

Charges are figures or bearings borne in an escutcheon. We may take the lozenge as an example. The shape is the same with that of a pane of glass in old casements. In this form the arms of maidens and widows should be borne. The true proportion of the lozenge is to have its width three parts in four of its height.

We may now proceed to examine the rules of *blazoning*. This branch of the science of heraldry, according to the *Notitia Anglicana*, is merely employed to describe the things borne in proper terms, according to their several gestures, positions, and tinctures; and how to *marshal* or dispose regularly various arms on a field, in which care ought to be particularly observed, because the adding or omitting any part is oftentimes an alteration of the coat.

In blazon the following rules are to be carefully observed:—

First, in blazoning a coat you must always begin with the field; noticing the lines wherewith it is divided, whether *per pale, per fess, per bend*, &c., as also the difference of those lines, whether *indented, engrailed*, &c.; then proceed to the next immediate charge. By an immediate charge is meant that which lieth next the field, and nearest the centre; this must first be named; and then those that are more remote; for example, *azure, a crescent between three stars, argent*; thus the crescent is first named, as being next the centre of the field. We may take one example of the rules of blazoning: it is shown at *fig.* 18, and is thus described,—*Argent, on a chief gules, two mullets pierced, or.*

We come next to examine the exterior ornaments of the escutcheon, which consist of the helmet, mantling, wreath, crest, badge, motto, supporters, and crown or coronet.

The *helmet*, being placed at the top of the escutcheon, claims our first attention. These pieces of armour for the head have varied in different ages and countries, both in form and the materials of which they were made; viz. those of sovereign princes are of gold; those of the nobility, of silver; and those of gentlemen, of polished steel.

The *mantling* was anciently attached to the helmet; it was used as a covering or trimming which commanders wore over their helmets to defend them from the weather.

Mantlings are now used like cloaks to cover the whole achievement, instead of the ancient mode of representing them as being coverings for the head, or ornaments flowing from the helmet.

The *crest* is the highest part of the ornaments of a coat of arms, and is placed on the wreath. Anciently it was worn on the heads of commanders in the field, and then only in order to distinguish them from others, by their followers.

After the institution of the order of the garter, and in imitation of King Edward III., who was the first king of England that bore a crest on his helmet, all knights companions of the order began to wear crests. This practice soon became more general, until at length they were assumed discretionally by all those who considered themselves as legally entitled to bear arms.

Badges anciently were intended to be placed on banners, ensigns, caparisons, and the breast or shoulders of private soldiers, servants, and attendants, and that without any wreath or other thing under them. Badges were much used from the reign of King Edward I. until that of Queen Elizabeth, when they grew into disuse.

The *supporters* are exterior ornaments, being placed at the sides of the escutcheon to support it. Ministrier says that supporters had their origin from tilts and tournaments, wherein the knights caused their shields to be carried by servants or pages under the disguise of lions, bears, griffins. Moors, &c., who also held and guarded the escutcheons, which the knights were obliged to expose to public view some time before the lists were opened.

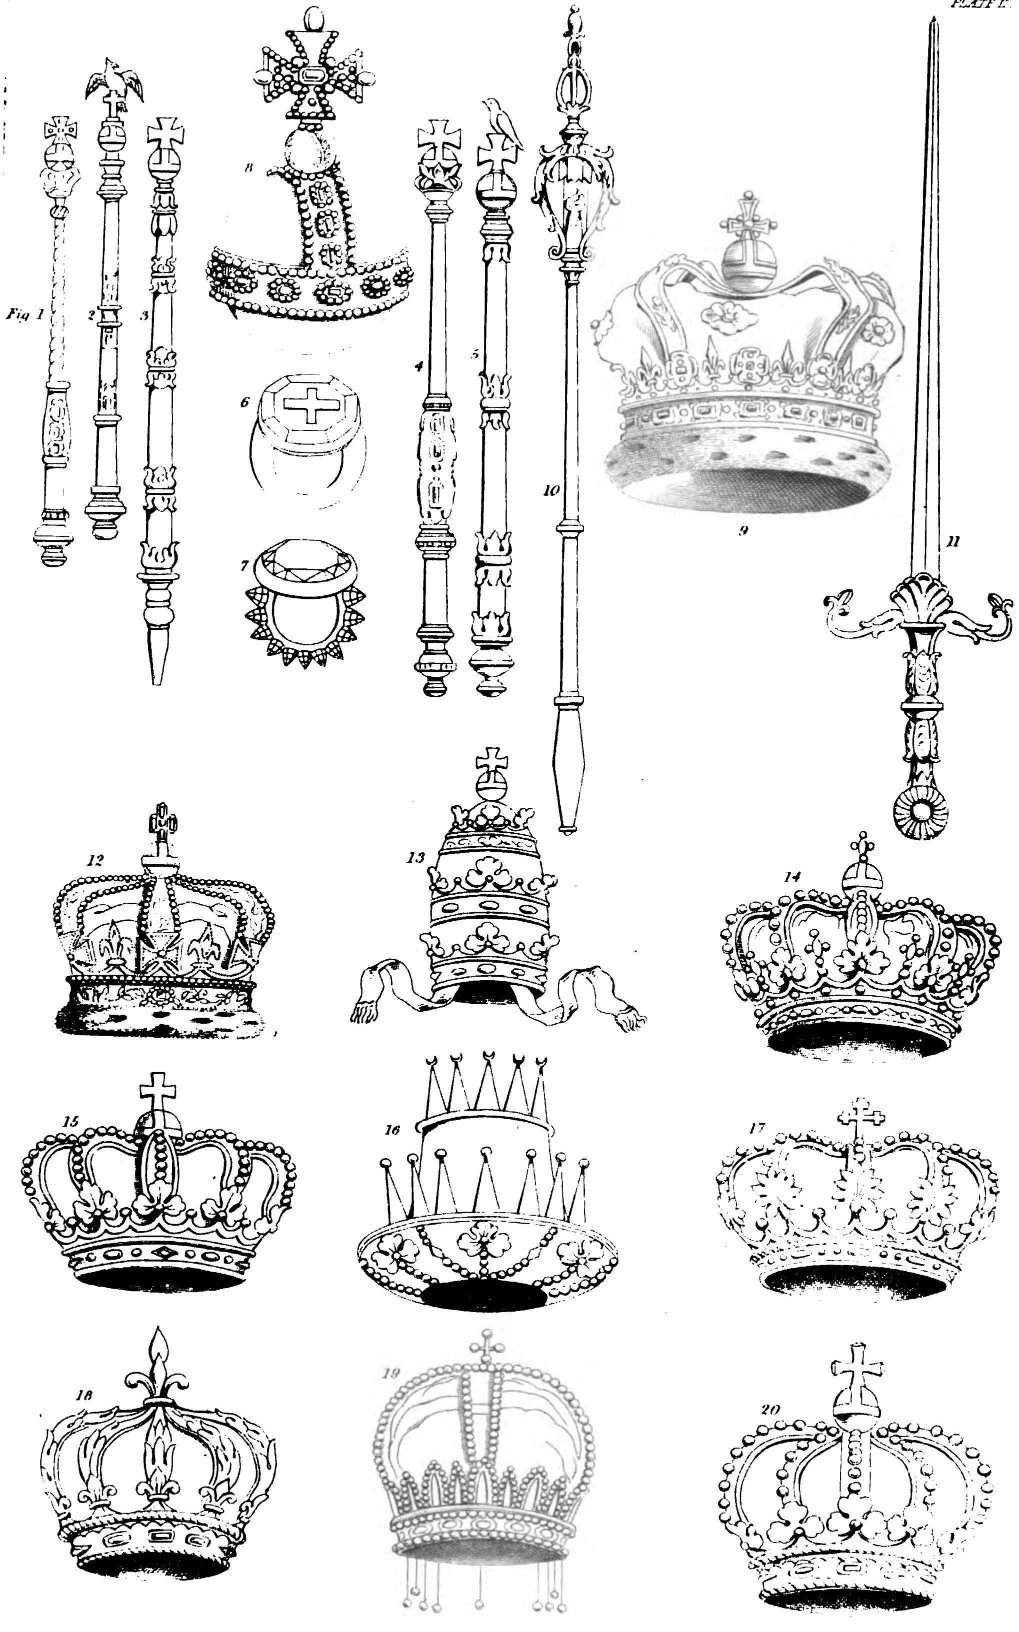
Having thus given a general outline of the principal divisions of heraldry, we may proceed to notice the orders of knighthood. According to the most authentic accounts, the order of the garter was instituted by Edward III., anno 1350, in the twenty-fourth year of his reign. This order, which has ever been considered as the highest in rank and dignity of knighthood, and with which kings and princes of all nations have deemed it most honourable to be invested, consists of the sovereign and twenty-five companions, called knights of the garter. There are besides five principal officers: the prelate, the chancellor, registrar, garter king of arms, and usher, or black rod. The habit and insignia of the order are garter, surcoat, mantle, hood, George, collar, cap, and feathers.

The *garter*, of dark-blue velvet, edged with gold, bearing the motto of "*Honi soit qui mal y pense*," in letters of gold, with buckle and pendant of richly chased gold, is worn on the left leg, below the knee. The *mantle* is of blue velvet, lined with taffeta. The hood affixed to the mantle is of crimson velvet. The *hat* is of black velvet, lined with white taffeta, and adorned with a large plume of white ostrich feathers, with a tuft of black heron's feathers in the centre, affixed to the hat by a band of diamonds. The *collar* is of gold, composed of twenty-six pieces (in allusion to the number of knights), each in the form of a garter, enamelled, blue, with the motto. To which is appended the badge, or figure of St. George on horseback. It is shown at *fig.* 19.

The order of the bath was instituted at the coronation of Henry IV., 1399, who conferred the dignity upon 46 esquires, who had watched during the previous night, and *had bathed themselves*; from which originated the title of knights of the bath. After the coronation of Charles II., who created sixty-eight knights, the order was neglected till the year 1725, when George I. determined to revive and re-organize it, to consist of the sovereign, grand-master, and thirty-six companions; since which time several alterations have been made. In January, 1815, it was declared that, "for the purpose of commemorating the auspicious termination of the long and arduous contests in which this empire has been engaged," the order should be composed of three classes.

The first class to consist of not exceeding seventy-two knights grand-crosses, exclusive of the sovereign and princes of the blood. The badge is commonly pendant by a ring on a broad red riband over the right shoulder, hanging on the left side; but on particular occasions it is worn pendant to the collar, as shown at *fig.* 23.

The knights commanders to be entitled to the distinctive appellation of knighthood, and to have the same rights and privileges as knights bachelors, taking precedence of them. The companions of the order take precedence of esquires, but are not entitled to the appellation of knights bachelors.



... by Charles Blunt London Published by William Orr Paternoster Row Engraved by ...

The order of the thistle is supposed to have been instituted by King Achaius, on the occasion of a bright cross, similar to that on which the patron, St. Andrew, suffered martyrdom, appearing in the heavens to him and Thurgus, king of the Picts, on the night previous to the battle gained by them over Athelstane, king of England. Some have thought the order of later date. It was, however, revived in 1540, by James V., of Scotland, and again by James II., in 1679, and has since been re-organized. The order now consists of the sovereign and 12 knights. The *collar* has thistles and sprigs of rue, of gold enamelled, to which is appended the badge, *fig*. 20. The star is worn on the left side, and the jewel is pendant to a green riband over the left shoulder, tied under the arm. Motto—"*Nemo me impune lacesset.*"

The order of St. Patrick was instituted by King George III., February 5, 1783, and consists of the sovereign, grand-master, a prince of the blood royal, and thirteen knights; the Lord Lieutenant of Ireland being grand-master *pro tempore.*

The collar is of pure gold, composed of six harps and five roses, alternately joined together by twelve knots; in the centre is a crown, and pendant thereto by a harp is the badge. The star is of silver embroidery, upon a circular centre *or*, a cross saltire *gules*, surmounted by a trefoil slipped *proper*, each leaf charged with a crown *or*, within a circular fillet of gold, with the motto, "*Quis separabit.*" The collar and star are shown at *fig*. 21.

The Royal Hanoverian Guelphic Order was founded by George IV. when Prince Regent, in 1815, in commemoration of the raising of Hanover into a kingdom, and for rewarding those persons who had performed any signal service to their country. His Majesty, as king of Hanover, is grand-master. The order is composed of three classes, into which civil and military men are admitted, viz. grand-crosses, commanders, and knights. The badges of the military grand-crosses, military commanders, and military knights, differ only in size according to their class. On the reverse, upon the centre, is a double cipher of G. R., with the crown, and date of foundation.

The badges of the civil grand-crosses, commanders, and knights are also alike, only differing in size, having a crown upon the upper limb of the cross (without the swords), by which it is suspended, and a wreath of oak leaves instead of laurel. It is worn on grand occasions suspended from the collar, but on ordinary occasions it is worn pendant from a sky-blue riband scarfwise. Commanders suspend it by a sky-blue riband worn round the neck, and knights by a riband and gold buckle from the button-hole.

The star worn by the military grand crosses is of eight points, &c., with the motto, "*Nec aspera terrent.*" See *fig*. 22. That worn by the civil grand-crosses only differs in the omission of the swords, and a wreath of oak leaves being substituted for laurel.

The order of St. Michael and St. George was also instituted by George IV., when Prince Regent, in 1819, in commemoration of the United States of the Ionian Islands being placed under his sovereign protectorship.

The order is composed of three classes, and consists of the sovereign, a grand-master, a first and principal knight grand-cross, eight grand-crosses, twelve knights commanders, and twenty-four knights, exclusive of British subjects holding high and confidential employ in the service of the United States of Malta.

The collar and badge are worn round the neck on grand occasions; but ordinarily the badge is worn pendant from a red riband with blue edges.

The star worn by the knights grand-crosses is shown at *fig*. 24. That worn by the knights commanders is of a similar description, but of less beauty. Motto, "*Auspicium meliorus ævi.*"

The regalia and crowns of England and Scotland, as well as those of the principal states of Europe, may now be illustrated. The crown of England, with which the kings of England have generally been crowned, is called St. Edward's crown. It is made in imitation of the ancient crown supposed to have been worn by that monarch, and which was kept in the abbey church of Westminster till the beginning of the late civil wars in the reign of King Charles I., when, with the rest of the regalia, it was taken away, and sold in 1642. The present crown was made against the coronation of King Charles II., and is embellished with pearls and precious stones. There is a mound of gold on the top of it, enriched with a band or fillet of gold, embellished also with precious stones. Upon the mound is a cross of gold, embellished likewise with precious stones, and three very large oval pearls, one of them being fixed on the top, and two others pendant at the ends of the cross. It is composed of four crosses pattée, and as many fleurs-de-lis of gold, placed on a rim or circlet of gold, all embellished with precious stones. From these crosses arise four circular bars or arches, which meet at the top in form of a cross. The cap within this crown is of purple velvet, lined with white taffeta, and turned up with ermine.

The golden sceptre, with its cross, is shown at *fig*. 1, *plate* II. Heraldry. It is set upon a large amethyst, of great value, garnished round with table diamonds. The handle of the sceptre is spiral, but the pummel is set round with rubies, emeralds, and small diamonds. The top rises into a fleur-de-lis of six leaves, all enriched with precious stones, from whence issueth a mound made of the amethyst already mentioned. The cross is decorated with precious stones; the sceptre is about thirty-three inches in length.

The sceptre has a dove, the emblem of peace, perched on the top of a Jerusalem cross, ornamented with diamonds. This emblem was first used by Edward the Confessor, as appears by his seal. The length of the sceptre, which is shown at *fig*. 2, is forty-three inches.

St. Edward's staff, in length fifty-five inches and a half, and three inches and three-quarters in circumference, all of gold. This sceptre is carried before the king at his coronation. See *fig*. 3.

The sceptre, *fig*. 4, was made by order of Queen Mary.

The ivory sceptre, *fig*. 5, with a dove on the top, was made for King James II.'s Queen; it is ornamented in gold, and the dove on the top is of gold, enamelled white.

The royal coronation rings are shown at *figs*. 6 and 7.

Fig. 8 represents the golden orb or globe, put into the king's right hand before he is crowned; and borne in his left, with the sceptre in his right, upon his return into Westminster Hall, after he is crowned. It is about six inches in diameter, edged with pearls,

nating the object by association of ideas, and conventional or arbitrary characters, are used together. Of this manner of writing we still find instances among the most civilized nations. The Germans use a †, in works where the saving of space is important, for the word *died*. This is an instance of symbolical hieroglyphics, the cross indicating *death*, either because it was generally planted upon graves, or because it called to mind the death of Him whose death is most important. In the same way they write □ *m.*, for *square miles*. This is a figurative hieroglyphic. The Atlas of Las Cases (Le Sage) is full of symbolical, figurative and conventional, or, as they should rather be called, *arbitrary hieroglyphics*. After the human mind has reached the point abovementioned in the formation of signs, it has two ways of farther progress. It may either generalise the sign, or generalise the thing signified by the sign. The first mode was adopted by the Egyptians. Thus the sign of an eagle, which, in the Coptic, that is, the Egyptian language, was called *ahòm*, was used by the Egyptians for the sound *A* in general. The other direction was taken by the Chinese, who founded their art of writing on the analogy of ideas. Thus, for instance, all the words which express manual labour or occupation are composed, in their written language, of the character which represents the word *hand*, with some other, expressive of the particular occupation intended to be designated, or of the material employed.

Plato tells us that Thoth, secretary to the Egyptian King Thamus, invented the alphabet, and Champollion has actually discovered that the Egyptians had a kind of hieroglyphic writing which was merely phonetic, that is, was composed of a series of signs not having reference to the objects represented, but merely to the sounds of the words expressed. Thus the figurative signs passed over into mere phonetic characters. This was not only the case in Egyptian writing: the names of the letters of the Hebrew alphabet lead us to suppose a similar transformation. We quote the following passage from a note of Professor Moses Stuart to his son's translation of J. G. H. Greppo's Essay on the Hieroglyphic system of M. Champollion. "One need only to read the interpretation of the names of the Hebrew alphabet successively, in order to believe that, originally, there was some analogy between the shape of the respective letters and the objects by whose names they are called. For example, beginning with the alphabet, we proceed thus: *ox, house, camel, hollow, hook, armour, travelling-scrip, serpent, hand, hollow-hand, ox-goad, water, fish, prop, eye, mouth, screech-locust, ear, head, tooth, cross*. These make out the whole original alphabet of the Hebrews; and no one can well suppose that these names rather than others were given to the letters, except on account of some resemblance between them and the objects which bore these names. That the resemblances to these respective objects are not found in the present Hebrew alphabet is no argument against the position; for all critics are agreed that the ancient Hebrew letters have exchanged their forms for those of a later alphabet," &c. So far Professor Stuart. Before we give the system of Egyptian hieroglyphics, according to Champollion's ingenious discoveries, one remark may be allowed to us.

In a certain sense of the word, the course which the Chinese have taken may be considered more philosophical than that of the invention ascribed to Thoth, the former being founded on the combination of ideas, and the latter on the mere external sounds: and yet the latter system has become, at least in our view of the matter (a Chinese, of course, would differ from us), much the more important. By about forty signs we are able to express almost every sound, and, through them, every idea in its various shades (and, with most languages, from twenty-three to twenty-seven signs are sufficient), whilst the Chinese have 10,000 characters in common use. Our system has become much the most abstract, and with this the Chinese reproach it, when they say, "That which enters the mind of a European enters through the ear" (meaning that our letters represent sounds), "while what enters the mind of a Chinese enters through the eye;" and the learned Remusat mentions the lively effect of the Chinese picture-writing, in comparison to that of our conventional signs. Suppose the Chinese to designate the word *tyrant* by a sign which their well-executed writing should show to be derived from a tiger: the ferocity of the man would at once be pourtrayed by the habits of the animal. But the difference, in common cases, is not probably so great as at first appears. In general, if we read a book, the signs do not suggest to us the sounds which they represent, and then the idea (though this is the case with children and illiterate people, who are accustomed to read aloud, or, at least, moving the lips, a proof that, to them, the characters actually represent the sounds), but, from habit, the word suggests an idea. If we read, for instance, a word like *loveliness*, the idea which it represents is not produced within us by the slow process that the characters for *love* reminds us of the sound *love*, and then of the idea, next *li* of *like*, and, at last, *ness* of the sound and the general meaning of this syllable, and then the whole word of the sound *loveliness*, and the idea which this sound is intended to convey; but the whole word presents itself as one sign to the eye, and suggests, at once, the idea of *loveliness*. Now, generally speaking, there is probably the same process in the mind of a Chinese in common cases. He sees the sign, and it produces, at once, the idea. We may remark, too, as an advantage of our mode of writing, that the etymology of a word frequently has a wonderful effect on us, particularly in original languages, as Greek or German, and, to a certain extent, in derivative languages, as Italian and English. With these reservations, we may allow that, in certain cases, the Chinese writing may have a much superior effect upon the mind, by presenting a visible image of the thing signified, since impressions received by the eye are almost always much more lively than those conveyed by sounds. A play, read in a room, does not excite our sorrow or our mirth so much as if we see it represented, and a hundred things may well be said or written, which would be considered highly improper or disgusting if painted or drawn. This explains what Champollion says of the remarkable effect which hieroglyphics have on one who understands them, because they include both symbolic and phonetic characters.

We may now give a survey of the hieroglyphic system. The characters used by the ancient Egyptians, before their conversion to Christianity (after which they adopted the Greek alphabet, with a few supplementary letters), were threefold: 1. hieroglyphic; 2. hieratic; 3. demotic. The first were

composed of images of visible objects; the second, of rude and indistinct outlines of the whole, or of parts of such images; and the third, of a still farther reduction of such outlines in a similar manner. The first kind, from which the others were derived, was originally a real picture-writing, representing ideas by their visible images when possible, or by obvious symbols when any direct representation was impossible. This mode of writing is only suited for a nation in the first stages of civilization, and man would soon discover some more complicated but more perfect mode of representing what is usually expressed by words,—of speaking, in short, by means of visible signs. But words are combinations of sounds, and the next step, therefore, was to devise some method of expressing sounds. As soon as such a device was adopted, any combination of sounds,—that is, any word, whether the name of a visible object or of a mere abstraction,—could be immediately represented to the eye.

The Egyptians, who were, as every day shows more clearly, the most civilized of all nations known to us at a very remote period, arrived at this point very early. They selected several common and well-known hieroglyphics, such as immediately suggested some word of frequent occurrence, and used them to express the initial sound of that word, or, as we should say, its first letter. The more simple outlines or fragments of these hieroglyphics, used in the hieratic character, would therefore have the appearance as well as perform the functions of letters; and when rounded off into the demotic, epistolographic, enchorial or running-hand, would lose all resemblance to the figures from which they were originally derived.

It is plain that these last characters might entirely supersede the use of hieroglyphics, or other symbols, from the facility with which they were formed. We shall see that they actually did so, for the ordinary purposes of life. Thus the demotic characters were, as has been now settled beyond doubt, nearly if not strictly alphabetical. The hieroglyphic character was thus rendered capable of expressing sounds, and consequently words, independently of pictured signs. These signs are, according to Champollion's great work, *Précis du Système Hiéroglyphique*, divisible into three distinct classes: 1. figurative signs, such as were the images of the things expressed; 2. symbolic; 3. phonetic, or expressive of sound. At a later period, probably, a fourth class was brought into use; that of enigmatical symbols, derived either from some very remote affinity between the object represented and the idea implied, or formed by a combination of different figures, apparently incapable of being thus united. We will mention here, in the outset, that Champollion's object, in the work above referred to, is to demonstrate the six following important points:—

1. That the phonetic-hieroglyphical alphabet can be applied with success to the legends of every epoch indiscriminately.
2. Which is, in fact, the consequence of the first statement, that this phonetic alphabet is the true key of the whole hieroglyphical system.
3. That the ancient Egyptians constantly employed this alphabet to represent the sounds of the words in their language.
4. That all hieroglyphical legends and inscriptions are composed principally of signs purely alphabetical.
5. That these alphabetical signs were of three different kinds, the demotic, hieratic, and the hieroglyphical, strictly so called; and,
6. That the principles of the graphic system which he has laid down, and which he proves by a great variety of applications and examples, are precisely those which were in use among the ancient Egyptians.

As all visible objects, with all their parts, and in almost any position, besides an endless variety of arbitrary combinations, come within the scope of the hieroglyphic draughtsman, it might, at first, be supposed that the number of the characters would be almost unlimited: but the necessity of limitation must soon have been felt; for, unless the sense assigned to each character was fixed, the reader would be lost in vague conjectures, and, unless the number of characters was confined within certain bounds, no memory could retain them all. The whole number therefore observed by M. Champollion, after more than twenty years' study, was only 864, of which perhaps some are duplicates. He arranges them in the eighteen following classes:

Celestial bodies	10
Human figures in various positions	120
Human limbs, taken separately	60
Wild quadrupeds	24
Domestic quadrupeds	10
Limbs of animals	22
Birds, either whole or in parts	50
Fishes	10
Reptiles, either whole or in parts	30
Insects	14
Vegetables, plants, flowers, and fruits	60
Buildings	24
Furniture	100
Coverings for feet and legs, head-dresses, weapons, ornaments, and sceptres	80
Tools and instruments of various sorts	150
Vases, cups, and the like	30
Geometrical figures	20
Fantastic forms	50
Total	864

The figures were arranged in columns, vertical or horizontal, and grouped together as circumstances required, so as to leave no spaces unnecessarily vacant, which of course would often have happened had they written their signs successively, as we do our letters, since the signs differ so much in shape and size. Here we must remember that the hieroglyphic writing is eminently monumental. Its special use was in inscriptions that were engraved or sculptured upon public edifices. It is also found executed in similar ways upon objects which preserve the religious or domestic usages of ancient Egypt. It is delineated in numerous manuscripts; also on the wooden coffins of the mummies, and, finally, upon harder substances, such as baked or enamelled earth, &c. Hence, both from the nature of the signs employed, and from the situations in which they were chiefly used, the hieroglyphic writing is a species of painting, and the reason of the rule just stated is therefore easy to be conceived. Beauty of appearance was never forgotten, and Champollion, in his letters from Egypt, dwells on the fine appearance of these various objects, executed with admirable exactness, and often painted with colours, which still continue very bright.

The general order in which the characters are to be perused is shown by the direction in which they are placed, as their heads are invariably turned towards the reader, or, which is the same thing, to that side of the tablet at which the inscription begins, whether it be right or left; for either was admissible in the pure hieroglyphic, though not in the demotic character. To this general rule, Champollion has met with only one exception, which occurs in a hieroglyphical MS. in the royal collection; the figures, therefore, form a sort of procession, and seem, from their relative position, to be connected with each other.

The figurative, or, as they are called, the *pure hieroglyphics*, or the images of the things signified, occur often either in an entire or an abridged but intelligible form; and some of that class were often used merely to determine the sense of the preceeding figures, just as capital letters are employed by us to distinguish proper names or words of peculiar importance. This was the more necessary among the Egyptians, as their names were all significant, and liable to be taken as such, unless accompanied by some indication of their peculiar use. The hieroglyphic of *man* or *woman*, *god* or *goddess*, was consequently subjoined, according to the sex of the person or deity named. Thus the characters expressing *Ammon mai*, when alone, signify *Beloved by Ammon;* but, when followed by that which stands for *man*, represent a proper name, which the Greek would probably have expressed by *Philammon* or *Ammonophilus:* temple, image, statue, child, asp, and monumental pillar, were, in like manner, expressed by figures, evidently representing the things meant. In the bass-reliefs at Medínet-tábu, the scribe recording a victory has a hand with ciphers, expressing 3000, placed in the hieroglyphic column over his head, plainly indicating 3000 heads of men, slain or conquered in battle. Above this is the figure of a man, followed by 1000, evidently signifying 1000 prisoners taken. The figure or outline of a boat, followed by a line signifying *n* (*of*), and the name of a god, signifies the vessel of that god, in which his image or shrine was carried on solemn occasions. *Sun, moon, star, vessel, scales, bed, bull, loaf, sistrum, fish, goose, tortoise, ox, cow, calf, haunch, antelope, bow, arrow, dish, altar, censer, flower-pot, enclosure, chapel, shrine*, &c., are among the words expressed hieroglyphically by images of the objects themselves. These hieroglyphics, therefore, are called, by Champollion, *figurative proper*.

Other terms, such as *sky* or *firmament*, and the names of the different gods, are rendered by very obvious symbols, still in some degree representing the object expressed, at least, according to the notions and dogmas of the Egyptians; the former, by the section of a ceiling, with or without stars subjoined; the latter, by an outline of the animals sacred to the deity to be represented. These are termed *figurative conventional*.

Sometimes only part of the object to be represented is painted or engraved, as the plan of a house, instead of a house itself. These hieroglyphics are called *figurative abridged*. Abstract ideas, however, could not well be expressed by images of visible objects; and metaphors, common in spoken language, when clothed in a visible form, gave birth to a second class of hieroglyphics—that of images used in a symbolical sense. These are the characters generally alluded to by the ancients, when they speak of hieroglyphics; and the circumstance that they are, from their nature, more abstruse and difficult of interpretation, was the occasion of the prevalent but mistaken notion that all the figures on the Egyptian monuments are strictly symbolical—an error which led the learned world, for so many centuries, to such extravagant and contradictory interpretations.

Almost all the figures of speech are, if we may so express it, placed before the eye by this class of hieroglyphics. "Two arms stretched up towards heaven" express the word *offering;* "a censer with some grains of incense," *adoration;* "a man throwing arrows," *tumult*. These instances, therefore, furnish examples of *synechdoches*. *Metonymies* are exhibited in "a crescent, with its horns bent down," for *month;* in "a pencil and a pallette," or "a reed and an inkstand," for *writer, writing, letter*, &c. The "bee," to signify *an obedient people;* "forequarters of a lion," for *strength;* "a hawk on the wing," for the *wind;* "an asp," for *power of life* and *death;* are so many metaphors symbolically expressed. As we are unacquainted with many of the ancient notions, prejudices, &c., and therefore with many of their associations of ideas, and with the transitions of meaning which many signs must have undergone, this class is the one which will always cause the greatest trouble to the decipherer.

An ancient Egyptian writer, Horapollo, tells us that *paternity* and the *world* were expressed by the figure of a "beetle;" *maternity* by a "vulture." Who could have ascertained the signification of these signs, if not assisted by direct information of this kind? The head of the animal sacred to a deity is often placed upon the figure of a man, to signify the deity itself. This certainly produced figures monstrous to us, but it is founded on the notion, which has prevailed among mankind from time immemorial, that some particular animal enjoyed the protection of a particular god. Even at present, in many Christian countries, certain animals are believed to be under the particular protection of certain saints; certain animals, too, are used in paintings, as symbolical accompaniments of apostles and saints.

Now the Egyptians, in writing their hieroglyphics, put the head of this animal upon the statue, instead of putting it by the side of it, as the owl is placed, by the Greeks, by the side of Minerva; thus the figure of a man, with the head of a ram, signified *Jupiter Ammon;* with the head of a hawk, the god *Phré;* with the head of a jackal, *Anubis*, and so on. The gods were also represented by leaving out altogether the figure, and exhibiting only the sacred animal, with some of the divine attributes. Thus a hawk, with a circle on its head, signifies *Phré;* a ram, having its horns surmounted by a feather, or, more generally, by a circle, *Cnuphis*, &c. Lastly, there is a kind of hieroglyphics for the Egyptian gods which we may call either *symbolic or enigmatical;* such as an *eye* for *Osiris;* an *obelisk* for *Jupiter Ammon;* a *nilometer* for the god *Phtha*. Spineto (see lecture iv. of his valuable *Lectures on the Elements of Hieroglyphics*, &c., London, 1829) ascribes these hieroglyphical representations of the deities to the sacred dread which all Oriental nations, and even, in some degree, the Greeks and Romans, had of pronouncing the names of the gods. "And although we find," he says, "these mystic names expressed phonetically in the hieroglyphical legends, yet we are to remember that the characters

themselves were considered as sacred, and peculiarly fitted to be employed in religious matters. This is so true that, in all documents written in the demotic or common characters of the country, the names of the gods and goddesses were invariably written symbolically; just as the Jews never wrote at full length the ineffable name of *Jehovah*, but always expressed it by a short mark, which they pronounced *Adonai*."

Champollion asserts that the Egyptians wrote the names of their principal deity, at least, in one way, and pronounced it in another. As the Egyptians were a very civilized nation, it is clear that hieroglyphics like those described (we mean the figurative and symbolical) could by no means suffice to designate their various wants, occupations, and ideas; and this want may be reasonably supposed to have led to the invention of the third class of hieroglyphics, which M. Champollion calls *phonetic*, as designating a sound. He has also discovered the principle on which these signs were chosen to express one certain sound; it is this, that the hieroglyphic of any object might be used to represent the initial sound of the name of that object.

The following table shows this more clearly: the first column gives the letter expressed by a hieroglyphic; the second, the English name of the object represented; and the third, the corresponding word in the Coptic, or rather Egyptian language.

Letter.	Hieroglyphic.	Egyptian Name.
A,	an eagle,	ahom.
—,	a piece of meat,	af *or* ab.
A, O,	a reed,	aka *or* oke.
B,	a censer,	berbe.
K,	a knee,	keli.
K,	a basin,	knikiji.
G.	———,	gnikiji.
K,	a cup,	klaft.
T, Th,	a beetle,	torres. thorres.
L,	a lion,	laboi.
M,	an owl,	moulaj.
—,	water,	môou.
N,	inundation,	neph.
—,	vulture,	noure.
P, Ph,	mát,	prêsh. phrêsh.
R,	mouth,	rô.
—,	tear	rimé.
—,	pomegranate,	roman.
S,	star,	sion.
—,	child,	si.
—,	egg	soouhi.
T,	hand,	tot.
—,	wing,	ten-h.
SH,	garden,	shnê.
—,	antelope,	shash.
J,	swallow,	jal.
Kh,	fan,	khai.

This principle being admitted, it follows that the number of phonetic hieroglyphics might be increased almost without limit, as the names of a great many different objects might have the same initial sound.

The whole number of elementary sounds intended to be represented was twenty-nine, which is certainly very great for so early an alphabet—a circumstance which deserves still more attention, if we consider that phonetic hieroglyphics were in use with the Egyptians from time immemorial (see *Spineto*, page 95, et seq.). The great number of hieroglyphics which the principle above-mentioned would assign to each of these sounds would have been a continual source of error. The characters, therefore, thus applied, were soon reduced to a few; and, as far as has been hitherto ascertained, eighteen or nineteen is the largest number assigned to any one letter, while few have more than five or six representatives, and several only one or two. The pronunciation of the Egyptian language was probably rapid and indistinct; besides, several dialects were spoken in different parts of the country, and thus consonants were easily interchanged, as we find to be the case at present with so many other languages. This was probably one of the reasons, or the only one, why the vowels were so often left out in the hieroglyphics; just as is the case in Hebrew.

The rule which may be considered as having generally guided, in choosing between so many signs for the same sound, was, to take that sign which seemed most appropriate to the meaning of the word which was to be written phonetically. If the name of a king was to be written, those phonetic hieroglyphics would be taken which represented things of a noble character. The goose, called *chenalopex*, we find usually representing the *S* of *Si*, the word for *son*, on account, as Horapollo says, of the attachment of this bird for its young. If we had to write the word *London* in hieroglyphics, and were to choose between the sign of the *lamb* and of the *lion*, both of which might be used for an *L*, we should certainly take the latter, on account of the heraldic relation which this animal bears to England; and, for the *N*, we might choose, among the many figures capable of representing it, that of a *fishing-net* or a *navy*, as reminding us of the sea, to which London is so much indebted; and so on. Thus the *eagle* is frequently used for *A*, in the names of Roman emperors, and the *lion* for *L*, in those of Ptolemy and Alexander. With the Chinese *hing-ching*, or phonetic signs, a similar choice takes place. This is a great addition in writing certain words, because it assists in conveying a favourable or unfavourable idea, and thereby adds to the force of the word itself. What a scope for wit would such a choice of signs afford, in the correspondence of modern fashionable society!

The Egyptians used a very great number of abbreviations in writing phonetically, of which the late Doctor Young has shown many in the registries of deeds, drawn up under the Ptolemies, and published by him. Though, as we have stated, Champollion considers the phonetic alphabet the true key to the whole hieroglyphical system, yet all the sorts of hieroglyphical characters are used together; and, had not so much already been done by the critical ingenuity of the learned, we should almost despair of ever being able to read inscriptions in which such different signs are used promiscuously; yet it is stated that Champollion has acquired much skill in deciphering these writings, so mysterious for thousands of years, and reads most of them with comparative ease. Those hieroglyphics which are called *enigmatical* may be considered a division of the symbolical. They are a more complicated and obscure kind, probably formed by the *anaglyphs* or allegorical sculptures, mentioned by Clement of Alexandria. They appear to have been bass-reliefs or tablets, containing mythological or historical subjects, expressed in allegorical delineations, or implied by the figures of human beings, with the heads of

birds and beasts, such as those with which the Egyptian temples were filled, and among which we must rank the sphinxes, forming avenues at their entrance. Symbols such as these, grouped and combined according to certain rules, might be so disposed as to form an allegorical representation of the religious and philosophical doctrines of the Egyptians.

None but the initiated were suffered to dive into these mysteries, and the key to them was kept exclusively in the hands of the priesthood. As the ordinary style of hieroglyphics must have been legible for every well-educated Egyptian, a more refined system was devised: a language more strictly ideographical was invented; metaphors, similes, imagery, and allegory were embodied in actual forms, and the links connecting the chain of ideas thus expressed were implied, by the relative position of figures, their attributes, or their ornaments, so as to present to the eye of the initiated an intelligible, and, if such an expression may be allowed, a legible picture, in what appeared to the uninitiated an incoherent tissue of extravagance. "The images of the gods in the sanctuaries, the human beings with heads of beasts, or beasts with human limbs, might be termed," says Champollion, "the *letters* of that secret writing which consisted of the anaglyphs or enigmatical sculptures, forming the fourth class of hieroglyphics." "It was in this sense, probably," he adds, "that the Egyptian priests called the ibis, the hawk, and the jackal, the images of which were carried in procession on certain solemn occasions, *letters*, as being the true elements of a sort of allegorical mode of writing."

It is in the interior of their temples and their sepulchres that these symbolical records are found "distinguishable without difficulty," says the same writer, "from the historical scenes, and civil or religious ceremonies, represented in the bass-reliefs and paintings on the walls of their public buildings." The origin and characteristics of the *hieratic* or sacred character, so denominated to distinguish it from the *demotic*, or popular, have already been briefly stated. It consists of nothing more than imperfect and dashing sketches of the hieroglyphics, which thus assumed the form of a flowing and rapid hand. For figures and symbols, it often substitutes phonetic groups, or arbitrary characters, which bear no resemblance to the hieroglyphics for which they stand. Religion and science, both fostered by the priest, seem to be the only subjects for which this character was used; nor did it undergo any material change in its form and structure, during the many ages through which it was used, resembling, in this respect, the use of a *court hand*, as it was called for centuries, in copying records and other legal proceedings in England and the continent of Europe, and the long continuance of a particular phraseology in legal instruments.

The real hieratic character resembles the Chinese, and is written with as much rapidity. One peculiarity of this character deserves notice here. In hieratic texts, the oval frame enclosing the name of kings, called *cartouche*, is expressed by a semi-circle at the beginning of the word, as might be expected; but at the end, instead of a corresponding curve followed by a straight line, expressive of the remainder of the frame, as is usually the case in the demotic character, three, four, or five dashes, either straight or slightly curved, are substituted for it.

The common Egyptian character, called *demotic* from its popular use, *epistolographic* from its fitness for letter-writing, and *enchorial* from its being peculiar to Egypt and distinct from the Greek, so familiarly known there under the Ptolemies, seems to have been derived from the hieratic by nearly the same process as the latter from the hieroglyphics. It is, however, more simple; not strictly alphabetic, because a small number of images or figures are still found in it; some few symbols, also, connected with religious subjects, occur; but these figures and symbols are almost invariably so curtailed and simplified as to lose all resemblance to the objects expressed. The whole, therefore, has the appearance of a written alphabet. The number of equivalent signs is much smaller, the whole of those which clearly differ from each other not exceeding forty-two. In the direction of the lines from right to left, and in the suppression of many vowels, this system of writing resembles that of the Phœnicians and Hebrews.

Numeration by Hieroglyphics. The units are expressed by single upright strokes, and they are always repeated to mark any number below 10. The number 10 is represented by an arch, either round or angular. The repetition of these arches produces the repetition of as many tens up to 90. A hundred is exhibited by a figure very much resembling our 9. This same figure is again repeated for every 100, for any number below 1000. One thousand is represented by a cross, over which is a figure like Ɔ. Thus, to express the numbers 2, 3, 4, 7, &c., we are to mark 2, 3, 4, or 7 upright strokes. To signify 20 or 90, we are to write 2 or 9 angular or round arches: the number 42, for instance, is expressed by 4 arches, which mean 4 times $10 = 40$, and by two upright strokes, which mean 2. To signify the ordinal numbers, we are to place at the top of each of the numbers a figure, which resembles our 8 placed horizontally (∞); thus a single upright mark, with the horizontal ∞ over it, would signify *first;* and, if this figure be changed into one like three sides of a square, then the numbers will signify the *first time*, &c. (*Spineto*, lect. ii. p. 72). This system, though much inferior to that admirable invention by which the place of the number indicates what product of 10, or 100, or 1000, &c., it is, is yet greatly superior to the Greek and Roman numeration.

HIGH WATER; that state of the tides when they have flowed to the greatest height, in which state they remain nearly stationary for about fifteen or twenty minutes, when the water begins again to ebb. The time of high water is always nearly the same in the same place at the full of the moon, and, at all other times, the time of high water depends upon the age of the moon; the rule for finding which, the age of the moon being given, is as follows, viz.: add four-fifths of the days of the moon's age, as so many hours, to the time of high water at the full of the moon, and the sum is the time of high water answering to that day, nearly.

HOLD; the whole interior cavity or belly of a ship, or all that part of her inside which is comprehended between the floor and the lower deck, throughout her length. This capacious apartment usually contains the ballast, provisions, and stores of a ship of war, and the principal part of the cargo in a merchantman; in the former, it is divided into several apartments (by bulk-heads), which are denominated according to the articles which they contain, as the

fish-room, the *spirit-room*, the *magazine*, the *bread-room*, &c.

The *after-hold* is that which lies abaft the main-mast, and is usually set apart for the stowage of the provisions in ships of war.

The *fore-hold* denotes that part of the hold which is situated in the fore part of the ship, or about the fore hatchway. It is usually in continuation with the main-hold, and serves the same purposes.

The *main-hold* is that part which is just before the main-mast, and which generally contains the fresh water and beer, for the use of the ship's company.

Hollow Square, in the *military art;* a body of foot soldiers drawn up with an empty space in the middle.

Holly is a wood much employed in manufactures. It is very hard, susceptible of a fine polish, and more capable of receiving a black colour than any other: it is used principally for veneering; the black lines with which cabinet work is frequently ornamented are formed of this wood, dyed with sulphate of iron. It is a good wood for turning the cogs of wheels, and for the pulleys of machinery; but for the latter purpose lignum vitæ is preferable.. The European holly is very similar to the American in size, appearance, and the qualities of the wood.

Home-sickness, in medicine *nostalgia*. The natural feeling of grief at a separation from the paternal home and native soil becomes, in men of great sensibility, who go to a different climate (especially from a mountainous to a champaign country), and are surrounded by different scenery, without active occupation, a real disease. It shows itself by a deep melancholy, under which the whole nervous system in a short time suffers. The miud of the patient is filled with thoughts of his country, and with associations which serve to recal it. The desire of seeing it, and despair of gratifying the desire, engross him. As the disease of the nerves increases, spasms come on. The respiration of the individual becomes difficult, interrupted, and consists almost wholly of sighs. His appetite is lost. A deadly paleness extends over all his countenance, and his sight grows dim and weak. His heart beats immoderately, and throbs with the slightest motion. His secretions become irregular; sleep flies from him, or consists principally of dreams, which are filled with the scenes he has left. Sudden death sometimes puts an end to this situation; but more commonly a slow, nervous, and hectic fever ensues, which carries off the individual, if it is impossible to overcome the disease. A return to his home is the most effectual remedy. The confidence that this will happen has cured many. But, when this is impossible, agreeable occupation is a better remedy than medicine. It is a curious fact that those who inhabit mountain districts are much more susceptible of this home-sickness than those born in savannahs or level ground. The love of country exhibited by the Swiss mountaineer has become proverbial.

Homœopathy; the name of a system of medicine, introduced by Samuel Hahneman, and which, for about twenty years, has attracted much attention in Germany, and, of late, in other countries also. The name expresses the essential character of the new system, which consists in this—that such remedies should be employed against any disease as, in a healthy person, would produce a similar, but not precisely the same disease. The fundamental principle of this system is, therefore, *similia similibus curantur*. To find such medicines against any given disease, experiments are made on healthy persons, in order to determine the effect on them. In the conviction that every disease carries with it a great susceptibility for the proper medicine, and that the power of medicine increases by minute division, the homœopathist gives but one drug at a time, and does not administer another dose, or a new medicine, until the former has taken effect. At the same time, a strict diet is prescribed, that the operation of the medicine may not be disturbed. Homœopathy directs the attention chiefly to the symptoms of the disease, which are followed up and observed with much greater accuracy than formerly. Disease is considered by it as only an aggregate of symptoms; and therefore the business of the physician is to extinguish the symptoms. The disciples of this system care little about the customary names and divisions of diseases; they regard only the particular pains and debilities of which the varieties of sickness are composed. The proximate causes of diseases, therefore, are little regarded, though the more remote causes are studied, at least in relation to diet.

Every disease is considered as requiring a specific remedy. Homœopathy is thus placed in opposition to the Hippocratic system, which has existed, under various forms, for twenty-two centuries; and it has been exposed to numerous attacks on this account. We will mention some of the points in dispute. Homœopathy objects to the Hippocratic system, that it acts on the maxim *contraria contrariis curantur*, and therefore effects merely a palliative cure. This reproach is unjust, because the judicious physician endeavours to restore the diseased organs by the influence of the healthy organs, and the merest empiric alone attempts to cure by absolute *contraries*. The Hippocratic medicine does not even reject the homœopathic principle, as the treatment of nervous diseases proves. Secondly, the homœopathists accuse their opponents of directing their efforts against what cannot be known, the proximate cause of the disease; while, in turn, the homœopathist may be reproached with attaching himself merely to the superficial external appearance of the disease, and with a pedantic minuteness in regard to those symptoms which disease assumes in a given case. Thirdly, the homœopathist accuses the others of administering remedies of which they do not know the effects; to which it may be replied that the effect of a medicine becomes perfectly known only through a patient, never by a healthy person. Fourthly, the minuteness of the dose prescribed by the homœopathists is objected to by other physicians, who, however, should not forget that they constantly order a solution of one grain of tartar-emetic in eight ounces of water. The injudicious mixture of medicines has become less common than formerly among the Hippocratic physicians. The Hippocratic school cannot reconcile itself to the idea that all classification of diseases under generic names is, in itself, without meaning, and that the course of acute diseases, the doctrine of the crisis, &c. (the basis of the Hippocratic medicine), is imaginary, since it rests on a faithful observation of nature. The old system, therefore, reproaches homœopathy not only with not knowing, but with disdaining to know the nature of diseases. Since the knowledge of the nature and the course of diseases is the indisputable basis of the Hippocratic medicine, a great revolution in medicine

is not to be expected from homœopathy. If its principles should prove true, it will result in a knowledge of specific means of cure, and thus make a valuable addition to medicine, as other systems have done.

Hone; a species of whetstone, employed for sharpening cutlery. This useful implement is now likely to be superseded by a metallic cylinder, invented by Mr. Knight, President of the Horticultural Society. It is highly spoken of as perfectly effective and much more convenient than an oil-stone, answering all the purposes of a hone, and rendering a strop unnecessary.

This instrument is a cylindrical rod of steel, about a quarter of an inch thick, and five inches long. It is rendered perfectly smooth in the first instance, while in its soft state, and is then worked into extremely fine longitudinal lines, by means of fine emery or glass-paper, previous to the steel being hardened. It has a silver or plated knob at the top-end, by which it is to be held when in use; and, when out of use, it is slipped into a cylindrical sheath, as a guard to its surface.

In using this instrument for sharpening the finer kinds of cutlery, such as razors, its surface is to be first moistened with a small quantity of sweet oil, and a little rotten-stone, or rouge, or indeed any kind of extremely fine grit, is to be powdered upon it. The razor, being then held perfectly flat upon the surface of the cylinder, is to be worked about in the same way as on a hone; and, if it has not been previously rounded by careless setting, the fine lines and the powder upon the steel will very soon bring it to a beautiful smooth cutting edge.

Honey; a valuable product, very similar in its properties to sugar. It is found, in large quantities, in a number of vegetables, is collected by the bee, and is fed upon by many insects. It is always formed in the flower, chiefly at the base of the pistil, and seems designed to receive and retain the fecundating pollen. Honey differs much in colour and in consistence; it contains much saccharine matter, and probably some mucilage, from which it derives its softness and viscosity. It very readily enters into the vinous fermentation, and yields a strong liquor called *mead.* There are two species of honey; the one is yellow, transparent, and of the consistence of turpentine; the other white, and capable of assuming a solid form, and of concreting into regular spheres. These two species are often united; they may be separated by means of alcohol, which dissolves the liquid honey much more readily than the solid.

Honey has never been accurately analyzed, but some late experiments go to prove it to be composed of sugar, mucilage, and an acid. The honey made in mountainous countries is more highly flavoured than that of low grounds; that which is made in the spring is more esteemed than that gathered in the summer; and that of the summer more than that of the autumn: there is also a preference given to that of young swarms. Yellow honey is obtained, by pressure, from all sorts of honey-combs, old as well as new, and even from those whence the virgin honey has been extracted. The combs are broken, and heated, with a little water, in basins or pots, being kept constantly stirring; they are then put into bags of thin linen cloth, and these into a press, to squeeze out the honey. The wax stays behind in the bag, excepting some particles which pass through with the honey.

Honey is the production of most countries; it is, however, more abundant in the island of Candia, and in the greater part of the islands of the Archipelago, than any where else. The Sicilian honey seems to be particularly high-flavoured, and, in some parts of the island, even to surpass that of Minorca, which no doubt is owing to the quantity of aromatic plants with which that country is overspread. This honey is gathered three times in the year, in July, August, and October. It is found, by the peasants, in the hollows of trees and rocks. The country of the lesser Hybla is still, as formerly, the part of the island that is most celebrated for this article. Considerable quantities of honey are produced by the wild bees in the woods of North America. Honey is used in preserves and confectionery, and, in its pure state, to put upon bread; also as a demulcent medicine against hoarseness, catarrhs, &c., and externally, as a softening application, to promote suppuration. In its clarified state, it is used to sweeten certain medicines. It is more aperient and detergent than sugar, and is particularly serviceable in promoting expectoration in disorders of the breast, and as an ingredient in cooling and detergent gargles. For these, and other similar purposes, it is sometimes mixed with vinegar, in the proportion of two pounds of clarified honey to one pint of the acetic acid, boiled down to a proper consistence over a slow fire, and thus forms the oxymel simple of the shops. It is also impregnated with the virtues of different vegetables, by boiling it in the same manner, with their juice or infusions, till the watery parts have exhaled. It is the basis of several compositions in pharmacy, though in this way it is less used than formerly. When collected from poisonous plants, as *rhododendron, ponticum,* &c., it partakes of the qualities of the plants. The inferior qualities of honey, and what remains when it is purified, can be used in the preparation of brandy, vinegar, or any other fermented liquor.

Honey, as may be easily imagined, was one of the first articles of human nourishment. The gods of Greece were supposed to live on milk and honey (ambrosia). Aristotle, Celsus, Pliny, Ælian, and probably the ancients in general, did not know where honey originally came from; they thought it was a dew which fell from heaven. Pliny does not decide whether it issued from the heavens in general or from the stars, or was a juice produced by the purification of the air, and which, afterwards, was collected by the bees. The juice of the flowers, they believed, produced only the wax. Hence we find the honey flowing from the trees in great abundance, in the descriptions which the poets give of the golden age. In the Bible, we find mention made of bees'-honey, grape-honey (must, boiled to a syrup, and still used), and tree honey, which is found upon the leaves of certain trees and shrubs, having been thrown out by certain insects. In all the works on agriculture left by the ancients, we find much importance attached to honey and the care of bees. The ancients also ascribed medicinal powers to honey.

Honey-comb; a waxen structure, full of cells, framed by the bees to deposit their honey and eggs in. The construction of the honey-comb seems one of the most surprising works of the insect kingdom. The wax is secreted, by the peculiar organisation of the insect, in the form of small and thin oval scales, in the incisures or folds of the abdomen. The regular structure of the comb is also equally wonderful.

The comb is composed of a number of cells, most of them exactly hexagonal, constructed with geometrical accuracy, and arranged in two layers, placed end to end, the openings of the different layers being in opposite directions. The comb is placed vertically; the cells, therefore, are horizontal. The distance of the different cakes of comb from each other is sufficient for two bees to pass readily between them, and they are here and there pierced with passages, affording a communication between all parts of the hive. The construction of the cells is such as to afford the greatest possible number in a given space, with the least possible expenditure of material. The base of each cell is composed of three rhomboidal pieces, placed so as to form a pyramidal concavity. Thus the base of a cell on one side of the comb is composed of part of the bases of three on the other. The angles of the base are found, by the most accurate geometrical calculation, to be those by which the least possible expense was required to produce a given degree of strength. The sides of the cells are all much thinner than the finest paper; and yet they are so strengthened by their disposition, that they are able to resist all the motions of the bee within them.

HONG MERCHANTS; a body of from eight to twelve Chinese merchants at Canton, who alone have the privilege of trading with Europeans, and are responsible for the conduct of the Europeans with whom they deal.

HOOPING-COUGH; a disease known by a convulsive, strangulating cough, with hooping, returning by fits, which are usually terminated by a vomiting. It is contagious. Children are most commonly the subjects of this disease, and it seems to depend on a specific contagion, which affects them but once in their life. The disease being once produced, the fits of coughing are often repeated without any evident cause; but, in many cases, the contagion may be considered as only giving the predisposition, and the frequency of the fits may depend upon various exciting causes, such as violent exercise, a full meal, the having taken food of difficult digestion, and irritation of the lungs by dust, smoke, or disagreeable odours. Emotions of the mind may likewise prove an exciting cause. Its proximate or immediate cause seems to be a viscid matter or phlegm lodged about the bronchia, trachea, and fauces, which adheres so closely as to be expectorated with the greatest difficulty.

The hooping-cough usually comes on with a difficulty of breathing, some degree of thirst, a quick pulse, and other slight febrile symptoms, which are succeeded by a hoarseness, cough, and difficulty of expectoration. These symptoms continue, perhaps, for a fortnight or more, at the end of which time the disease puts on its peculiar and characteristic form, and is now evident, as the cough becomes convulsive, and is attended with a sound, which has been called a *hoop*. The coughing continues till either a quantity of mucus is thrown up from the lungs, or the contents of the stomach are evacuated by vomiting. On the first coming on of the disease, there is little or no expectoration; or, if any, it consists only of thin mucus; and, as long as this is the case, the fits of coughing are frequent and of considerable duration; but, on the expectoration becoming free and copious, the fits of coughing are less frequent, as well as of shorter duration. The disease, having arrived at its height, usually continues for some weeks longer, and at length goes off gradually. In some cases, it is however, protracted for several months, or even a year. It is seldom fatal, except to very young children, who are always likely to suffer more from it than those of a more advanced age. The danger seems, indeed, always to be in proportion to the youth of the person, and the degree of fever and difficulty of breathing which accompanies the disease, as likewise the state of debility which prevails.

HOPS. The mode of cultivating this plant will be found in our division devoted to NATURAL HISTORY. The fruit is a sort of cone, composed of membranous scales, each of which envelopes a single seed. These cones are the object for which it is so extensively cultivated, and their principal use is to communicate to beer its strength and their agreeably aromatic bitter. The young shoots, however, are sometimes boiled and eaten like asparagus; the fibres of the old stems make good cords; and it is, besides, employed in medicine as a tonic, sudorific, and sedative. The cultivation of the hop is more carefully attended to in England than in any other country. A light and somewhat substantial soil should be selected. The time of planting is in the autumn, and that of harvesting about six weeks or two months after the flowers are expanded; if the fruit is suffered to get too ripe, it loses many of its good qualities. Other low plants may be cultivated in the intervals between the hop-poles. The hops, on being gathered, should be taken immediately to the kiln for drying, and afterwards packed in bags, the closer the better will they preserve their smell and flavour. The whole process, from the time of planting to the preparation for the purposes of commerce, requires much experience and many precautions. The crops are excessively variable, often in a ten-fold proportion in different seasons and situations. The excellence of hops is tested by the clammy feeling of the powder contained in the cones.

HORARY, or HOUR CIRCLE OF A GLOBE, is a small brazen circle, fixed upon the brazen meridian, divided into twenty-four hours, having an index movable round the axis of the globe, which, upon turning the globe 15°, will show what places have the sun an hour before or after us.

Horary Circles or Lines, in dialling, are the lines or circles which mark the hour on sun-dials.

Horary Motion of the Earth; the arch it describes in the space of an hour, which is nearly 15°, though not accurately so, as the earth moves with different velocities.

HORIZON; the line that seems to link the land or sea and sky, and it is either *rational* or *sensible*. The *rational, true*, or *astronomical* horizon, which is also called simply and absolutely *the horizon*, is a great circle, whose plane passes through the centre of the earth, and whose poles are the zenith and nadir. It divides the sphere into two equal parts or hemispheres. The *sensible, visible*, or *apparent* horizon is a lesser circle of the sphere, which divides the visible part of the sphere from the invisible. Its poles are likewise the zenith and nadir; and, consequently, the sensible horizon is parallel to the rational, and it is cut at right angles, and into two equal parts, by the vertical. These two horizons, though distant from each other by the semi-diameter of the earth, will appear to coincide when continued to the sphere of the fixed stars, because the earth, compared with this sphere, is but a point. The sensible horizon is divided into eastern and western. The

eastern horizon is that part of the horizon wherein the heavenly bodies rise. The *western* horizon is that wherein the stars set. By *sensible horizon* is also frequently meant a circle which determines the segment of the surface of the earth, over which the eye can reach, called also the *physical horizon*. In this sense we say, "a *spacious horizon*, a *narrow, scanty horizon*." It is manifest that the higher the spectator is raised above the earth the farther this visible horizon will extend. On account of the refraction of the atmosphere, distant objects on the horizon appear higher than they really are, or appear less depressed below the true horizon, and may be seen at a greater distance, especially on the sea. Legendre says that, from several experiments, he is induced to allow for refraction a fourteenth part of the distance of the place observed, expressed in degrees and minutes of a great circle. Thus, if the distance be 14,000 toises, the refraction will be 1000 toises, equal to the fifty-seventh part of a degree, or 1′ 3″.

Horizon of a Globe; the broad, wooden, circular ring on which the globe is fixed. On this are several concentric circles, which contain the months and days of the year, the corresponding signs and degrees of the ecliptic, and the thirty-two points of the compass.

Horn, in *physiology;* a tough, flexible, semi-transparent substance. The hollow horns of the ox, goat, &c., the hoof, the horny claw and nail, and the scale of certain animals, as the shell of the tortoise, resemble each other in chemical characters; but they differ very widely from stag's horn, ivory, &c. Horn is distinguished from bone in being softened very completely by heat, either applied immediately or through the medium of water, so as to be readily bent to any shape, and to adhere to other pieces of horn in the same state. It contains but a small portion of gelatine, and in this it differs from bone, which contains a great deal.

Horn consists chiefly of condensed albumen, combined with a small and varying portion of gelatine, with a small part of phosphate of line. The fixed alkalies readily and totally dissolve horn into a yellow saponaceous liquor. With some animals, the horn is an instrument of defence; with others, not. In some species of animals, the males only have horns; as, for instance, the stag. Female sheep seldom have horns. The female goats have horns, but they are always smaller than those of the male. In cattle, the horn is particularly developed. The bull generally has a shorter, denser, firmer horn than the cow. There are, however, hornless cattle. In the case of most horned animals, the horns are not entirely developed until they have become capable of continuing their species.

Horns admit of being divided into at least four kinds: 1. those of the rhinoceros; 2. of the ox, antelope, goat, and sheep; 3. of the camelopard or giraffe; 4. of the deer kind. The horns of the rhinoceros are composed entirely of a horny substance. They are situated not upon the *os frontis*, but on the nasal bones, and are attached to the skull only at the surface of their basis. They appear to be composed of a number of fibres, resembling strong hairs, consolidated together. They are not deciduous, but increase from the root or base in proportion as they wear. Those of the second sort are most common. They belong to many of the ruminating quadrupeds, and some birds have similar processes on their heads. They consist of three parts—an osseous substance, a vascular investment, and the external sheath. The bone is first formed. It appears as a knob, covered with skin, and movable on the *os frontis*. As it elongates, the skin becomes callous, and appears to wear off, when the osseous process is found to be clothed in a real case of horn. It then becomes fixed to the *os frontis* by anchylosis. The horny case grows from the roots, and the increase in each year is marked by a circular groove near the root of the horn. The third sort are the short, straight processes on the head of the camelopard, which are a porous bone, united to the *os frontis* by anchylosis, and terminating in a convex knob; the stem is covered with the skin, but the bulb on the end sustains a number of short, strong hairs, analogous to the fibres composing the horns of the rhinoceros. Those of the fourth kind are peculiar to the deer genus. They are composed entirely of bone, and are shed and reproduced annually. They first appear like two small knobs under the skin. These develope their different branches in succession, still covered with the skin, and a delicate soft hair, forming together what has been called their *velvet coat*, which is extremely vascular. When the horn is completely formed, the velvet coat becomes insensible and dry, and is rubbed off by the deer. The horns of the deer appear to be entirely analogous to the osseous parts of the horns of the other ruminant quadrupeds. The horns of the rhinoceros, and those of the deer, are the two extremes in these organs: the one wants the osseous basis, the other the horny covering. Those of the camelopard and ox exhibit examples of the intermediate structure. Instances are given of horses, cats, and particularly hares, found with horns, but they want confirmation. The human body sometimes produces horny protuberances on various parts.

The horns of animals, literally speaking, formed the most ancient drinking cups. Pindar, Æschylus, and Xenophon make mention of them as being appropriated to this purpose. Philip of Macedon is said to have made use of one. It is from this ancient usage that the general name of *horns* has been given to a species of drinking cup, as, after the actual employment of the animal substance had been discontinued, the shape remained in use. The horns of victims sacrificed to the gods were gilt, and suspended in the temples, more especially in those of Apollo and Diana. From the most remote times, the altars of the heathen divinities were likewise embellished with horns, and such as fled thither to seek an asylum embraced them. Originally the horns were doubtless symbolical of power and dignity, since they are the principal feature of gracefulness in some animals, and the only instrument of defence in others. Hence these ornaments have been frequently bestowed on pictorial representations of gods and heroes; ancient medals frequently present the figures of Serapis, of Ammon, of Bacchus, and of Isis, with these additions. The kings of Macedon were actually in the habit of wearing the horns of a ram in their casques, and the same thing is asserted of various other princes and chieftains.

There is a new patent process for manufacturing articles of horn which must not be passed over without a particular notice. The patentee, in his specification, describes the precise mode of making

rings for bell-pulls; knife and fork handles; the knobs for drawers, and knobs or pins for other articles of furniture.

In making a ring of horn, the required piece is to be first cut out of the flat horn, of its proper dimensions, and nearly in the shape of a horse-shoe; it is then pressed in a pair of dies to give its surface the desired pattern, but, previous to pressing, both the piece of horn and the dies are to he heated; the piece of horn is to be introduced between the dies, and pressed in a vice, and, when cold, the impression or pattern will be fixed upon the horn.

One particular feature, however, is to be observed in the construction of the dies for forming a ring. They are to be so made that the open ends of the horse-shoe piece of horn, after being pressed, shall have at one end a nib and at the other a recess, of a dove-tailed form, corresponding to each other; and the second operation in forming this ring of horn is to heat it, and place it in another pair of dies, which shall bring its open ends together, and cause the dove-tailed joints to be locked fast into each other, which completes the ring, and leaves no appearance of the junction..

In forming the handles of table-knives and forks, or other things which require to be made of two pieces, each of the two pieces or sides of the handle is formed in a separate pair of dies: the one piece is made with a counter-sunk groove along each side, and the other piece with corresponding leaves or projecting edges. When these two pieces are formed, by first being cut out of the flat horn, and then pressed in the dies in a heated state, for the purpose of giving the pattern, the two pieces are again heated and put together, the leaves or edges of the one piece dropping into the counter-sunk grooves of the other piece; and, being introduced between another pair of heated dies, the joints are pressed together, and the two pieces formed into one handle.

In making the knobs for drawers which have metal stems or pins to fasten them into the furniture, the face of the knob is to be first made to a die, as above described, and then the back part of the knob with a hole in it; a metal disc of plate-iron is then provided, in which the metal stem or screw-pin is fixed, and the stem being passed through the aperture in the back piece, and the two—that is, the back and front pieces of horn—put together, they are then heated and pressed in dies as above described, the edge of the back piece falling into the counter-sunk groove of the front piece; and by the heat they are perfectly cemented together.

Horn, or Bugle-Horn; a wind instrument, used chiefly in hunting, to animate the chase and call the dogs together. The hunting horn was formerly flexible, whence the old phrase to "wind a horn."

Horn, French. The French horn, or *cor de chasse*, is a wind instrument, consisting of a long tube twisted into several circular folds, and gradually increasing in diameter from the end at which it is blown to that at which the sound issues. The intervals of the natural scale of the French horn are conformable to those of the trumpet, but its pitch is an octave lower. In order to produce tones which the horn does not otherwise yield, the performer puts his hand into the horn, so as to prevent, more or less, the egress of the air. The Germans have done most for the horn, and by their inventions of valve-horns, and even machine horns, have carried this instrument to much perfection. The horn is not proper for the expression of the grand, but the tender and plaintive. Nevertheless, in Germany, some of the rifle regiments have only horn music, which sounds very finely; and a Russian horn band of more than twenty instruments have lately exhibited their peculiar powers in our own metropolis.

Hornblende, or Amphibole, is one of the most abundant and widely-diffused substances in the mineral kingdom, next to quartz, feldspar, and mica, and is very remarkable on account of the various forms and compositions of its crystals and crystalline particles, and of its exceedingly diversified colours, thus giving rise to almost numberless varieties, many of which have obtained distinct appellations. The primitive form of the species is an oblique rhombic prism of 124° 30′ and 55° 30′, in which the terminal planes are inclined to the obtuse lateral edges, under angles of 105° and 75°. The former planes are easily developed, by cleavage from its crystals and crystalline masses; but the latter have never been obtained in this way, having been inferred from calculation. See Natural History.

Horology. See Watch and Clock Making.

Horoscope; a scheme or figure of the position of the heavens at any time. The heavens were divided by astrologers, for this purpose, into twelve parts, called *houses*, to each of which was assigned its particular virtue or influence. The ascendant was that part of the heavens which was rising in the east at the moment; this is the first house, or house of life, and contained the five degrees immediately above the horizon and the twenty-five beneath it; the second was the house of riches, &c.; the seventh, or angle of the west, the house of marriage; the eighth, the house of death.

Horse Power, in *mechanics*. A horse's power of draught or carriage of course diminishes as his speed increases. The proportion which it bears, according to Professor Leslie, is as follows:—If we represent his force when moving at the rate of two miles an hour by the number 100, his force at three miles per hour will be eighty-one; at four miles, sixty-four; at five miles, forty-nine; at six miles, thirty-six; which results agree pretty nearly with the observations of Mr. Wood (*Treatise on Rail-Roads*). At his height of speed, of course, he can carry only his own weight. A horse draws to the greatest advantage when the line of draught inclines a little upwards. Desaguliers and Smeaton consider the force of one horse equal to that of five men, but writers differ on this subject. The measure of a horse's power, as the standard of the power of machinery, given by Mr. Watt, is, that he can raise a weight of 33,000 lbs. to the height of one foot in a minute. Care should be taken, when a horse draws in a mill, or an engine of any kind in which he moves in a circle, that the circle be large; for, since he pulls obliquely, and advances sideways as well as forwards, his fatigue is greater as the circle is smaller. In some paddle-boats, and machinery, horses are placed on a revolving platform, which passes backward by the pressure of their feet, as they pull forward against a fixed resistance, so that they propel the machinery without moving from their place. A horse may act within still narrower limits, if he stand on the circumference of a large vertical wheel, or on a bridge supported by endless chains, which pass round two

drums, and are otherwise supported by friction-wheels. Various other modes of applying the force of animals are practised, but most of them are attended with great loss of power, either from friction or from the unfavourable position of the animal.

HORSEMANSHIP. The earliest writer on this subject whose work has come down to us is Xenophon. He gives rules for judging of horses, dressing them, and riding. The Romans have left us no work on the manege; and though the mounted hordes who overthrew the Roman empire, and the knights of the later periods of chivalry, must have been skilled in the care and guidance of the horse, the earliest modern treatise on horsemanship was written in the 16th century, by Grisone, an Italian. "There are," says a French writer, "three principal European races, the Latin, the Teutonic, and the Sclavonic, each of which is no less characterized by its manner of riding on horseback than by its language. The Poles and Hungarians, however, who belong to the Sclavonic race, have adopted the Teutonic manner; but the three Latin nations—the French, Italians, and Spaniards—are all of the Italian school." The English, according to this very erudite division, belong to the Teutonic school; and, among "the noble and royal authors" of Walpole, the Duke of Newcastle appears as the author of two treatises, which later writers have done little more than copy or abridge. The principal matters in which the pupil is to be instructed at the manege are, to sit on horseback with firmness, ease, and gracefulness, and to guide his horse accurately in going straight forward, to the right or left, or sideways, at a walk, trot, or gallop, to halt at once, and to rein back without difficulty. In mounting, the rider approaches the horse near the left shoulder, and, grasping the reins firmly, takes a handful of the mane in his bridle-hand, puts the left foot into the stirrup, and, raising himself up, passes the right leg clear over the saddle. The reins must not be taken too short, lest it should make the horse rear, run or fall back; but they ought to be of equal length, and neither tight nor slack. The rider should be placed upright in the saddle, with the body rather back, and the head held up with ease, but without stiffness. The breast should be pushed out a little; the thighs and legs turned in without restraint, so that the fore part of the inside of the knees may press on the saddle, and the legs hang down easily and naturally, the feet being parallel to the horse's sides, neither turned in nor out, but so that the toes should be kept a little higher than the heels.

By this position, the natural weight of the thighs has a proper and sufficient pressure of itself, and the legs are in readiness to act when necessary. For this purpose, they should always be near the horse's sides, but without touching or tickling them. The body must be kept easy and firm when in motion; the left elbow should lean gently against the body, a little forward, and the hand, in general, should be of about the same height as the elbow; the right arm must be placed in symmetry with the left, only let the right hand be a little more forward or backward, as occasion may require. The left hand, which holds the reins, must be kept clear of the body, about two inches and a half forward from it, and immediately above the pommel of the saddle; the nails should be turned towards the buttons of the waistcoat, and the wrist a little rounded with ease, the joint being kept easy and pliable, yielding and taking occasionally, as necessary.

A firm and well-balanced position of the body is of the utmost consequence, as it affects the horse in every motion. The body must always go along with the horse, and the leaning, therefore, should be towards that side to which he moves. It is requisite, in horsemanship, that the hand and legs should act in correspondence with each other in every thing, the latter being always subservient to the former. Upon circles, the outward leg (the one from the centre) is the only one to be used, and that only for a moment at a time, to make the horse go true, if he be false. If the horse be lazy, or in any way retain himself, both legs must be used, and pressed to his sides at the same time. In general, however, the less the legs are used the better. In reining back, the rider should be careful not to use his legs, unless the horse backs his shoulders, in which case they must both be applied gently, at the same time, and correspond with the hand. If the horse refuse to back at all, the legs must be gently approached, until he lift up a leg as if to go forward, when the rein of the same side with the lifted leg will easily bring him backward. If he attempt to rear, the legs must be instantly removed and the reins slackened.

HORTICULTURE includes, in its most extensive signification, the cultivation of esculent vegetables, fruits, and ornamental plants, and the formation and management of rural scenery for the purposes of utility and embellishment. The classification of the vegetable kingdom, as well as the description and particular treatment of plants individually, belongs to another division of this work; we shall, therefore, in the present article, apply ourselves to the history of *horticulture* only as it is connected with general science. The earliest effort of man to emerge from a state of barbarism was directed to the tillage of the earth: the first seed which he planted was the first act of civilization, and gardening was the first step in the career of refinement; but still it is an art in which he last reaches perfection.

When the savage exchanges the wild and wandering life of a warrior and hunter for the confined and peaceful pursuits of a planter, the harvests, herds, and flocks, take the place of the simple garden. The mechanic arts are next developed; then commerce commences, and manufactures soon succeed. As wealth increases, ambition manifests itself in the splendour of apparel, of mansions, equipages, and entertainments. Science, literature, and the fine arts are unfolded, and a high degree of civilization is attained. It is not until all this has taken place that horticulture is cultivated as one of the ornamental arts. Egypt, the cradle of civilization, so far perfected her tillage that the banks of the Nile were adorned by a succession of luxuriant plantations, from the cataract of Syene to the shores of the Delta; but it was when Thebes, with its hundred brazen gates, and the cities of Memphis and Heliopolis, were rising in magnificence, and her stupendous pyramids, obelisks, and temples, became the wonders of the world.

The hills and plains of Palestine were celebrated for beautiful gardens; but it was not until the walls and temple of Jerusalem announced the power and intelligence of the Israelites, and the prophets had rebuked their luxury and extravagance. The queen of the East "had heard of the fame of Solomon;" his fleets had brought him the gold of Ophir, and the

treasures of Asia and Africa; the kings of Tyre and Arabia were his tributaries, and princes his merchants, when he "made orchards," "delighted to dwell in gardens," and planted the "vineyard of Baalhaman." The Assyrians had peopled the borders of the Tigris and Euphrates, from the Persian Gulf to the mountainous regions of Ararat, and their monarchs had founded Nineveh and Babylon, before we hear of the gardens of Semiramis. The Persian empire had extended from the Indus to the Archipelago, when the paradise of Sardis excited the astonishment of a Spartan general, and Cyrus mustered the Grecian auxiliaries in the spacious garden of Celænæ. The Greeks had repulsed the invasions of Darius and Xerxes, and Athens had reached the height of her glory, when Cimon established the Academus, and presented it to his fellow citizens as a public garden. Numerous others were soon planted, and decorated with temples, porticoes, altars, statues, and triumphal monuments; but this was during the polished age of Pericles, when Socrates and Plato taught philosophy in the sacred groves—when the theatre was thronged to listen to the poetry of Euripides and Aristophanes—when the genius of Phidias was displayed in rearing the Parthenon and sculpturing the statues of the gods—when eloquence and painting had reached perfection, and history was illustrated by Herodotus, Thucydides, and Xenophon. Rome had subjugated the world, and emulated Athens in literature, science, and the arts, when the superb villas of Sallust, Crassus, Pompey, Cæsar, Mæcenas, and Agrippina were erected, and the palaces of the emperors were environed by magnificent gardens.

The history of modern nations presents similar results. Horticulture long lingered in the rear of other pursuits. Most of the common fruits, flowers, and vegetables which had been collected by the Greeks and Romans, from Egypt, Asia, and other distant climes, were successively extended over Western Europe; but so gradual was their progress, after the dark ages, that, till the reign of Henry VIII., scarcely any kitchen vegetables were cultivated in England, and the small quantity consumed was imported from Holland. Fuller observes that "gardening was first brought into England for profit, about the commencement of the seventeenth century. Peaches, nectarines, apricots, plums, pears, cherries, strawberries, melons, and grapes, were luxuries but little enjoyed before the time of Charles II., who introduced French gardening at Hampton Court, Carlton, and Marlborough, and built the first hot and ice houses. At this period Evelyn translated the *Complete Gardener*, and a treatise on orange trees, by Quintinyne; and, having devoted the remainder of his life to the cultivation of his rural seat at Sayes Court, near Deptford, and the publication of his *Sylva*, *Terra*, *Pomona*, and *Acetaria*, he "first taught gardening to speak proper English." In the Netherlands, France, Germany, and Italy, a formal and very imperfect system of gardening was practised, with considerable success; but it was generally in a languishing condition throughout the world, until the commencement of the eighteenth century, when it attracted the attention of some of the first characters of Great Britain; but the establishment of the present improved style of horticulture is of very recent date. "Bacon was the prophet, Milton the herald, and Addison, Pope, and Kent the champions of true taste." The principles which were developed in their writings, and those of Shenstone, the Masons, and Wheatly, were successfully applied by Bridgeman, Wright, Brown, and Eames; the system soon became popular, and gradually extended over Europe.

But the labours of the London Horticultural Society have mainly contributed to the perfection and present high estimation of gardening. That noble institution has given an impetus to cultivation, which is felt in the remotest countries. Its example has been followed in the most flourishing kingdoms of the eastern continent, and many similar institutions have been founded in the United States of America. The effect of these is to diffuse through every country the knowledge and products of all. The history, literature, and science of gardening, open a wide field for study and inquiry. The pleasure which gardens afforded men, even in the earliest times, appears from the scriptural account of the garden of Eden. The garden of Gethsemane, and that of the good and just Arimathean, are memorable in the sacred history of the Messiah. The Elysian fields were the heaven of classic mythology, and the devout Mussulman hopes to renew his existence in a celestial garden. The bards, scholars, and philosophers of the classic ages, have transmitted descriptions of the gardens of the ancients, from those in which Homer places the palace of Alcinous and the cottage of Laertes, to the splendid villas of Pliny and Lucullus. Among the ancient Greek writers, Hesiod, Theophrastus, Xenophon, and Ælian treated of gardens to a certain extent; and the works of those who wrote after the seat of government was removed to Constantinople were collected under the title of *Geoponica*, and have been translated by Owen. Among the Latins, Varro was the first author, to whom succeeded Cato, Pliny the Elder, Columella, and Palladius. Passages are to be found relative to the subject in Martial, Virgil, and Horace; but Pliny's *Natural History*, and Columella's book on gardens, contain the most correct information on Roman horticulture.

Literature and the arts having revived in Italy, that country was the first to produce books on agriculture and gardening, and that of Crescenzia became celebrated. The field and garden cultures of Italy are so nearly allied, and horticulture and agriculture have been so blended by the writers, that is difficult to ascertain under which department to include their works. The best for general information on the tillage of that delightful region is the *Annali dell' Agricoltura*. The Germans, as in all the branches of letters, science, and arts, have an immense number of books in the department of gardening, especially on the subject of planting and forest trees. The Dutch excel more in the practice than the literature of gardening. The Journal of a *Horticultural Tour* in Holland and Flanders, by a deputation of the Caledonian Horticultural Society, gives the most satisfactory account of gardening in that part of the continent, in 1817. The *Transactions* of the Stockholm and Upsal academies furnish the chief information which is to be obtained in relation to the rural economy of Sweden. The first author was Rudbeck, who was a contemporary of Commelin.

Russia and Poland have produced but very few original books on horticulture. The *Agricultural Transactions*, occasionally published by a society in Warsaw, with those of the Economical Society of St. Petersburg, may be considered as affording the most accurate intelligence as to the culture of those countries. In the latter city is an extensive imperial

botanical garden, which, being under the direction of able professors, emulates those of the more favoured portions of southern Europe. The only recorded information on the subject of Spanish tillage will be found in the *Transactions* of the Royal Agricultural Society of Madrid. The horticultural literature of France is of an early date, and the authors are not only numerous, but many of them in the highest repute. Etienne and Belon were the pioneers, while Du Hamel, Girardin, D'Argenville, Rosier, Tessier, Calvel, Noisette, Du Petit Thours, Jean and Gabriel Thouin, Bosc, and Vicomte Hericart de Thury, may be considered as among the most able of their followers, in the various branches of rural economy. For a general knowledge of French culture, the *Nouveau Cours d'Agriculture*, in thirteen volumes, published in 1810, should be consulted; but the most valuable publications on the existing mode of gardening are the *Annales de la Société d' Horticulture*, the *Annales de l'Institut Royal Horticole de Framont*, and the *Bon Jardinier*. The first English treatise on rural economy was Fitzherbert's *Book of Husbandry*, which was published in 1634. The works of Tusser, Googe, and Platt soon after appeared, and, early in the eighteenth century, the celebrated treatise of Jethro Tull excited much attention, and several new works of considerable merit were announced before 1764, when the valuable publications of Arthur Young, Marshal, and numerous other authors, spread a knowledge of cultivation, and cherished a taste for rural improvements throughout Great Britain. Thus the literature of horticulture rapidly advanced; but, as many of the most eminent writers have been named in treating of the science and art of GARDENING, it is unnecessary to mention them in this place.

The scientific relations of horticulture are numerous, and require an extensive acquaintance with the various branches of natural history and physics. Botany, mineralogy, chemistry, hydraulics, architecture, and mechanics, must furnish their several contributions, which it is the province of the artist to apply.

After the illustrious Linnæus published his *System of Nature*, botany became a popular science, and a variety of interesting elementary works awakened attention to the beauties of nature, so that a passion for experimental and ornamental planting was induced, which has been productive of great results. Mineralogy enables us to obtain an accurate knowledge of terrestrial substances, and the mode of distinguishing the divers kinds of earths which constitute a good soil; and chemistry instructs us as to the nature and properties of these various earths, having for its objects, when applied to horticulture, all those changes in the arrangements of matter which are connected with the growth and nourishment of plants, the comparative value of their produce as food, the constitution of soils, and the manner in which lands are enriched by manure, or rendered fertile by the different processes of cultivation. Inquiries of such a nature cannot but be interesting and important, both to the theoretical horticulturist and the practical gardener. To the first they are necessary in applying most of the fundamental principles on which the theory of the art depends. To the second they are useful in affording simple and easy experiments for directing his labours, and for enabling him to pursue a certain and systematic plan of improvement.

To hydraulics belong, not only the conducting and raising of water, with the construction of pumps and other engines for those purposes, but the laws which explain the nature of springs and fountains. By the principles of that science, artificial lakes, canals, and aqueducts are formed, irrigations projected, and water rendered subservient to the useful purposes of life, as well as to the embellishment of pleasure-grounds by *jets d'eau*, cascades, and streams.

Architecture, as a branch of horticulture, is of the first importance. Without its aid, it would be impossible to give that propriety and elegance to the scenery, and to produce that pleasing effect, which is the chief object of landscape gardening. Mechanics, in all its branches, is required for the purposes of horticulture. Great improvements have been effected in gardening within the last half century. During the age of Cicero, a formal kind of gardening prevailed, characterized by clipped hedges and long avenues of trees. Pliny the Younger has given an account of his villa at Laurentum, and, judging from the description, it was rather distinguished for its numerous superb edifices, extensive prospects, and the systematical arrangement of the pleasure grounds, than for the improvements and decorations of the surrounding scenery, in accordance with those principles which are derived from a close observance of the pleasing effects of nature. The rural residences of the Romans appear to have been mere places of temporary retreat; they were planted with odoriferous flowers and shrubs, and ornamented rather by the civil architect than the horticultural artist. From the establishment of the papal government to the commencement of the thirteenth century, the monks were the only class of persons who attended to ornamental gardening.

After that period, the style prevalent throughout Europe consisted in tall hedges, square parterres fantastically planted, straight walks, and rows of trees uniformly placed and pruned. In fact, but little improvement was made from the time of the emperors Vespasian and Titus until the beginning of the reign of George III. It is true, Hampton Court had been laid out by Cardinal Wolsey; Le Nôtre had planted Greenwich and St. James's Park during the reign of Charles II.; and, in that of George II., Queen Caroline had enlarged Kensington Gardens, and formed the Serpentine River; but Lord Bathurst was the first who deviated from straight lines, as applied to ornamental pieces of water, by following the natural courses of a valley. Still, what has been emphatically called the *Dutch system* universally prevailed: the shearing of yew, box, and holly into formal figures of various kinds, and the shaving of river banks into regular slopes, went on until their absurdity became contemptible, and a better and more natural taste was induced.

Verdant sculpture, regular precision in the distribution of compartments, and rectangular boundary walls, yielded to more chaste designs. Bridgeman succeeded to Loudon and Wise, and became a distinguished artist; he rejected many of the absurd notions of his predecessors, and enlarged the bounds of horticulture. Other innovators departed from the rigid rules of symmetry; but it was reserved for Kent to realize the beautiful descriptions of the poets, and carry the ideas of Milton, Pope, Addison, and Mason more extensively into execution. According to Lord Walpole, he was painter enough to taste the charms of landscape, sufficiently bold and opinionative to dare and to dictate, and born with a genius to strike out a great system from the twilight of im-

perfect essays. He leaped the fence, and saw that all nature was a garden. The great principles on which he worked were perspective, light, and shade. Groups of trees broke a too extensive lawn; evergreens and wood were opposed to the glare of the champaign, and by selecting favourite objects, and veiling deformities, he realized the compositions of the great masters in painting. Where objects were wanting to animate his horizon, his taste as an architect could immediately produce them. His buildings, his temples, his seats, were more the work of his pencil than of his science as a constructor. He bade adieu to all the stiff modes of canals, circular basins, and cascades tumbling over marble steps. Dealing in none but the true colours of nature, and seizing upon its most interesting features, a new creation was gradually presented. The living landscape was chastened or polished, not transformed.

The elegant works of Repton, the unrivalled essays of Price on the picturesque, and the valuable publications of Gilpin, Madock, Panty, Sang, and Loudon, with those of many other writers on landscape and ornamental gardening, have had an extensive influence in promoting correct ideas of natural scenery. The improved style of horticulture every where apparent in Great Britain attracted the attention of the other nations of Europe, and English gardening became the designation for all that was beautiful in that pleasing art—the synonyme of perfection in rural culture. At the period when this new system of laying out grounds was gaining converts, and began to be practically adopted, Viscount Girardin, a French military officer of high rank, travelled through England, and, on his return, he not only improved his seat at Ermenonville in conformity to that style, but published a work of great celebrity on the *Composition des Paysages sur le Terrain, ou des Moyens d'embellir la Nature près des Habitations.*

The French style of laying out gardens had been settled by Le Nôtre, during the reign of Louis XIV., and continued in repute for upwards of a century; for it appears to have been in vogue as late as 1770. The court and nation wished to be dazzled by novelty and singularity, and his long, clipped alleys, triumphal arches, richly decorated parterres—his fountains and cascades, with their grotesque and strange ornaments—his groves full of architecture and gilt trellisses—and his profusion of statues, enchanted every class of observers. His principal works were the gardens of Versailles, Meudon, St. Cloud, Sceaux, Chantilly, and the terrace of St. Germain. Gray, the poet, was struck with their splendour when filled with company, and when the water-works were in full action; but Lord Kaimes says, they would tempt one to believe that nature was below the notice of a great monarch. Le Nôtre was succeeded by Dufresny, who, differing considerably in taste from that great artist, determined on inventing a more picturesque style: but his suggestions were rarely carried into full execution. He, however, constructed, in a manner superior to his predecessor, the gardens of Abbé Pajot and those of Moulon and Chemin Creux.

After the peace of 1762, the English system began to pass into France, and portions of ancient gardens were destroyed, to make way for young plantations *à l'Anglaise*. Laugier was the first author who espoused the English style, and the next in order was Prevot. It was at this time that Viscount Girardin commenced his improvements at Ermenonville, and the change of the horticultural taste in France may be referred to the last quarter of the eighteenth century. The English style has gradually found its way into most civilized countries. A horticultural society was established in Paris in 1826, and has already more than two thousand members, and the number is rapidly increasing. It has been patronised by the court, and most of the nobles and men of distinction in France have eagerly united with the proprietors of estates and practical cultivators to collect and disseminate intelligence throughout that flourishing empire.

In the various provinces where horticultural societies have not been founded, those of agriculture, or of the sciences and arts, have established departments expressly devoted to that interesting pursuit; and during the year 1827 a practical and theoretical institution was founded at Fromont, by the enlightened and munificent Chevalier Soulange Bodin, for educating gardeners, and introducing improvements in every department of horticulture. The garden is divided into compartments for every variety of culture. Extensive green-houses, stoves, and orangeries have been erected, and all the other appendages furnished which are requisite for rendering the establishment effectual for instruction and experiment. The nursery of the Luxembourg long supplied a great part of Europe with fruit-trees.

The *Jardin des Plantes*, in Paris, includes compartments which may be considered as schools for horticulture, planting, agriculture, medical botany, and general economy, and is unquestionably the most scientific and best managed establishment in Europe. The flower garden of Malmaison, the botanical garden of Trianon, and numerous nursery, herb, medicinal, experimental, and botanical gardens, in various parts of the kingdom, are pre-eminent for the variety, number, and excellence of their products.

Holland has been distinguished, since the period of the crusades, for her flower-gardens, culinary vegetables, and plantations of fruit trees. The north of Europe and the United States of America are still dependent upon her florists for the most splendid varieties of bulbous-rooted plants. From St. Petersburg to the shores of the Mediterranean, horticulture has made a rapid progress, and each nation is emulous to perfect its culture, in accordance with the most improved principles of science, art, and taste. In the United States of America, a like spirit has been more recently developed.

Horticultural societies have been instituted in New York, Philadelphia, Boston, Albany, Geneva, and South Carolina, and a zealous disposition evinced to compete with the nations of the eastern continent. The environs of many of the cities are in a high state of cultivation, and the markets are beginning to be well stocked with numerous varieties of fruits and vegetables. Many of the most useful and magnificent acquisitions of the groves, fields, gardens, and conservatories of Europe are natives of the western hemisphere. The indigenous forest trees, ornamental shrubs, flowers, fruits, and edible vegetables of North America, are remarkable for their variety, size, splendour, or value. Extending from the pole to the tropics, and from the Atlantic to the Pacific, North America embraces every clime, and every variety of soil, teeming with innumerable specimens of the vegetable kingdom.

The natural divisions of horticulture are the esculent or kitchen garden, seminary, nursery, fruit-trees, and vines, flower garden, green-houses, *arboretum* of ornamental trees and shrubs, the botanical and medical garden, and landscape or picturesque gardening. Each of these departments requires to be separately studied before it can be managed so as to combine utility and comfort with ornament and recreation. To accomplish this on a large scale, artists, scientific professors, and intelligent and experienced practical superintendents, are employed in Europe, but they have not as yet been much required in America. The owners of the soil have generally designed and executed such improvements as have been made in the conveniences and embellishments of country residences. The kitchen garden is an indispensable appendage to every rural establishment. In its simplest form, it is the nucleus of all others: containing small compartments for the culture of esculent vegetables, fruits, and ornamental plants, these may be gradually extended, until the whole country assumes the imposing aspect of picturesque or landscape scenery.

Among the European productions on horticulture, there is no single work in the English language so valuable as Loudon's *Encyclopædia of Gardening;* but all the numerous publications of that distinguished writer, in the various branches of rural economy, are remarkable for the fund of intelligence which they contain.

HORTUS SICCUS. See NATURAL HISTORY.

HOSPITAL; a building appropriated for the reception of sick, infirm, and helpless persons, who are supported and nursed by charity; also a house for the reception of sick or insane persons, or an establishment for seamen, soldiers, foundlings, &c., who are supported by charity. Hospitals for the sick and wounded, and also those for the poor or infirm, were wholly unknown among the ancients. In Athens, those who had suffered in the public service were fed in the *prytaneum*, but there was no asylum for them in case of sickness. In Sparta, where all the citizens ate together, there was no institution for the sick. In Rome, neither Numa nor Servius, neither the consuls nor the emperors, thought of making any provision for the poor or the infirm. The first establishment of hospitals must be ascribed to Christians; some attempts had already been made by them in Rome, about the end of the fourth century. Fabiola, a pious Roman lady, established an institution for receiving poor and sick persons; and, after the establishment of Christianity, the emperors at Constantinople built many hospitals for poor infants, for aged people, for orphans, for strangers, &c. The Emperor Julian attributed the rapid progress of the Christian religion, in great part, to these charitable institutions, and proposed to imitate the example of the Christians in his attempts to restore paganism. Piety impelled many individuals to appropriate a part of their funds to religious and charitable purposes. Institutions thus formed were of great benefit to the sick poor, but soon became liable to abuses. The funds devoted to charitable purposes were alienated, and the monastic institutions with which they were connected were contaminated with looseness and extravagance.

In Catholic countries, the hospitals are generally attended by nuns, sisters of mercy, &c., of whom even Voltaire says that there is nothing nobler than the sight of delicate females sacrificing beauty, youth, often wealth and rank, to devote themselves to the relief of human miseries, under the most revolting forms. Hospitals are an honour to the nations of Europe. In less civilized countries, we find them to be frightful abodes of misery. The plague hospital at Alexandria, described by Madden, or the insane hospital at Cairo, presents a scene of horrors not inferior to Dante's description of the feverish people, one above the other, in his *Inferno*. If possible, it is best, in infirmaries, to separate certain patients. Thus, in all populous cities there should be an hospital for incurables. It is never advisable to have the insane hospital nor the lying-in hospital connected with others; still less, as is the case in many places in Europe, to connect the workhouses and the hospitals. In Paris there are thirty-two hospitals: in London about the same number. Those in France, Russia, and Turkey, are supported by government.

The name of *hôpital* is generally applied to the establishments for the sick, and that of *hospice* to those in which the aged, children, and infirm people, are received. More than 15,000 beds are made up at these different establishments, and the annual expenditure is very considerable. From 40,000 to 50,000 persons are annually accommodated in *hôpitaux*, or about 4000 at a time. The *hospices* generally contain nearly 10,000 persons at the same time. The hospitals of Paris are usually clean and in good order, for which they are indebted to the *sœurs de la charité*, who wait upon the sick, and nurse them with the greatest care. They are not always favourably situated, being often too much confined.

The *Hôtel des Invalides* is destined for military veterans, and contains 7000 men. It has a library of 20,000 volumes. The *Hôtel Dieu* is the most ancient hospital in Paris, and is situated in the most populous part of the city. Before the revolution, 5000 sick were here huddled together in 1400 beds; but several monasteries were then converted into hospitals, and lying-in women, scrofulous patients, lunatics, children, &c., who had all been crowded together, were separated, and placed in different establishments. The *Hospice de la Salpétrière* generally contains several thousand poor women, who are kept at work. In one part is a prison for prostitutes. The *Hôpital de la Charité* receives only men attacked by acute diseases; the *Hôpital St. Louis* is used as a pest-house; the *Hospice des Enfants Trouvés* is for foundlings, about 6000 of whom are annually born or received in it; the *Hospice de l'Accouchement* receives about 3000 women annually.

Among the hospitals in London and its vicinity are the Foundling Hospital; the Magdalen Hospital, for reclaiming prostitutes; the Greenwich Hospital and Naval Asylum. The Chelsea Hospital is appropriated for the reception of sick and superannuated soldiers; the number of pensioners is about 400, besides the out or extraordinary pensioners. The principal hospitals for the reception of sick persons in the metropolis are St. Thomas's, Guy's, St. Bartholomew's, St. George's, the London, the Westminster, and Middlesex. The whole of these establishments are easy of access, and noble monuments of the real Christian feeling of their founders.

Hospital Fever is a malignant form of fever, which has received this title from its being most frequently met with in places of this sort, especially in military and other large hospitals, where many men are shut

up in a small space and in close air. Under such circumstances, almost any fever will assume a more malignant character, and become more or less contagious. The causes of common hospital fever are to be found in the want of good and wholesome provisions, fatigue, care, and anxiety, and, more especially, the corruption of the air, which is always produced by many men living in even a large building, or by fewer, if shut up in a small space; and these causes are found to produce this effect not only upon the soldier, but upon the poor of all kinds and in all places.

A similar disease is developed among those confined in prisons and ships, and among the inhabitants of damp, narrow huts, and is called *gaol, ship*, or *typhus fever*. The common fever, which often prevails under the last name, has not, indeed, all the characteristics of this form of fever, although it easily assumes them. The *hospital fever* is only a high degree of that form of disease which is usually called a *putrid*, or *putrid nervous fever;* that is, a fever with diminished power and action of the whole nervous system. The contagion produced by hospital, or putrid fever, is capable of producing fever in others, although the fever so produced is often of a different character and appearance; and it should be remarked that it almost ceases to be contagious by a removal to a pure air and well-ventilated apartments.

The form assumed by the disease is much affected by the general state of the weather, and by the constitution of the individual. In strong, young, well-fed, and full-blooded persons, in whom the arterial system is full, and an inflammatory disposition much developed by stimulating drinks, or a dry, cold air, which is very favourable to inflammation, an inflammatory excitement of the whole nervous system takes place, which may even run to the height of an inflammation of the brain, with delirium, &c. In others, who have been much reduced by bad diet, and by exposure to warm, moist weather, a gastric form of fever is developed, attended also with violent nervous symptoms. If it happens to seize persons in whom the nervous and circulatory systems are much debilitated by any of the causes above named, a fever more like the true hospital fever is produced, which is termed a *typhus, putrid*, or *adynamic fever*. In truth we scarcely ever see a form of this fever which is quite unmixed, but all the forms pass into each other, with innumerable shades of accidental difference, arising from difference of the parts most affected, &c. It will therefore be at once evident that no universal mode of treatment can be laid down, but that the treatment must be varied according to the causes of the disease, the state, constitution, and previous habits of the sick, &c., and according to the changes which are constantly occurring in the course of the disease. The most important modes of guarding against the hospital fever are—to remove the causes of it, to purify the air, to improve the nourishment, allowing a generous diet, and to prevent the sick from being accumulated in great numbers in one apartment. The wards or rooms in which they are or have been collected should be purified by the vapours of strong mineral acids, which are easily obtained by mixing common salt with black oxide of manganese in a vessel of any sort, and then stirring into it a portion of oil of vitriol or sulphuric acid. But, above all, the rooms should be well ventilated, and the clothes of all kinds should be changed daily.

HOUR; the twenty-fourth part of a day. In many countries, the hours are counted from midnight, and twelve hours are twice reckoned. But in some parts of Italy twenty-four hours are counted, beginning with sunset, so that noon and midnight are every day at different hours. Each hour is divided into sixty minutes, these into sixty seconds, these into sixty thirds, &c. Many nations are totally unacquainted with the division of the day into twenty-four equal parts; with others, the hours of the (natural) day are longer or shorter than those of the night. (See SIDEREAL TIME.) The fixed stars complete their apparent revolution round the earth in twenty-four hours of sidereal time, and therefore pass through 360 degrees in twenty-four hours, or fifteen degrees in one hour. If we suppose two observers fifteen degrees of longitude distant from each other, one of them has the fixed star one hour of sidereal time, or the sun one hour of solar time, later in his meridian than the other. Meridians are thence called *hour-circles*, or *horary circles*, by which name they are known in dialling. A *horary angle* is that angle which any hour-circle makes with the meridian of the observer. If, for instance, it is 10 o'clock A. M. according to the sun-dial at the place of observation, and the sun is therefore two hours distant from the meridian, its hour-circle makes an angle of 30° with the meridian.

HOWITZER; a piece of ordnance which ranks midway between the cannon and mortar. It is mounted upon a carriage, and throws its grenades in a curve approaching a horizontal line (at the highest 16°). The arrangement of the chamber, and the extensive range of the piece, resemble those of the mortar. The length of the tube amounts to six times the caliber. The howitzer is used to throw grenades, case-shot, and sometimes fire-balls. Its principal object, however, is the discharge of grenades. Troops upon an open plain, who are secure from the fire of cannon, can be reached and injured by the discharge and bursting of grenades. By the same means villages and towns can be set on fire, and garrisons dislodged from their works. Howitzers are of German invention, and bore, originally, the name of *Haufenitz*, when they were loaded with old nails, broken glass, &c. From thence is derived the French *obusier*, and the English *howitzer*.

HUMORAL, in *medicine;* what has relation to the humours or fluids of the system. The humoral pathology is a medical theory which long prevailed, and attributed all diseases to irregular changes in the fluid parts of the body, without assigning any influence to the state of the solids. The opposite theory is that which refers every thing to the nervous energy resident in the solids, and considers diseases as arising from irregularities in their functions. The humoral pathology is exposed, in many ways, to the objection that it rests on hypothesis, and is very partial in its views. The views of the adherents of this theory have differed continually, with the progress of knowledge, from the days of Hippocrates and Galen, its great supporters, down to very late times. The nervous pathology is also liable to the objection of being of a partial and hypothetical character. Of late, the two systems have been blended, and both fluids and solids allowed a share in the changes of the body.

HURRICANE; a violent tempest of wind, attended with thunder and lightning, and rain or hail. Hurricanes appear to have an electric origin: at the mo-

ment that the electric spark produces a combination of oxygen and hydrogen, a sudden fall of rain or hail is thus occasioned, and a vacuum formed, into which the circumambient air rushes with great rapidity from all directions. The West Indies, the Isle of France, and the kingdoms of Siam and China, are the countries most subject to their ravages. What are called hurricanes, in the more northern latitudes, are nothing but strong whirlwinds, occasioned by the meeting of opposite currents. But, in the real hurricane, all the elements seem to have armed themselves for the destruction of human labours, and of nature herself: the velocity of the wind exceeds that of a cannon ball; corn, vines, sugar-canes, forests, houses, every thing is swept away. The hurricane of the temperate zone moves with a velocity of about sixty feet a second; those of the torrid zone, from 150 to 300 feet in the same time. They begin in various ways; sometimes a little black cloud rolls down the mountains, and suddenly unfolds itself and covers the whole horizon; at others, the storm comes on in the shape of a fiery cloud, which suddenly appears in a calm and serene sky.

Hydraulics; that branch of hydrodynamics which has for its object the investigation of the motions of liquids, the means by which they are produced, the laws by which they are regulated, and the force or effect which they exert against themselves or against solid bodies. This subject naturally divides itself into three heads: 1. the effects which take place in the natural flowing of fluids through the various ducts or channels which convey them; 2. the artificial means of producing motion in fluids, and destroying their natural equilibrium by means of pumps and various hydraulic engines and machines; and, 3. the force and power which may be derived from fluids in motion, whether that motion be produced naturally or artificially. The particles of fluids are found to flow over or amongst each other with less friction than over solid substances; and, as each particle is under the influence of gravitation, it follows that no quantity of homogeneous fluid can be in a state of rest, unless every part of its surface is on a level, that is, not a level plane, but so far convex as that every part of the surface may be equally distant from the centre of the earth. As the particles of all liquids gravitate, any vessel containing a liquid will be drawn towards the earth with a power equivalent to the weight it contains, and if the quantity of the fluid be doubled, tripled, &c., the gravitating influence will be doubled, tripled, &c. The pressure of fluids is, therefore, simply as their heights,—a circumstance of great importance in the construction of pumps and engines for raising water. As liquids gravitate independently, if a hole be made in the bottom of the vessel, the liquid will flow out, those particles directly over the hole being discharged first. Their motion causes a momentary vacuum, into which the particles tend to flow from all directions, and thus the whole mass of the water, and not merely the perpendicular column above the orifice, is set in motion. If the liquid fall perpendicularly, its descent will be accelerated in the same manner as that of falling solid bodies. When water flows in a current, as in rivers, it is in consequence of the inclination of the channel, and its motion is referable to that of solids descending an inclined plane; but, from want of cohesion among its particles, the motions are more irregular than those of solids, and involve some difficult questions. The friction between a solid and the surface on which it moves can be accurately ascertained; but this is not the case with liquids, one part of which may be moving rapidly and another slowly, while another is stationary. This is observable in rivers and pipes, where the water in the centre moves with greater rapidity than at the sides, so that a pipe does not discharge as much water in a given time, in proportion to its magnitude, as theoretical calculation would lead us to suppose. As water, in descending, follows the same laws as other falling bodies, its motion will be accelerated; in rivers, therefore, the velocity and quantity discharged at different depths would be as the square roots of those depths, did not the friction against the bottom check the rapidity of the flow. The same law applies to the spouting of water through jets or adjutages. Thus, if a hole be made in the side of a vessel of water, the water at this orifice, which before was only pressed by the simple weight of the perpendicular column above it, will be pressed by the same force as if the water were a solid body descending from the surface to the orifice; that is, as the square root of the distance of these two points; and, in the same way, water issuing from any other orifices, will run in quantities and velocities proportionate to the square root of their depths below the surface. Now, the quantity of water spouting from any hole, in a given time, must be as the velocity with which it flows: if, therefore, the hole *c*, *fig*. 5, *Plate* I., be four times as deep below the surface as a hole, *a*, it follows that *c* will discharge twice as much water in a given time as *a*, because two is the square root of four. A hole, *b*, in the centre of such a column of water will project the water to the greatest horizontal distance (or range), which will be equal to twice the length of the column of which the orifice is the centre. In like manner, two jets of water, spouting from holes at equal distances above and below the central orifice, will be thrown equal horizontal distances. The path of the spouting liquid will always be a parabola, because it is impelled by two forces, the one horizontal, and the other perpendicular.

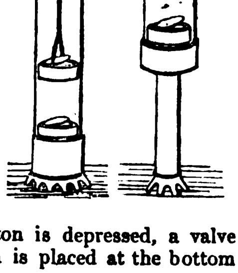
Fountains owe their operation to the weight or pressure of a column of water, and the *jet d'eau* shown at *fig*. 3 acts on this principle. The support of a ball on a simple column of water may be best understood by a reference to *fig*. 4. The ascending column of water carries with it a stream of air, represented by the arrows, which completely encloses the fluid, and the ball has a species of oscillatory balance, continually revolving round the centre of the jet.

Pipes for the conveyance of water are usually arranged on very imperfect principles. It must be obvious that fluids will flow most freely through a straight pipe; but, as there are many cases in which water must be conveyed in an angular direction, the workman should always form the pipe with as large a *sweep* or curve as possible. *Fig*. 6 shows the two forms; *a* being the best, and *b* the worst. It might, at first view, be supposed that the expansion at *c* was advantageous to the passage of the water; but, so far from this being the case, it would be considerably retarded by it, as the pipe should be as nearly straight as possible.

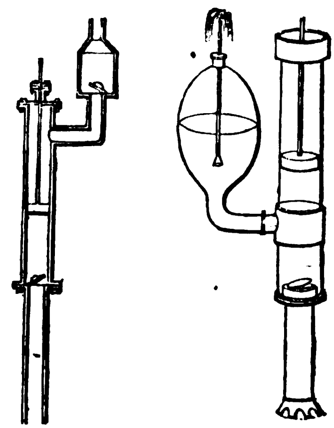
The second division of the subject, mentioned in the beginning of this article, is of the greatest practical utility, as embracing an account of the various pumps and machines which have been employed to

raise water; and, numerous as these may appear, it will be found that they may all be comprehended under four general heads: 1. those machines in which water is lifted in vessels by the application of some mechanical force to them. The earlier hydraulic machines were constructed on this principle, which is the simplest; such as the Persian wheel, consisting of upright buckets attached to the rim of a wheel, moving in a reservoir of water; the buckets are filled at bottom as they pass through the water, and emptied at top, so that the water is raised to a height equal to the diameter of the wheel. The wheel may be turned by living power, or, if in running water, by fastening float-boards to the circumference. The Archimedian screw, the bucket-engine or chain-pump, and the rope-pump of Vera, are modifications of the same principle. 2. The next class of machines are those in which the water is raised by the pressure of the atmosphere, and comprises all those machines to which the name of *pump* is more particularly applied. (See PUMP.) These act entirely by removing the pressure of the atmosphere from the surface of the water, which may thus be raised to the height of about thirty-two feet. Whenever it becomes necessary to raise water to greater heights, the third class of machines, or those which act by compression on the water, either immediately or by the intervention of condensed air, are employed. All pumps of this description are called *forcing-pumps*. Although atmospheric pressure is not necessary in the construction of forcing-pumps, it is, in most cases, resorted to for raising the water, in the first place, into the body of the pump, where the forcing action takes place. In machines of this kind, the water may be raised to any height.

In the accompanying diagram are shown two forms of the sucking-pump. This species of pump acts by the pressure of the atmosphere, and consists of a cylinder furnished with a piston made to fit air-tight. When the piston is raised, a vacuum is formed in the tube beneath, and the water raised by the pressure of the air. On depressing the piston, the water passes through a valve or trap-door placed in the centre; and on the second elevation the water is forced to the top of the pump-barrel. To prevent the water returning to the well when the piston is depressed, a valve similar to that in the piston is placed at the bottom of the pump.



The force-pump is of more general application than the one already described. It consists of a cylinder and piston as in the former case, but the latter is constructed without a valve. In the right-hand figure of the following engraving, the piston sucks the water by its upward motion, but, on depressing it, the water passes by the side-pipe and enters the air vessel. The pipe placed in the centre serves to discharge the water, and the air by its elasticity ensures a continuous flow. In the left-hand figure, the piston is pierced for a valve, which would be too small to be indicated in the engraving, and, when the water is above the piston, it is discharged by the air-vessel placed at the top, as in the former case. In this arrangement of the pump, the water may be raised to any required height.



The fourth class of hydraulic machines for raising water consists of such engines as act either by the weight of a portion of the water which they have to raise, or of any other water that can be used for such purpose, or by its centrifugal force, momentum, or other natural powers; and this class, therefore, includes some very beautiful and truly philosophical contrivances, too numerous for us to describe: the Hungarian machine, the centrifugal pump, and the water-ram, are among the number. See WATER-RAM.

The third general division of the subject relates to the means by which motion and power may be obtained from liquids, and includes the general consideration of water-wheels and other contrivances for moving machinery. Motion is generally obtained from water either by exposing obstacles to the action of its current, as in water-wheels, or by arresting its progress in movable buckets, or receptacles which retain it during a part of its descent. Water-wheels have three denominations, depending on their particular construction, on the manner in which they are set or used, and on the manner in which the water is made to act upon them; but all water-wheels consist, in common, of a hollow cylinder or drum, revolving on a central axle or spindle, from which the power to be used is communicated, while their exterior surface is covered with vanes, float-boards, or cavities, upon which the water is to act. The undershot-wheel is the oldest construction of this kind: it is merely a wheel, furnished with a series of plane surfaces, or floats, projecting from its circumference, for the purpose of receiving the impulse of the water, which is delivered under the wheel. As it acts chiefly by the momentum of the water, the positive weight of which is scarcely called into action, it is proper to be used only where there is a great supply of water always in motion. It is the cheapest of all water-wheels, and is more applicable to rivers in their natural state than any other form of the wheel; it is also useful in tide-currents, where the water sets in opposite directions at different times, because it receives the impulse equally well on either side of its floats. In the over-shot wheel, the circumference is furnished with a series of cavities or buckets, into which the water is delivered from above, and is of course more powerful.

Fig. 8, *Plate* I., exhibits a very simple mode of employing a small stream of water. *a b c* represents a ver, supporting the bucket *e*. Any small stream of ater may be allowed to flow into this bucket; and,

when it acquires a given weight, the lever is depressed, carrying with it the pump-rod at *b*. When the bucket reaches the ground, a valve is opened in the bottom, which allows the fluid to escape; the pump-rod will then preponderate; and thus, by a continuous reciprocating motion of the great beam, the pump *d* is made to raise water.

Hydrocephalus. See Dropsy.

Hydrogen; a simple body, producing water by its combination with oxygen, in allusion to which the name *hydrogen* has been applied. The most simple state in which we can procure it is in that of a gas, i. e. in union with caloric, and possibly with electricity and light. To effect this, water is employed, and one of the following arrangements is usually adopted: water, in the state of vapour, is passed over clean iron heated to redness, by adjusting a retort, half filled with this fluid, to one extremity of an iron tube containing clean iron wire, and laid across a heated furnace, the other extremity having a bent tube connected with it, and dipping under the shelf of a pneumatic cistern; the water in the retort is made to boil briskly, and the steam to come in contact with the heated iron; upon which hydrogen gas is copiously disengaged, and collected in the pneumatic apparatus. Or slips of sheet zinc, iron filings, or turnings, or small iron nails, are introduced into a small gas-bottle with a bent tube, or into a common retort, upon which sulphuric acid, diluted with five or six times its weight of water, is poured; effervescence ensues, and the escaping gas may be collected in the usual manner. One Troy ounce of zinc gives about 356 oz. measures = about 676 cubic inches; and 1 oz. of iron, 412 oz. measures = 782 cubic inches, of hydrogen gas. The hydrogen obtained in these processes is not absolutely pure. The gas evolved during the solution of iron is contaminated by a compound formed from hydrogen and the carbon contained in the iron. This compound is removed by transmitting the gas through alcohol. The gas obtained by means of zinc is more free from impurities; though the small proportion of sulphur and carbon still remaining in the zinc of commerce gives rise to the same compound as in the former case, and also to a little sulphuretted hydrogen.

The impurities in this instance are removed by passing the gas through a solution of caustic potash. Thus purified, hydrogen gas has neither taste nor odour; it is colourless, and the lightest of all ponderable matter known, its specific gravity being 0.073, that of atmospheric air being 1.000, or about thirteen times lighter than common air. This remarkable levity allows it to ascend with the greatest readiness through all liquids and gases, and is the cause of its being employed to fill balloons, which, notwithstanding the weight of the materials of which they are constructed, are sufficiently light, compared with the atmosphere, to rise to very great elevations, or until they meet with a medium whose density is such as to render them stationary.

Hydrogen gas is a powerful refractor of light, and has hitherto resisted all attempts to compress it into a liquid. It is sparingly absorbed by water, 100 cubic inches of that liquid taking up about $1\frac{1}{2}$ of the gas. It is incapable of supporting respiration; nor is it a supporter of combustion; for, when a lighted taper is passed up into an inverted glass full of hydrogen gas, it is immediately extinguished. But its most characteristic property is that of its inflammability, though, like other combustibles, it requires the aid of a supporter for enabling its combustion to take place. This is exemplified by bringing a lighted candle or taper to the mouth of a narrow jar, or wide-mouthed bottle, filled with the gas; it is immediately kindled, but only burns where it is in contact with the air, the combustion going on quietly in successive strata from the orifice to the bottom of the vessel. Mingled with oxygen gas, no action takes place so long as the compound remains cold; but, on the approach of a flame, the whole is kindled at the same instant; a flash of light passes through the mixture, followed by a violent explosion. The report is the loudest when the proportions observed in the mixture are two volumes of hydrogen and one of oxygen.

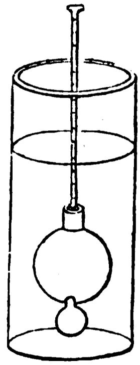
The same phenomena take place, though less strikingly, when atmospheric air is substituted for oxygen gas: in the latter case, however, the proportions are two measures of hydrogen to five or six of air. And not only is hydrogen gas inflamed when in contact with air or oxygen gas by the contact of a burning taper, but by a solid body heated to redness, and by the electric spark. If a jet of hydrogen is delivered upon recently-prepared spongy platinum (see Platinum), this metal very quickly becomes red-hot, and then sets fire to the gas. The electric spark ceases to cause detonation when the explosive mixture, formed of two measures of hydrogen to one of oxygen, is diluted with twelve times its volume of air, fourteen of oxygen, or nine of hydrogen, or when it is expanded to sixteen times its bulk by diminished pressure. Sudden and violent compression, likewise, causes an explosion of the gaseous mixture, apparently from the heat emitted during the operation; for an equal degree of condensation, slowly produced, has not the same effect. When the action of heat, the electric spark, and spongy platinum, no longer cause an explosion, a silent and gradual combination between the gases may still be occasioned by them. Oxygen and hydrogen gases unite slowly with one another when exposed to a temperature above the boiling point of mercury, and below that at which glass begins to appear luminous in the dark. An explosive mixture, diluted with air to too great a degree to explode by electricity, is made to unite silently by a succession of electric sparks. Spongy platinum causes them to unite slowly, though mixed with 100 times their bulk of oxygen gas. A very high temperature is excited by the combustion of hydrogen gas, especially when it is burned in oxygen gas, as in the compound blow-pipe of Doctor Hare. Water is the sole product of the combustion of hydrogen—a fact first demonstrated by Cavendish, who burned oxygen and hydrogen gases in a dry glass vessel, and obtained a quantity of pure water exactly equal to that of the gases which had disappeared during the experiment. The synthetic proof of the composition of water is obtained also by detonating two measures of hydrogen, mixed with one of oxygen, in a tube, over the mercurial cistern; the whole is condensed into water. Lavoisier first exhibited the composition of water analytically, by passing a known quantity of watery vapour over metallic iron heated to redness in a glass tube. Hydrogen gas was disengaged; and the weight of the hydrogen, added to the increase which the iron had experienced from combining with oxygen, exactly corresponded to the quantity of water which had been decomposed.

The processes for procuring a supply of hydrogen, described at the commencement of the present article, will now be intelligible. The first is founded on the fact that iron, at a red heat, decomposes water, the oxygen of which unites with the metal, while the hydrogen gas is set free. That the hydrogen which is evolved, when zinc or iron is put into dilute sulphuric acid, is derived from water, is obvious from the consideration that of the three substances iron or zinc, sulphuric acid, and water, the last is the only one which contains hydrogen. The product of the operation, besides hydrogen, is the sulphate of the protoxide of iron, if iron is used, or of the oxide of zinc, when zinc is employed. Hydrogen, therefore, is one of the most abundant substances in nature. Besides, with carbon and oxygen, it enters into the composition of all vegetable substances; and, with oxygen, carbon, and nitrogen, it forms a part of all animal substances. Large quantities of it, often united with more or less of carbon, are continually evolved into the atmosphere from the decomposition of vegetable and animal matters.

HYDROGRAPHY; that part of geography which treats of waters.—*Hydrographic maps;* such as make the rivers and other collections of water their chief subject.

HYDROMETER, a measurer of density (for fluids), is an instrument which, being immersed in fluids, as in water, brine, beer, brandy, determines the proportion of their densities or their specific gravities, and thence their qualities. The use of the hydrometer depends on the following propositions:—1. The hydrometer will sink in different fluids in an inverse proportion to the density of the fluids; 2. the weight required to sink a hydrometer equally far in different fluids will be directly as the densities of the fluids. Each of these two propositions gives rise to a particular kind of hydrometer: the first with the graduated scale; the second with weights. The latter deserves the preference.

There are various instruments used as hydrometers; one is a glass or copper ball, with a stem, on which is marked a scale of equal parts or degrees. The point to which the stem sinks in any liquid being ascertained and marked on the scale, we can tell how many degrees any other liquid is heavier or lighter, by observing the point to which the stem sinks in it. This instrument is shown in the accompanying figure.



Another kind is formed by preparing a number of hollow glass beads of different weights, and finding which bead will remain stationary in any liquid, wherever it is placed. An instrument of great delicacy, which will even detect any impurity in water too slight to be detected by any ordinary test, or by the taste, consists of a ball of glass three inches in diameter, with another joining it, and opening into it, one inch in diameter. A wire, about ten inches long and one-fortieth of an inch in diameter, divided into inches and tenths, is screwed into the larger ball. A tenth of a grain, placed on the top of the wire, will sink it a tenth of an inch. Now it will stand in one kind of water a tenth of an inch lower than in another, which shows that a bulk of one kind of water equal to the bulk of the instrument (which weighs 4000 grs.) weighs one-tenth of a grain less than an equal bulk of the other kind of water; so that a difference in specific gravity of one part in 40,000 is detected.

The *aræometer* is more simple and accurate. A glass phial, about two inches in diameter, and seven or eight long, is corked tight; into the cork is fixed a straight wire one-twentieth of an inch in diameter and thirty inches long. The phial is loaded with shot so as to sink in the heaviest liquid, leaving the wire just below the surface. The liquor is then placed in a glass cylinder three or four feet long, with a scale of equal parts on the side, by which the point to which the top of the wire sinks is marked. This instrument is so delicate that the sun's rays falling upon it will cause the wire to sink several inches; and it will rise again when carried into the shade.

HYDROPHOBIA; a specific disease, arising from the bite of a rabid animal. The animals most liable to be afflicted with madness are dogs; but cats, wolves, foxes, &c., are also subject to it. The accompanying description of the way in which rabies affects dogs is highly important when danger from the disease is apprehended. The symptoms of rabies in the dog are the following, and are given nearly in the order in which they usually appear:—An earnest licking, or scratching, or rubbing of some particular part; sullenness, and a disposition to hide from observation; considerable costiveness and occasional vomiting; an eager search for indigestible substances—as bits of thread, hair, straw, and dung. The dog becomes irritable; quarrels with his companions; eagerly hunts and worries the cat; mumbles the hand or foot of his master, or perhaps suddenly bites it, and then crouches and asks pardon. As the disease proceeds, the eyes become red: they have a peculiar bright and fierce expression. Some degree of strabismus, or squinting, very early appears—not the protrusion of the *membrana nictitans* over the eye, which, in distemper, often gives the appearance of squinting, but an actual distortion of the eyes; the lid of one eye is evidently more contracted than that of the other; twitchings occur round that eye; they gradually spread over that cheek, and finally over the whole face. In the latter stage of the disease, that eye frequently assumes a dull green colour, and at length becomes a mass of ulceration.

After the second day the dog usually begins to lose a perfect control over the voluntary muscles. He catches at his food with an eager snap, as if uncertain whether he could seize it; and he often fails in the attempt. He either bolts his meat almost unchewed, or, in the attempt to chew it, suffers it to drop from his mouth. This want of power over the muscles of the jaw, tongue, and throat increases, until the lower jaw becomes dependent, the tongue protrudes from the mouth, and is of a dark and almost black colour. The animal is able, however, by a sudden convulsive effort, to close his jaws, and to inflict a severe bite. The dog is in incessant action; he scrapes his bed together, disposes it under him in various forms, shifts his posture every instant, starts up, and eagerly gazes at some real or imaginary object; a peculiar kind of delirium comes on; he traces the fancied path of some imaginary object floating around him; he fixes his gaze intently on some spot in the wall or partition, and suddenly plunges and snaps at it; his eyes then close, and his head droops, but the next moment he

starts again to renewed activity: he is in an instant recalled from this delirium by the voice of his master, and listens attentively to his commands; but, as soon as his master ceases to address him, he relapses into his former mental wandering. His thirst is excessive (there is no hydrophobia, or fear of water, in the dog), and, the power over the muscles concerned in deglutition being impaired, he plunges his face into the water up to the very eyes, and assiduously, but ineffectually, attempts to lap. (In Johnson's *Shooter's Companion* the author observes, "In those instances of hydrophobia which have fallen under my notice, the animal has always been capable of lapping; however, in the disease called *dumb madness*, I have noticed symptoms similar to the above.") His desire to do mischief depends much on his previous disposition and habits. He springs to the end of his chain; he darts with ferocity at some object which he conceives to be within his reach; he diligently tears to pieces every thing about him; the carpet or rug is shaken with savage violence; the door or partition is gnawed asunder; and so eager is he in this work of demolition, and so regardless of bodily pain, that he not unfrequently breaks one or all of his teeth. If he effects his escape, he wanders about, sometimes merely attacking those dogs which fall in his way; and at other times he diligently and perseveringly hunts out his prey: he overcomes every obstacle to effect his purpose; and, unless he has been stopped in his march by death, he returns in about four and twenty hours, completely exhausted, to the habitation of his master. He frequently utters a short and peculiar howl, which, if once heard, can rarely be forgotten; or, if he barks, it is with a short, hoarse, inward sound, altogether dissimilar from his usual tone.

In the latter stages of the disease, a viscid saliva flows from his mouth, with which the surface of the water that may be placed before him is covered in a few minutes; and his breathing is attended with a harsh grating sound, as if impeded by the accumulation of phlegm in the respiratory passages. The loss of power over the voluntary muscles extends, after the third day, throughout his whole frame, and is particularly evident in the loins; he staggers in his gait; there is an uncertainty in all his motions; and he frequently falls, not only when he attempts to walk, but when he stands, balancing himself as well as he can. On the fourth or fifth day of the disease, he dies, sometimes in convulsions, but more frequently without a struggle. After death, there will invariably be found more or less inflammation of the mucous coat of the stomach; sometimes confined to the rugæ, at other times in patches, generally with spots of extravasated blood, and occasionally intense, and occupying the whole of that viscus. The stomach will likewise contain some portion of indigestible matter (hair, straw, dung), and, occasionally, it will be completely filled and distended by an incongruous mass. The lungs will usually present appearances of inflammation, more intense in one, and generally the left lung, than in the other. Some particular points and patches will be of a deep colour, while the neighbouring portions are unaffected. The sublingual and parotid glands will be invariably enlarged, and there will also be a certain portion of inflammation, sometimes intense, and at other times assuming only a faint blush, on the edge of the epiglottis, or on the rima glottidis, or in the angle of the larynx at the back of it. The hydrophobia seems to be spontaneous, and capable of being communicated only by certain animals—the dog, the wolf, the fox, and the cat.

All animals which have become rabid by a bite do not appear to be able to transmit it to others; as the hog, cow, sheep. In regard to man, it is not certain whether the disease is communicable from the human subject. The hydrophobia is not commonly manifested in the time of greatest cold or greatest heat, but usually in March and April in wolves, and in May and September in dogs. It is rare in very warm or very cold climates. No particular cause of the rabies is known; it is a mistake to attribute it to a total privation of food, as a great number of experiments prove that this is not the effect of such a treatment. All observations seem to prove the existence of a rabid virus, which is more violent when it proceeds from wolves than from dogs; as, out of a given number of persons bitten by a rabid wolf, a greater number will die than out of the same number bitten by a dog. The communication of the virulent hydrophobia by inoculation cannot be denied, and is the best proof of the existence of the virus. The virus appears to be contained solely in the saliva, and does not produce any effect on the healthy skin. But if the skin be deprived of the epidermis, or if the virus be applied to a wound, the inoculation will take effect. The developemént of the rabid symptoms is rarely immediate; it seldom takes place before the fortieth or after the sixtieth day. It begins with a slight pain in the scar of the bite, sometimes attended with a chill; if the bite was on the lower limbs, the pain extends and reaches the base of the breast, or, if on the upper extremities, the throat. The patient becomes silent; frightful dreams disturb his sleep; the eyes become brilliant; pains in the neck and throat ensue. These symptoms precede the rabid symptoms two or three days. They are followed by a general shuddering at the approach of any liquid or smooth body, attended with a sensation of oppression, deep sighs, and convulsive starts, in which the muscular strength is much increased. After the rabid fit the patient is able to drink. The disposition to bite does not appear to belong to any animals except those whose teeth are weapons of offence: thus rabid sheep do not bite, though they butt furiously. A foamy, viscid slaver is discharged from the mouth; the deglutition of solid matters is difficult; the respiration hard; the skin warm, burning, and afterwards covered with sweat; the pulse strong. The fits are often followed by a syncope; they return at first every few hours, then at shorter intervals, and death takes place generally on the second or third day.

A great number of applications have been recommended, but without success. The treatment of the disease is of two sorts: the one consists in preventing its developement; the other in checking its progress. The former consists in cauterizing the wound with iron heated to a white heat, the pain of the cautery being less as the temperature is greater. The cautery is preferable to the use of lotions, liniments, &c., but it should be employed within twelve hours after the bite. It has been said that, in patients who were about to become rabid, several little pustules filled with a serous matter appeared under the tongue, the opening of which would prevent the disease; but this is not well established. A mode of treatment which has in many cases been attended

HYDROSTATICS & HYDRAULICS.

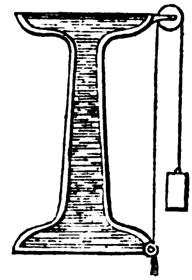
with success must now be adverted to. It consists in the application of a cupping-glass to the lacerated part, which, by forming a vacuum over the wound, prevents the virus being imbibed, and taken into the system. It will be obvious that the application of the cupping instrument must speedily follow the infliction of the wound, and, when the poison is brought to the surface, the knife or cautery may be resorted to. Various remedies have been prescribed for the cure of a declared hydrophobia. Bleeding, even to syncope, appears to have produced the greatest effect, but without complete success. Preparations of opium administered internally or by injection, mercurial frictions, belladonna, emetics, sudorifics, purgatives, &c., have been tried ineffectually. Yet the physician should not despair, as a remedy which has failed in one case may succeed in another. Above all, the patient should be treated gently, and his sufferings alleviated by consulting his comfort as much as possible; and the attendants should not forget that there is no instance of the rabies having been communicated from one man to another.

Hydrostatics is the science which treats of the weight, pressure, and equilibrium of liquid fluids. The particles in liquids are freely movable among each other, so as to yield to the least disturbing force; but, though it was formerly believed that liquid fluids were incompressible, recent experiments have shown that they may be indefinitely condensed by pressure. The fundamental truth, on which the whole science of hydrostatics rests, is equality of pressure. All the particles of fluids are so connected together that they press equally in every direction, and are continually pressed upon; each particle presses equally on all the particles that surround it, and is equally pressed upon by them; it equally presses upon the solid bodies which it touches, and is equally pressed by those bodies. From this, and from their gravity, it follows that when a fluid is at rest, and left to itself, all its parts rise or fall so as to settle at the same level, no part standing above or sinking below the rest.

The freedom of motion which is peculiar to all fluid bodies is supposed to arise from their particles being of a spherical form. *Fig.* 1, *Plate* I., Hydrostatics and Hydraulics, represents a series of these particles; and a slight reference to their arrangement must show that they can only arrange themselves in a position parallel to the plane of the horizon. The perpendicular line of globules would evidently slide by each other and assume parallel horizontal strata, occupying the lower part of the vessel; and between the interstices of the circles smaller spherules might be placed, as is the case when we add certain crystalline bodies to water without increasing its bulk.

In *fig.* 2 we have an illustration of this fact, the water rising to the same height in the small tube as in the larger vessel.

The general rule for estimating the pressure of any fluid is to multiply the height of the fluid by the extent of the surface on which it stands. If any portion of the fluid be supported by a tube above the remainder, the pressure on the bottom of the vessel will be the same as if the water were throughout at the same height as that in the tube, so that the height of the tube is properly multiplied by the extent of the bottom of the vessel to determine the whole pressure. This principle of equal pressure has been called the *hydrostatic paradox*, though there is nothing in reality more paradoxical in it than that one pound at the long end of a lever should balance ten pounds at the short end: it is, indeed, but another means, like the contrivances called *mechanical powers*, of balancing different intensities of force by applying them to parts of an apparatus which move with different velocities.



The glass apparatus for exhibiting the hydrostatic paradox is shown in the accompanying wood-cut. This law of pressure is rendered very striking in the experiment of bursting a strong cask by the action of a few ounces of water. Suppose a cask already filled with water, and let a long tube be screwed tightly into its top, which tube will contain only a few ounces of water; by filling this tube the cask will be burst. The explanation of the experiment is this: if the tube have an area of a fortieth of an inch, and contain half a pound of water, this will produce a pressure of half a pound upon every fortieth of an inch over all the interior of the cask. The same effect is produced in what is called the *hydrostatic bellows*. The tube is made to communicate with an apparatus constructed like a common bellows, but without a valve. If the tube hold an ounce of water, and have an erea equal only to one-thousandth of that of the top board of the bellows, an ounce of water in the tube will balance weights of a thousand ounces resting on the bellows. The bellows as usually constructed for this experiment are shown at *fig.* 9, *Plate* I., Hydrostatics and Hydraulics.

Hydrostatic Press. The press originally invented by Mr. Bramah is one of the most valuable hydrostatic machines yet constructed. *Plate* II., Hydrostatics and Hydraulics, contains a very accurate view of its various parts, drawn to such a scale as to admit of any competent workman making a similar press.

Fig. 10 is an elevation of the press, consisting of wrought-iron rods, connecting cast plates, which form the base and upper part of the frame. In this rises the ram-head, *a*, which operates on the materials to be pressed at *b*. At the side of the press is placed a force-pump with its handle and piston, *d e*. The water raised by the pump is injected by the pipe *c*. A plan of the machine, taken from the base of the press, is given at *fig.* 11.

The principle of the press may be best explained by reference to *fig.* 12. If we suppose the area of the piston *a* to contain 100 inches, and the injecting pipe *c* to be equal to one inch, a column of water entering with a force of 20lbs. would operate with a force of 2000lbs. on the piston. To make this more clear, we should bear in mind that, as fluids press equally in every direction, each inch of the piston must be acted upon with a force equal to that in the injecting pipe. It must not, however, be forgotten that the ascending velocity of the piston will only be one-hundredth of that of the water in the force-pump; and, as such, that it will take 100 times longer to press the goods than would be the case if that enormous power could at once be applied to the great piston. The force-pump, by which the water is introduced, is shown at *fig.* 13. At each elevation

of the piston, *d*, the water rises by the suction-pipe *c*, and when it is depressed the water passes on towards the screw *g*. If that be forced down by the lever above, the water passes along by a side-pipe, and enters the great cylinder.

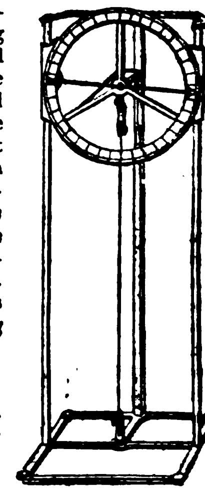
The safety-valve with its weight is shown in *figs.* 10 and 11. In *fig.* 13 an end view of the safety-valve is given, and at *fig.* 14 the entire series of valves are delineated on a larger scale. The screw which holds down the first valve is shown at *fig.* 15. To insure the accurate fitting of the piston, a very beautiful contrivance is usually resorted to: it consists in the employment of a flexible band of leather, a portion of which is given at *fig.* 16; so that, when the pressure of the water is increased, it raises the leather, and increases the resistance, thus preventing the escape of the fluid.

If we suppose the goods to have received the requisite amount of compression, the piston is depressed by slightly withdrawing the screw *g*, when the water descends the pipe, and enters the cistern, whence it may be raised by the pump, as in the previous operation.

HYGROMETER, HYGROSCOPE. It is of the greatest importance in meteorology to ascertain at any time the quantity of water contained in the air. The instruments used for this purpose are called *hygrometers* (measurers of moisture). Daily experience shows that some bodies possess a great capability of absorbing the humidity suspended in the atmosphere, and, according to their respective construction, becoming longer or shorter in the direction of the fibres of their length or breadth. Thus, for example, cordage and catgut are shortened and untwisted by moisture.

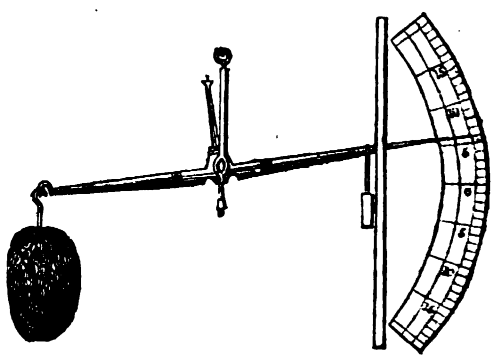
There is a mode of constructing this instrument which is cheap as well as delicate in its operation. It consists of a small bag made of the internal membrane of the *arundo phragmites*. This bag or bladder is tied to the end of a capillary tube, and filled with mercury. Any change in the moisture of the atmosphere will change the dimensions of the bag, and, as such, cause the mercury to rise or fall in the tube. The zero of the scale in this instrument marks absolute humidity, and the other extremity absolute dryness. The lower end of the glass tube, instead of being merely inserted in the top of the bag, may pass through it, the mercury in the bag communicating with that in the tube by one or more openings made through the sides of the tube. By this means, the bag may be supported by the glass and prevented from being injured by any slight accident, and the instrument is also less affected by any change of temperature.

The principle thus developed is the foundation of the hygrometer of Lambert, which, however, on account of the irregularity of the motion produced in the catgut by the humidity, does not altogether answer its purpose, but properly deserves the name of a *hygroscope* (indicator of moisture). Saussure and De Luc, therefore, sought for other substances, which are regularly lengthened or shortened by the absorption or loss of humidity. Saussure believed this property might be found in a human hair, freed from all unctuosity by boiling in ley; De Luc, in a very thin piece of whalebone, cut in a direction transverse to the fibre. Saussure stretched the hair, properly prepared, and fastened at one end, over a delicate and easily movable wheel, by a small weight, while De Luc made use of a small wire of gold to stretch the whalebone. Whenever the hair in Saussure's hygrometer is lengthened or shortened by the action of the moisture or dryness, the wheel, and an index attached to it, must be turned, and thus mark the increase or diminution of the water suspended in the atmosphere.



This species of hygrometric apparatus is shown in the accompanying figure. The following means were employed to find the points of extreme moisture and dryness. Saussure fixed the point of extreme moisture in his hygrometer by placing it in a glass receiver, enclosed in water and moistened with water within; De Luc, on the other hand, accomplished the same object by simply immersing his hygrometer in water. The point of extreme dryness Saussure determined by placing his hygrometer under a receiver, which stood on a tin plate, heated to a red heat, and covered with red-hot potash; De Luc by suspending the hygrometer in a close vessel, partly filled with hot quick-lime.

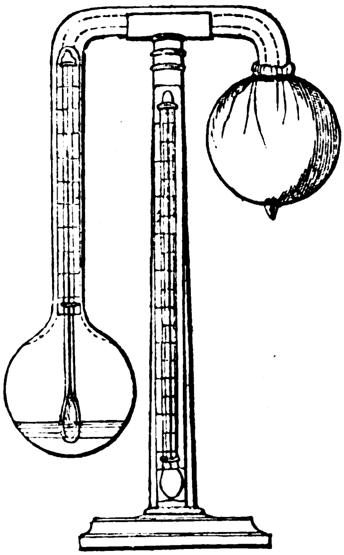
There is a very simple form of the hygrometer which may now be adverted to. The instrument consists of a balance beam, furnished with a piece of sponge at one extremity, and a slender rod or index at the other. The sponge should be prepared by steeping in pearl-ash and water, which renders it more hygrometric. The balance is usually constructed so that the points of suspension are considerably higher than the centre of gravity of the entire beam, so that, when the sponge imbibes moisture from the air, the opposite end gradually ascends; and when, on the contrary, the water is again absorbed, the index passes towards the opposite end of the graduated circle shown in the figure.



The weight at the index end of the balance is in the present case employed only as a couuterpoise to the sponge.

The hygrometer invented by Mr. Daniell is more accurate than those we have already described. It is, however, more costly, and requires a longer period of time for registering each observation. An en-

graving of the apparatus is given beneath. It consists of two thin glass balls of 1½ inch in diameter, connected together by a tube, having a bore of about one-eighth of an inch. The tube is bent at right angles over the two balls, and one arm contains a small thermometer, whose bulb, which must be of a lengthened form, descends into the ball. This ball, being about two-thirds filled with ether, is heated over a lamp till the fluid boils, and the vapour issues from the capillary tube, which terminates the highest ball. The vapour having expelled the air from both balls, the capillary tube is closed hermetically by the flame of a lamp. The upper ball is now to be covered with a piece of muslin. The stand is of brass, and the transverse socket at top is made to hold the glass tube, in the manner of a spring, allowing it to turn and be taken out with little difficulty. A small thermometer is inserted into the pillar of the stand.



The manner of using the instrument may be thus described:—After having driven all the ether into the lower ball, by the heat of the hand, it is to be placed in an open window, or out of doors, with the ball so situated as that the surface of the liquid may be upon a level with the eye. A few drops of ether are then to be poured upon the covered ball. Evaporation immediately takes place, which, producing cold upon the ball, causes a rapid and continuous condensation of the ethereal vapour in the interior of the instrument. The consequent evaporation from the included ether produces cold in the lower ball, the degree of which is measured by the thermometer within. This action is almost instantaneous. The thermometer begins to fall in two seconds after the ether has been dropped. A depression of thirty degrees is easily produced, and sometimes the ether boils, and the thermometer falls below 0° of Fahrenheit's scale. The artificial cold thus produced causes a condensation of the atmospheric vapour upon the lowest ball, which first makes its appearance in a thin ring of dew coincident with the surface of the ether. The degree at which this takes place is to be carefully noted. A little practice may be necessary to seize the exact moment of the first deposition, but certainty is very soon acquired. It is advisable to have some dark object behind the instrument, such as a house or a tree, as the cloud is not so soon perceived against an open horizon. The depression of temperature is first produced at the surface of the liquid where evaporation takes place; and the currents which immediately ensue, to restore the equilibrium, are very perceptible. The bulb of the thermometer is not quite immersed in the ether inclosed in the bulb. The greatest difference that Mr. Daniell observed, in the course of four months' daily experiments, between the external thermometer and the internal one, at the moment of precipitation, in the natural state of the atmosphere, was twenty degrees. In very damp weather the ether should be slowly dropped upon the ball, otherwise the descent of the thermometer is so rapid as to render it impossible to be certain of the degree. In dry weather, on the contrary, the ball requires to be well wetted more than once, to produce the requisite degree of cold. It is almost superfluous to observe that care should be taken not to permit the breath to affect the glass. With these precautions the observation is simple, easy, and certain.

When the instrument is required to act merely as a weather-glass, to predict the greater or less probability of rain, &c., which is the commonest use to which it can be applied, the difference between the constituent temperature of the vapour and that of the air is all that is necessary to be known. The probability of rain, or other precipitation of moisture from the atmosphere, is in an inverse proportion to this difference. As a weather-glass, this hygrometer is more to be depended upon than any instrument that has yet been proposed.

By combining the rise and fall of the barometer with the effects of this instrument, we learn to modify their results, and by so doing can hardly be deceived in the weather for many hours in advance. The indications are to be corrected according to circumstances in the following manner:—In summer time, when the diurnal variations of temperature are great, regard is to be had to the time of day at which the experiment is made. In the morning, supposing the difference between the temperature of the air and the constituent temperature of the vapour to be small, it is to be recollected that the accession of heat during the day is great, and that the difference will therefore probably increase. If the point of condensation should at the same time be lowered, it is an indication of very fine weather. If, on the contrary, the heat of both should increase with the day in nearly equal progression, rain will almost infallibly follow, as the heat of the air falls with the setting sun. In showery weather the indications of this instrument vary rapidly three or four degrees, and a person making observations at short intervals of time may easily predict the approach of a storm.

Fogs also, and mists, must be taken into consideration. They produce the same effect upon the instrument as the greater precipitation of rain. A change from fine weather to rain is more quickly perceptible in low situations than one from wet to fine; for the effect of a shower lasts rather longer than the state of the atmosphere in higher regions would warrant, on account of the damp exhalations from the moistened ground.

In cases of mist, fog, and cloud, the instrument will sometimes exhibit a different kind of action. If it be brought from an atmosphere of a higher temperature into one of a lower degree, in which condensed aqueous particles are floating, the mist will begin to form upon the ball at a temperature several degrees higher than that of the air. The difference, Mr. Daniell believes, is proportionate to the density of the cloud or mist; but, this philosopher says, "I speak with diffidence upon this point, as I have not had sufficient opportunities of verifying it by experi-

ment. I have sometimes thought that I have perceived a difference in this respect in different modifications of the cloud, but this must be referred to future more extended observations. This action upon floating water does not at all interfere with it as measuring the force and quantity of vapour; for in all such cases the full saturation of the atmospheric temperature must take place, and consequently the temperature of the vapour must be coincident with that of the air."

The hygrometer we have now described excels all others in the sensibility and accuracy with which it marks the comparative degrees of moisture and dryness in the atmosphere, and, by exhibiting them in degrees of the thermometer, refers them to a known standard of comparison, and thus speaks in a language which every body understands.

Hypochondriasis; one of the most troublesome of diseases. Its seat is in the abdomen, particularly under the short ribs; but, when it has increased to a certain degree, it manifests itself in the most various ways in the whole body, as there are few diseases of which the hypochondriac does not at some time or other complain. He feels a pressure on the right side, and thinks it is owing to a complaint of the liver; he has pains in the breast, and immediately apprehends inflammation of the lungs; his head feels heavy, and nothing is more certain than an approaching apoplexy; he sees specks before his eyes, and a cataract is unavoidable; and, if the heart beats stronger than usual, a polypus in that organ is probable. All these effects of the disease are explicable, from its nature, seat, and causes.

Hypochondria is a disturbance of the functions of the nervous system of the abdomen. Hence the sensibility of the nervous system is morbidly heightened, but its power of action lessened. At the same time, the separation between the nervous system of the abdomen and that of the brain is rendered less complete, so that certain feelings reach the brain, and thus affect the thoughts much more than in a state of health. The disturbance in the function of the abdominal nervous system produces next a weakness and disturbance in the digestion, which generally produce the first and most numerous attacks of hypochondria, from which all the others originate, in proportion as the morbid sympathy extends over the whole body. Hence, first, is produced spasmodic contractions under the short ribs, sometimes on one side, sometimes on the other, sometimes in the pit of the stomach; torpidity of the bowels, flatulency, inflation of the abdomen, want of appetite, increased pressure, and, generally, disagreeable feelings after eating.

In the progress of the disease, a slow and somewhat difficult inspiration comes on, indescribable anxiety, and pain and giddiness in the head. Also, when the stomach is empty, this organ sometimes suffers pain and sickness, and vomiting takes place. For moments, particularly after digestion is finished, the hypochondriac feels easy, well, and serene; but, all at once, the old complaints seize again upon their victim. The disturbance of the nervous system also has, as may well be conceived, a great influence upon the mind and humour of the patient. Sometimes he is melancholy, sometimes gay to an excess. Uninterruptedly occupied with the state of his body, he takes notice of every feeling, and wishes to have every trifling pain explained, considering every one as a symptom of a serious disease. For every thing he wants medicine. In the hours of anxiety, hypochondriacs are constantly in dread of death. Sometimes anxiety attacks them so suddenly that they must jump up, and cannot find quiet any where. Sometimes memory leaves them, so that they cannot think of their name. In the midst of the most serious conversation, nay, even of prayers, the most ludicrous ideas or images strike them. Others, all at once, feel a desire to perform the strangest actions, from which they can restrain themselves only with great difficulty.

This deplorable disease may be occasioned by any circumstances which disturb the functions of the abdominal nervous system, heighten its sensitiveness, debilitate digestion, and lessen the separation of the reproductive nervous system from the sensitive. Among the chief causes are great exertions of the mind in studying, a sedentary or dissipated life, excess in exciting liquors, and even coffee; also want of exercise of the physical and mental powers, producing *ennui*. Hypochondria is physically considered not a dangerous disease. It is true, the genuine hypochondriac believes, at least for six days of every week, that his hour is come. He passes a wretched existence, and is a real torment to his family and physician. Hypochondria can be cured but slowly. A hypochondriac must abstain from much medicine, but the difficulty is to persuade him to do so. He ought to master his feelings, but the body has become the governing power; he ought to take much exercise, but his indolence finds continual excuses for omitting it; he ought to observe a strict diet for years, but he is impatient to be cured immediately, and his most solemn promises are forgotten in a week. Thus it happens that a hypochondriac is seldom entirely cured, but, after having suffered for years, he dies of some additional disease: or, in very advanced age, when the irritability of the nerves is lessened, the disease disappears.

Hypogastric (from ὑπο, under, and γαστηρ, the abdomen); seated in the lower part of the belly.

Hysterics are with women nearly the same as hypochondria with men, the difference which really exists arising from the peculiar character and constitution of women. It arises from a morbid excitement of the nervous system, and manifests itself by great uneasiness, unusual susceptibility, occasioning great trouble, often from imaginary causes, and affecting the sufferer even to tears. To these is added the sensation of a ball mounting from the abdomen, and particularly from the pit of the stomach, where the most important nerves concentre, and occasioning a feeling of strangulation. From the greater susceptibility in the system of women, these affections are more universal, and appear quicker in other parts of the body, particularly in the muscles, than in men. Hence spasms of various kinds, contractions of the neck, pains in the head, fainting fits, palpitation of the heart, appear very frequently, and are sometimes so severe that persons afflicted with them seem to be dying. These complaints were once ascribed to vapours arising from the stomach, and were called by that name. Women of a delicate habit, and whose nervous system is extremely sensible, are the most subject to hysterical affections; and the habit which predisposes to these attacks is acquired by inactivity and a sedentary life, grief, anxiety, and various physical disorders. They are readily excited,

in those who are subject to them, by strong emotions, especially if sudden. Hysterical complaints are best prevented by a judicious care of the moral and physical education of girls. Men of uncommon nervous sensibility are sometimes subject to disorders not essentially different.

ICE; every frozen liquid: in a more limited sense, frozen water. As soon as the temperature is raised, the solid state again gives way to the liquid. We see, then, that ice is nothing but water deprived of its caloric. The freezing of water is a phenomenon so remarkable that the greatest naturalists have thought it worthy of a careful investigation. Expose a glass, filled with water, to a degree of cold producing ice; an extremely thin film of ice is observed first on the surface of the water in contact with the cold air. Slender threads of ice are soon seen to shoot out from the sides of the vessel, generally forming with it obtuse or acute, seldom right angles; from these rays, new ones continually shoot out, till the whole surface is covered with a single coating; while this process is going on, a great number of air-bubbles arise, as in boiling, which pass out of the water when the congelation is slow; but, when it is sudden, they are frozen in, and by their expansion cause rents in the ice.

Although cold generally produces contraction, ice occupies a larger space than water; it is hence specifically lighter, and floats upon it. Those persons are in an error who suppose that *ground-ice*, as it is called, rises from the bottom of the water after freezing. A species, however, called *anchor-ice*, appears to be formed at the bottom, or, at least, under the surface, of rapid rivers, perhaps owing to the comparatively slow motion of the water at the bottom of a stream. It is well known that stagnant water freezes sooner than flowing water: perfect rest, however, seems to be unfavourable to freezing; for we know by experience that water perfectly still is not frozen when its temperature is reduced much below the freezing-point; but a little agitation is sufficient to change it into ice. Sea-water, and in general all salt water, freeze with greater difficulty, because the salt and other ingredients retain the caloric longer. Salt is, moreover, separated in the process of freezing, and precipitated to the bottom, so that ice from sea-water sometimes affords water which is fit for drinking.

The more severe the cold, the greater the hardness and firmness of the ice; and the ice of the polar regions can hardly be broken with a hammer. In the severe winter of 1740, a house was built at Petersburg, from the ice of the Neva, fifty-two feet and a half long, sixteen and a half wide, and twenty high; and notwithstanding the enormous weight of the roof, which was likewise of ice, the lower parts of the building did not receive the smallest injury. The pieces of ice were hewn to the form and shape required, adorned, and arranged according to the rules of architecture. Before the edifice stood six cannons of ice, which were turned in a lathe, with the carriages and wheels of ice, and two mortars formed like cast pieces. The cannons were six-pounders, which are commonly loaded with three pounds of powder; these, however, were loaded with only a quarter of a pound, and carried a ball of stuffed hemp, and sometimes of iron. The balls, at a distance of sixty paces, passed through a board two inches in thickness: the ice of the cannons could not have been much more than three or four inches in thickness, and yet it resisted the force of the explosion.

ICE-HILLS are a species of structure common upon the river Neva, at St. Petersburg. They are constructed in the following manner:—A scaffolding is raised upon the river about thirty feet in height, with a landing-place on the top, the ascent to which is by a ladder. From the summit a sloping plane of boards, about four yards broad and thirty long, descends to the superficies of the river: it is supported by strong poles gradually decreasing in height, and its sides are defended by a parapet of planks. Upon these boards are laid square masses of ice, about four inches thick, which, being first smoothed with the axe, and laid close to each other, are then sprinkled with water: by these means they coalesce, and, adhering to the boards, immediately form an inclined plane of pure ice. From the bottom of this plane the snow is cleared away for the length of 200 yards upon the level bed of the river, and the sides of this course, as well as the sides and top of the scaffolding, are ornamented with firs and pines. Each person, being provided with a sledge, mounts the ladder; and, having attained the summit, he seats himself upon his sledge at the upper extremity of the inclined plane, down which he suffers it to glide with considerable rapidity, poising it as he goes down, when the velocity acquired by the descent carries it above 100 yards upon the level ice of the river. At the end of this course, there is usually a similar ice-hill, nearly paralled to the former, which begins where the other ends, so that the person immediately mounts again, and in the same manner glides down the other inclined plane of ice. The boys also are continually employed in skating down these hills; they glide chiefly upon one skate, as they are able to poise themselves better on one leg than upon two. These ice-hills exhibit a pleasing appearance upon the river, as well from the trees with which they are ornamented as from the moving objects which at particular times of the day are descending without intermission.

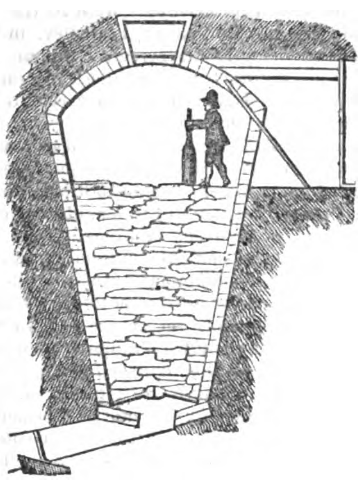
ICE-HOUSE. The preservation of ice, as an article of luxury, is less attended to in this country than in any other part of Europe; we propose, therefore, in the present article, pointing out the mode of constructing an ice-house by which it may be preserved at all seasons, and at a comparatively small expense.

The best soil for an ice-pit to be made in is chalk, as it conveys away the waste water without any artificial drain; and next to that a loose stony earth, or gravelly soil, is the most advantageous. The site should be elevated, that there may be a sufficient descent to convey off any wet that may happen to enter, or from the ice melting; and it should be as much exposed to the air as possible; not under a fall of water, or in the shade of trees, as is too often the practice, under the supposition that if exposed to the sun the ice will melt away in the summer.

The external shape of the building may be according to the convenience of the owner; but, for the well into which the ice is put, a circular form is the most convenient, the depth and diameter of it being proportioned to the quantity of ice wanted; but it is always best to have sufficient room, as, when the house is well built, it will keep the ice two or three years.

Where the quantity wanted is not great, a well of six feet diameter, and eight feet deep, will be large

enough; but, for a large consumption, it should not be less than nine or ten feet in diameter and as many deep: where the situation is either of a dry chalky, gravelly, or sandy kind, the pit may be made entirely below the surface of the ground; but in strong loamy, clayey, or moist ground, it will be better to raise it so high above the surface as that there may be no danger from the wetness of the soil about it. The accompanying engraving represents a well of small cost, but well fitted for its intended object.



At the bottom of the well there should be a space about two feet deep left, for receiving any moisture that may drain from the ice, and a small under-ground drain should be laid from this, to carry off the wet; over this space should be placed a strong grate of wood to let the moisture fall down, which may at any time happen, from the melting of the ice. The sides of the well must be walled up with brick or stone, at least two feet thick; but if it be thicker it will be better, as the thicker the walls are made the less danger there is of the well being affected by external causes. When the wall of the well is brought within three feet of the surface, there must be another outer arch or wall begun, which must be carried up to the height of the top of the intended arch of the well; and, if there be a second arch turned over this, the house will be so much the better; but this must depend on the resources of the person who builds. When complete, the plate into which the roof is to be framed must be laid on the outer wall, which should be carried high enough above the inner arch to admit of a door way for reaching the ice. Where the building is to be covered with slate or tiles, there should be a thickness of reeds, straw, or other similar materials laid under, to guard against the effects of the sun and external air; where they are laid two feet thick, and plastered over with lime and hair, there will be no danger of the heat penetrating in such a way as to prove injurious. The door to enter by, for taking out the ice, should be no larger than absolutely necessary for that purpose, and must be strong and close, to exclude the air; and, at five or six feet distance from this, another door should be contrived, which should be shut before the inner door is opened, whenever the ice is taken out of the house.

In the choice of the ice, the thinnest should be selected: indeed, the smaller it is broken the better, as it will the more readily unite when put into the well. In putting it in, the ice should be rammed close, and a space left between it and the wall of the well, by placing straw for that purpose, so as to admit the passage of any moisture that may be collected by the partial melting of the frozen water.

ICONOGRAPHY; the representation of statues, busts household gods, mosaic works, and pictures in water-colours. Michael Angelo and Ursinus were the restorers of this art, which was carried farther by John Angelus Canini and Bernard de Montfauçon. Canini published his Iconography at Rome, in 1669 (1 vol. 4to.), and Montfauçon the *Antiquites Expliquées*. The latest work of this kind is Visconti's *Iconographie Ancienne* (Paris, 1808—23, 6 vols. 4to.); it contains the portraits of the princes and celebrated men of antiquity. Three volumes form the *Iconographie Grecque;* the following the *Iconographie Romaine;* the fifth volume was published, in 1821, by A. Mongez; the sixth volume concludes the whole.

IDEAL, in the *fine arts*, is distinguished from the exact imitation of reality, by avoiding the imperfections which always disfigure the individual, and giving to each excellence its highest perfection. Imagination creates ideals, in the fine arts, by abstractions from individual forms, separating the individual and casual from the general and the essential, and thus producing ideals of a particular kind. If it performs the same process on these, again abstracting the general and essential, it creates new ideals of a still higher kind; and, if this abstraction is carried on farther, we arrive at last at the pure ideal, which is incapable of any farther separation and generalization—the ideal form of the whole genus. Thus man creates forms elevated above the real forms of nature: we do not say above nature itself, because we understand by nature not only the actual appearances of the sensible world, but also the laws and prototypes which lie at their foundation, and at which imagination arrives in the way indicated. As in thousands of crystals we do not find one which forms a perfect mathematical figure, while the effort of nature to produce such a figure is obvious in all, so is it with the beautiful. All the individual instances may be regarded as the imperfect attempts of nature to produce a faultless model.

In creating the ideal of beauty, man does not follow, as some suppose, the arbitrary suggestions of fancy, but strives to discover and present the prototypes of nature. Imagination finds the materials of the ideal in reality, but she unites the separate traits of the grand and the beautiful, dispersed through nature in one perfect ideal. So, too, there may be ideals of the hateful, the horrid, the malignant; for the ideal aims merely at completeness, whether in the good or the bad, the grand or the mean, the graceful or the ugly, the heroic or the ridiculous. Dante often gives us the ideal of physical suffering; whilst the Koran aims to present the ideal of sensual enjoyment. The caricature is, under a certain point of view, an ideal. The characteristic, which is founded on the deviation of the individual form from the generic, is therefore opposed to the ideal, which loses by any deviation from the generic form; but, on the other hand, the representation gains in character, and thus satisfies the claims of the fine arts, which require not only the beautiful, but the true. Truth must in

no case be sacrificed to beauty. A medium must therefore be employed, by which the truth may be represented as beautiful. This medium is the true ideal of the intuitive arts. Genius only can decide how far the characteristic and the generic are to be mingled.

IDIOSYNCRACY means the peculiar effect produced by certain agents upon the bodily frame; or the peculiar, and frequently morbid state of feeling, of liking or dislike which a person has, with regard to certain objects, whether physical or intellectual.

IGNIS FATUUS. A very interesting description of this curious natural phenomenon, which is seen in the neighbourhood of lakes and stagnant pools, has lately been published in the *Edinburgh New Philosophical Journal;* and the author, Mr. Blesson, has investigated the matter with such care and accuracy as to warrant our quoting the description in his own words.

"The first time," says Mr. Blesson, "I saw the ignis fatuus was in a valley in the forest of Gorbitz, in the New Mark. This valley cuts deeply in compact loam, and is marshy on its lower part. The water of the marsh is ferruginous, and covered with an iridescent crust. During the day, bubbles of air were seen rising from it, and in the night blue flames were observed shooting from and playing over its surface. As I suspected that there was some connection between these flames and the bubbles of air, I marked during the day-time the place where the latter rose up most abundantly, and repaired thither during the night; to my great joy I actually observed bluish-purple flames, and did not hesitate to approach them. On reaching the spot they retired, and I pursued them in vain; all attempts to examine them closely were ineffectual. Some days of very rainy weather prevented farther investigation, but afforded leisure for reflecting on their nature. I conjectured that the motion of the air, on my approaching the spot, forced forward the burning gas, and remarked that the flame burned darker when it was blown aside; hence I concluded that a continuous thin stream of inflammable air was formed by these bubbles, which, once inflamed, continued to burn, but which, owing to the paleness of the light of the flame, could not be observed during the day.

On another day, in the twilight, I went again to the place, where I waited the approach of night: the flames became gradually visible, but redder than formerly, thus showing that they burnt also during the day: I approached nearer, and they retired. Convinced that they would return again to the place of their origin when the agitation of the air ceased, I remained stationary and motionless, and observed them again gradually approach. As I could easily reach them, it occurred to me to attempt to light paper by means of them; but for some time I did not succeed in this experiment, which I found was owing to my breathing. I therefore held my face from the flame, and also held a piece of cloth as a screen; on doing which I was able to singe paper, which became brown-coloured, and covered with a viscous moisture. I next used a narrow slip of paper, and enjoyed the pleasure of seeing it take fire. The gas was evidently inflammable, and not a phosphorescent luminous one, as some have maintained. But how do these lights originate? After some reflection, I resolved to make the experiment of extinguishing them. I followed the flame; I brought it so far from the marsh that probably the thread of connection, if I may so express myself, was broken, and it was extinguished. But scarcely a few minutes had elapsed when it was again renewed at its source (over the air-bubbles), without my being able to observe any transition from the neighbouring flames, many of which were burning in the valley. I repeated the experiment frequently, and always with success. The dawn approached, and the flames, which to me appeared to approach nearer to the earth, gradually disappeared.

On the following evening I went to the spot and kindled a fire on the side of the valley, in order to have an opportunity of trying to inflame the gas. As on the evening before, I first extinguished the flame, and then hastened with a torch to the spot from which the gas bubbled up, when instantaneously a kind of explosion was heard, and a red light was seen over eight or nine square feet of the marsh, which diminished to a small blue flame, from two and a half to three feet in height, that continued to burn with an unsteady motion. It was therefore no longer doubtful that this ignis fatuus was caused by the evolution of inflammable gas from the marsh."

IGNITION (glowing heat) denotes that state of certain bodies in which, from being exposed to a high temperature, they appear luminous. Two kinds of ignitible bodies are distinguished: namely, such as become entirely changed by ignition, as charcoal, sponge, &c.; and such as retain their former state, as iron, for example. The first is a regular combustion, in which, however, no gas rises from the bodies in the form of flame. The second is mere heat. Of the metals, many liquefy before they become ignited: for example, lead and tin. Iron, on the other hand, becomes ignited long before it melts. Three stages of ignition may easily be distinguished. Iron, at about 770° of Fahrenheit, becomes brownish-red, which is the commencement of ignition. At a higher temperature, it becomes red hot; at about 1000° of Fahrenheit, it becomes white hot, and emits a very white brilliant light. If gradually cooled, ignition diminishes in the same inverse order. In this gradual transition, we perceive all the different colours of light.

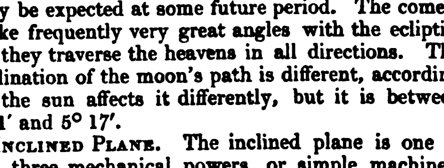
IMPRESSION, in the arts, is used to signify the transfer of certain figures by pressure from a hard to a soft substance. This transfer affords the means of multiplying copies, and takes place in typography, copper-plate printing, lithography, &c. Engravers in copper and wood work in plain surfaces; the gem and stamp engravers, however, produce elevated or sunk figures; consequently, the impressions appear in relievo, and the substances which receive them must be susceptible of being raised or depressed. In order to obtain impressions from copper-plates, a colouring substance must be put in the incisions of the plate. In the case of wood-cuts, the colouring matter is applied to the elevations. In both cases, the copy is procured by pressure.

There are two kinds of impressions:—1. That executed upon plane surfaces, as in lithography, copper-plate printing, and copies from wood-cuts. The instruments for it are the printing, rolling, and lithographic press. The goodness of the copies depends partly on the care and skill of the printer; partly also on the degree in which the plate has been used. The best copies are always among the first hundred. These are sold at a higher price than the subsequent

impressions. An engraved plate affords more good copies than an etched one, and this more than one in aqua tinta. Copies are taken from wood-cuts in the same way as from copper-plates, only the ink is applied to the surface of the figure as in typography. 2. Copies in relievo are impressions of medals and gems, or stamps, so as to leave raised or sunken figures. Medals and engraved gems are valuable as historical monuments and works of art, and the mode in which copies of them are made is a matter of importance. Representations of them in copper-plate engravings cannot properly express their character as works of art. Impressions are therefore taken immediately from them, by means of fine sealing-wax, sulphur, wax, glass, &c. Copies in vitreous substances are called *pastes*.

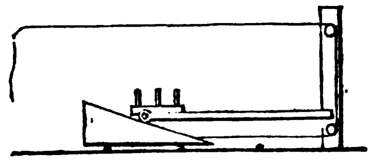
Inclination, in *mathematics*, means the direction of a line, with regard to a certain point (according to the sense of the ancient mathematicians, Apollonius and Pappus particularly). In astronomy, this word signifies the angle which the orbits of the planets and comets make with the ecliptic or orbit of the earth. This angle is the smaller, the less the planet or comet is distant from the ecliptic. According to the latest observations of Lalande and Bode, this angle of inclination is, in the different planets, as follows:—Mercury 7°, Venus 3° 23′ 20″, Mars 1° 51′ Pallas about 30°, Ceres 10° 47′, Jupiter 1° 19′ 10″, Saturn 2° 30′ 20″, Uranus 0° 43′ 45″. More exact determinations with regard to Ceres, Pallas, Juno, and Vesta may be expected at some future period. The comets make frequently very great angles with the ecliptic, for they traverse the heavens in all directions. The inclination of the moon's path is different, according as the sun affects it differently, but it is between 5° 1′ and 5° 17′.

Inclined Plane. The inclined plane is one of the three mechanical powers, or simple machines, formed, as its name imports, by a plane surface, supposed to be perfectly hard and inflexible, and which is always inclined obliquely to the weight or resistance to be overcome. The wedge is a modification of this machine, being formed of two inclined planes placed base to base. The screw is another modification, being, in fact, merely an inclined plane wound round a cylinder. This machine enables us to raise a given weight along the inclined surface to a given elevation, with less expense of force than would be required to raise it perpendicularly to the same elevation. The perpendicular height is called the *elevation of the plane*, and the two lines enclosing the angle which it subtends are called the *base* and the *length* of the plane.



There are two modes of exhibiting the power of the inclined plane. The arrangement exhibited above consists of three paths, inclined to the plane of the horizon at different angles. To carry a loaded carriage up the first would require a weight of one pound, the second two pounds, and the steepest plane three pounds. If the inclined path be three times the length of the perpendicular lift, it will require only one-third the weight to raise the carriage, but then it will require three times as long to accomplish the work.

In the second arrangement of the inclined plane, the mechanical advantage is precisely the same, but the plane itself is put in motion. This is in reality the operating power in a common screw.



Indeterminate Problem and Analysis, in *algebra*; that which admits of innumerable solutions. In such cases, the number of unknown quantities concerned is greater than the number of conditions, or equations, by which they are to be found, whence it happens that some other quantities are assumed to supply the defect. Diophantes was the first writer on this subject, and the result of his labours was published by Xylander in 1575. Mr. Leslie has given an ingenious paper on the solution of indeterminate problems in the second volume of the *Edinburgh Philosophical Transactions*.

Indigo. The knowledge of this most valuable vegetable substance, which forms an important part of East and West Indian commerce, and is beginning to receive considerable attention as a domestic production, is alike interesting to the chemist and to the dyer. The ancients were acquainted with it under the name of *indicum*. Pliny knew that it was a preparation of a vegetable substance, though he was ignorant of the plant which furnished it, and of the process by which it was prepared. From its colour, and the country from which it was imported, some authors call it *atramentum indicum*, and *indicum nigrum*. The American name is *nil*, or *anil*, from which the Portuguese have adopted their *anileira*, the other European nations generally call it *indigo*.

In treating of indigo, it will be the most convenient to explain, in the first place, its physical and chemical properties, and afterwards to allude to the sources from which it is derived, and the method by which it is manufactured. As it is found in commerce, it presents the form of little square or oblong cakes, of an intense blue colour, approaching to black; is brittle and friable; rather light, and without taste or odour. When heated, it has a disagreeable odour, subliming at 55° F.,—a degree of heat near that at which it is decomposed. Its vapour is of a rich violet red-colour, and condenses by cold into delicate acicular crystals, which consist of perfectly pure indigo. Water, by being boiled on indigo, dissolves only about a ninth or a twelfth its weight; the solution is of a reddish-brown colour, and contains what may be called the *extractive* part or the substance; but the colouring matter remains unaltered, except in having assumed a brighter hue. Alcohol and ether, when digested upon it, are also attended with similar effects. Sulphuric acid is the only single agent that dissolves indigo without destroying its colour. When it is put into this acid, a yellow solution is at first formed, which, after a few hours, acquires a deep blue colour. From the solution, diluted with water, potash and its sulphate throw down a deep dark-

blue precipitate, capable of imparting to water, containing only $\frac{1}{300000}$ of its weight, a distinctly blue tinge. It is no longer subject to vaporization, however; from which circumstance, and its property of solubility in water, it is inferred to be a different substance from indigo, and has received the name of *cerulin*. When properly diluted with water, it forms the *liquid blue*, or *Saxon blue*, of the dyers.

Another compound of indigo and water, under the name of *phenecin*, is obtained when water is added to a solution of indigo in sulphuric acid, which has been suffered to stand for several hours, till it has lost its yellow colour, and become blue. It appears to consist of one equivalent of indigo and two of water. In the formation of these substances, indigo is conceived to combine with water; but whether the effect is produced by the sulphuric acid, or whether the sulphuric acid operates merely to prepare the indigo for combining with water afterwards, is not yet fully determined. When indigo, suspended in water, is brought into contact with certain deoxidizing agents, it is deprived of a part of its oxygen, becomes green, and is rendered soluble in water, and still more so in the alkalies. It recovers its former colour, however, on exposure to the air, by again absorbing oxygen of $\frac{1}{7}$ or $\frac{1}{8}$ of the whole weight of the resulting indigo. Its deoxidizement is effected either by allowing it to ferment along with bran, or other vegetable matter, or by decomposing in contact with it the proto-sulphate of iron, by the addition of lime. Substances dyed by deoxidized indigo receive a green tint at first, which becomes blue by exposure to the air. This is the usual method of colouring cloth by means of indigo, which, when fully oxidized, affords a permanent dye, not removable by soap or by acids.

Chlorine, whose power in extinguishing vegetable colours is universal, destroys the colour of indigo; and, from the known fact that a given quantity of free chlorine discolours always the same quantity of pure indigo, a solution of indigo in sulphuric acid has been employed for measuring the strength of solutions of chlorine and of chloride of lime, in order to regulate their application to the art of bleaching; and, reciprocally, a solution containing a known quantity of chloride of lime may be employed as a test of the strength or value of indigo. Indigo may be said to be a rare production of the vegetable kingdom, it hitherto having been found only in a small number of species belonging to the genera *indigofera*, *isatis*, and *nerium*; but it is almost exclusively from the first of these that the indigo of commerce is extracted. In describing the culture of the indigo plant, and the mode of manufacturing the indigo, we shall draw our materials mainly from the methods pursued in the East Indies, where this article is prepared in its greatest perfection. The plant requires a rich, light soil, and a warm exposure. It succeeds best on newly-cleared lands, on account of their moisture; it requires protection against high winds, and needs irrigation in times of drought. The ground, after being properly prepared for the reception of the seed by ploughing, is sown pretty thickly, the time of sowing being so chosen that rain may fall upon the plant as soon as it shows itself above the ground, by which it is not only greatly invigorated, but cleansed from those innumerable insects which otherwise are liable to destroy it. From this time, comparatively little rain is needed; for the dews are so copious as to supply nearly all the moisture required; and, besides, its spindle-shaped root, which descends into the ground perpendicularly, to the depth to nearly three feet, enables it to endure temporary droughts. The prevalence of cloudy weather and much moisture, however, cause the indigo plant to thrive more luxuriantly, but occasion a great deficiency in the colouring matter, which, as it contains an extraordinary quantity of carbon, requires the plant to decompose carbonic acid gas very abundantly,—an operation which it is unable to perform when deprived of the direct influence of the sun's rays. As the young shoots furnish larger and more numerous leaves, it is usual to plant every year; but the Egyptians, who seem to cultivate it most successfully, plant only every third or fourth year. As the plant approaches to maturity, the leaves undergo a sudden change in colour, from a light to a dark green. As soon as this change is observed, the branches are severed from the parent stem early in the morning, and spread out in the sun till the afternoon, by which time they become sufficiently dry to be beaten from the branches by a stick. The leaves, so separated, are housed in warehouses, closely packedand well trodden down by natives. The plants from which the leaves have been severed send forth a new crop, which is gathered, when mature, like the first. Rain, however, is necessary after the cutting, to enable the plant to shoot again in a thriving manner. The cuttings, in a favourable season, are repeated three or four times, after which the ground is ploughed up for another sowing; but each successive growth of the branches produces an increased deterioration of the qualities of the leaves, so that one part of the leaves of the first cutting yields as much indigo as two parts of the third crop.

The dried leaves are not immediately used, but are kept packed for one month, during which time they suffer a material change, which is indicated by their having passed to a light lead-colour. By additional keeping, the lead-colour gradually darkens, until it becomes black. The maximum quantity of indigo is to be obtained when the lead-colour is effected; and any delay in extracting it, after it has reached this point, is attended with a loss in the quantity of the indigo. The lead-colour, however, does not appear in a month after the leaves are gathered, unless, from fear of rain, or any other cause, they were cut before being ripe; and, on the other hand, if the cutting was deferred till after the plant was fully ripe, the leaves will not require to be kept so long. The dried leaves, after having suffered the change of colour alluded to, are transferred to the steeping-vat (an uncovered reservoir, thirty feet square, and twenty-six inches deep, constructed of brick, and lined with stucco), where they are mingled with water, in the proportion of about one volume of leaves to six of water, and allowed to remain two hours. The great affinity of indigo for oxygen is here very manifest, in the quick change of the colour of the leaves which float on the surface, and are exposed to the action of the atmosphere, to a blackish-blue, when contrasted with those below, which remain unchanged. On this account the vat is frequently stirred, so that the floating leaves may be immersed. After two hours' infusion, the water, which, from the solution of imperfectly oxygenized indigo, has acquired a fine green colour, is allowed to run off from the leaves, through straners, into the beating-vat, where it is agitated by the paddles of ten or twelve

people, being obliged to contend, without discipline, against well-trained troops, adopted the irregular mode of fighting, protected by trees or other objects, being, at the same time, mostly skilful marksmen. The efficiency of this method of fighting was evident; and when, in 1791, the French revolutionary war began, the French sent swarms of *tirailleurs* against the allies, and injured them exceedingly. In the wars from 1791 to 1802, the French greatly improved this mode of fighting, which, in the interval of peace that followed, was reduced to a system, the consequences of which were seen in 1805, 1806, and 1807, against the Austrians, Prussians, and Russians. These nations, after the disasters which they suffered, adopted the same system, as well as the greater use of columns, particularly as the ordinary mode of arranging the troops before they came into the fire. Under equal circumstances, well-trained infantry is generally successful against any other kind of troops.

INFLUENZA; a term used in *medicine* to denote an epidemic catarrh which has, at various times, spread more rapidly and extensively than any other disorder. It has seldom occurred in any country of Europe, without appearing successively in every other part of it. It has sometimes apparently traversed the whole of the eastern continent, and in some instances has been transferred to America, and has spread over this continent likewise. The French call it *la grippe*. In all the known instances of its occurrence from the fourteenth century, its phenomena have been pretty uniform, and have differed little, except in severity, from those of the common febrile catarrh. In 1802, such an influenza attracted universal attention. In February it set out from the frontiers of China, traversed all Russia, extended along the Baltic, to Poland and Denmark, reached Germany and Holland in April and May, and France and Spain in June. It could even be followed to Gibraltar. No sex, age, or state of health was exempted. It showed itself chiefly as a severe cold, attended with a catarrhal fever of a more or less imflammatory or bilious character. Generally, it passed over within a few days, yet, in some places, it gave a check to business. Few persons died of it, except those who were afflicted at the same time with other diseases, but almost every one was attacked. G. F. Mort, a German physician, attempted to prove that Europe suffered periodically from the influenza. He maintained that, during the greater part of the period which had elapsed since 1712, this epidemic had visited Europe at intervals of about twenty years, and still more frequently in the early part of the period. Accordingly, he prophesied a new one for 1820, which, however, did not happen.

The epidemic which commenced in the month of February of the present year (1833) may be considered as one of the most rapid and dangerous instances of influenza which has ever appeared. More persons fell victims to its insidious attacks in the metropolis than were destroyed in a similar time by the cholera. Not that the influenza was in itself a mortal ailment to persons previously in good health; but it developed, and brought into active operation, almost every disease which might previously have been considered of a constitutional character.

INGOT, in *the arts*, is a small bar of metal, made of a certain form and size, by casting it in moulds. The term is chiefly applied to the small bars of gold and silver intended either for coining or exportation to foreign countries.

INJECTIONS belong partly to surgery and partly to anatomy. In surgery, fluids, differing according to the different effects desired to be produced, are thrown by means of a small syringe into the natural cavities of the body, or those occasioned by disease, partly to remove unhealthy matter, and partly to bring the remedy immediately to the seat of the disorder, and thus effect a cure. Wounds and sores are usually cleansed in this way, when they extend far below the skin, or an excitement and cure are produced by the same method. Cato the Censor had one applied to himself when he suffered from a fistula. In diseases of the nose and the cavities connected with it, in those which have their seat in the neck, in disorders of the ears, the bladder and urethra, the uterus and vagina, and for the radical cure of hydrocele, injections are often used, and with important advantages. Pure warm water is injected, with the highest success, for the removal of pus, blood, or even foreign bodies. Sometimes astringent medicines to restrain excessive evacuations, sometimes stimulating ones to excite inflammation, as in hydrocele, or even to increase and improve evacuations, sometimes soothing medicaments to mitigate pain, &c., are added to the water. In diseases of the throat which hinder the patient from swallowing, and thus tend to produce death by starvation, nourishing fluids are injected into the stomach.

The blood of beasts, or of men, has been sometimes injected into the veins, which is called *transfusion*. In the same way medicines are introduced immediately to the blood; for instance, tartar emetic to excite vomiting, if a foreign body is fixed in the throat so firmly as to restrain the patient from swallowing, and can neither be moved up nor down. According to the place where the injection is to be made, the instrument must be either longer or shorter, a straight or a curved tube. The size is regulated by the quantity of the liquid to be injected, and the force which is to be applied. Anatomists inject into the vessels of bodies various coloured fluids, which are liquid when hot, and coagulate when cold, to make the smaller ones visible. Thus the arteries, veins, and lymphatic vessels are injected. Anatomy has carried this art so far as to make very minute vessels visible to the naked eye. (See TRANSFUSION.)

INK, WRITING. This material can be prepared of various colours, but black is the most common. Doctor Lewis gives the following recipe:—In three pints of white wine, or vinegar, let three ounces of gall-nuts, one ounce of powdered logwood, and one ounce of sulphate of iron, be steeped half an hour; then add one ounce and a half of gum-Arabic, and, when the gum is dissolved, pass the whole mixture through a hair-sieve. Van Mons recommended the following preparation:—Let four ounces of gall-nuts, two ounces and a half of sulphate of iron calcined to whiteness, and two pints of water, stand in a cool place twenty-four hours; then add one ounce and a quarter of gum-Arabic, and keep it in a vessel open, or slightly stopped with paper. Another recipe is this:—Take one pound of gall-nuts, six ounces of gum-Arabic, six ounces of sulphate of iron, and four pints of beer or water. The gall-nuts are broken, and stand as an infusion twenty-four hours; then coarsely-pounded gum is added, and suffered to dissolve; lastly, a quantity of sulphate of iron is introduced, and the whole passed through a hair-sieve. It is generally observed that unboiled inks are less

good red ink is obtained as follows.—A quarter of a pound of the best logwood is boiled with an ounce of pounded alum, and the same quantity of cream of tartar, with half the quantity of water, and, while the preparation is still warm, sugar and good gum-Arabic, of each one ounce, are dissolved in it. Solutions of indigo with pieces of alumina, and mixed with gum, form a blue ink. Green ink is obtained from verdigris, distilled with vinegar and mixed with a little gum. Saffron, alum, and gum-water, form a yellow. It is not well ascertained how soon the present kind of writing-ink came into use. It has certainly been employed for many centuries in most European countries; but the ancient Roman inks were, for the most part, of a totally different composition, being made of some vegetable carbonaceous matter, like lamp-black, diffused in a liquor. Sometimes the ink of very old writings is so much faded by time as to be illegible. Doctor Blagden (*Philosophical Transactions*, vol. 77), in his experiments on this subject, found that, in most of these, the colour might be restored, or, rather, a new body of colour given, by pencilling them over with a solution of prussiate of potash, and then with a dilute acid, either sulphuric or muriatic; or else, *vice versâ*, first with the acid, and then with the prussiate.

INLAND NAVIGATION. A general account of CANAL NAVIGATION has already been given under that head; and a view of river navigation will appear under RIVERS. We now purpose giving a general view of the canals in Canada. Those of the United States of America will be noticed in their several geographical divisions, as they are too numerous to be brought into one article.

Welland Canal was constructed between the years 1824 and 1829. Its length is forty-one miles and a half; its breadth at the surface fifty-eight feet, at the bottom twenty-six feet, and its depth eight feet. This line of navigation passes from the mouth of Ouse River, on Lake Erie, north-eastward, to strike at a point of the Welland or Chippewa River; and, taking the course of that river, downwards, eleven miles, proceeds thence northward, across the mountain ridge, and down to the mouth of Twelve-Mile Creek, on Lake Ontario. The distance from lake to lake is forty-three miles. The deepest cutting, near the summit, is fifty-six feet. It has thirty-five locks, one hundred to one hundred and twenty-five feet long, twenty-two to thirty-two feet wide. The capital stock of the company is 200,000*l.*; the number of shares 16,000. This canal admits of sloop navigation, and opens a communication between Lake Erie and Lake Ontario in the same vessels, which are thus enabled to navigate those lakes without discharging and reloading cargoes. One of the purposes of its construction was, to prevent the trade of that part of Upper Canada which communicates with the great western lakes from being diverted to New York, by the route of the Erie Canal. It was an arduous and stupendous work, as appears sufficiently from the dimensions and length of the canal. Its execution was, however, facilitated by taking advantage of natural channels of slack-water.

La Chine Canal is ten miles in length, from Montreal, on the St. Lawrence, directly to Upper La Chine, on Lake St. Louis, cutting off a bend in the river, and avoiding the rapids of St. Louis. Cost, 220,000*l.*; for sloop navigation.

L'Isle Perrault Canal is a projected work of five miles in length, from St. Louis Lake, at the foot of St. Anne's rapids, to the head thereof, by a canal, passing either at the back of St. Anne's or else across the Isle Perrault.

Grenville Canal is a projected work of twelve miles in length, from the head of Long Sault, or Ottawa falls, at the village of Grenville, by a lateral canal to the foot of Carillon rapids, opposite Point Fortune; for sloop navigation. Estimated cost, 250,000*l.*

La Petite Nation Canal is a projected artificial channel of navigation, of fifty miles in length, from the foot of Carillon rapids, at Hawkesbury, on the Ottawa, across the peninsula, to the St. Lawrence, at Prescott.

The *Rideau Canal*, which is now just completed, is described, and a view of its locks given, under the cut CANADA, in the Second Division of this work.

INSTRUMENT, in *music*; any sonorous body, artificially constructed for the production of musical sound. Musical instruments are divided into three kinds—wind-instruments, stringed instruments, and instruments of percussion. Of the stringed instruments among the ancients, the most known are the lyre, psalterium, and trigonium; the principal wind-instruments are the tibia, fistula, tuba, cornu, and lituus; those of percussion, the tympanum, cymbalum, and crepitaculum.

INSTRUMENTAL MUSIC; music produced by *instruments*, as contradistinguished from vocal music. The term *instrumental* is particularly applied to the greater compositions, in which the human voice has no part. The first instrument invented was probably the pipe or flute. An idle shepherd might very naturally, from accident, or in imitation of the effects of the wind, blow through a simple reed, and thus invent the pipe, from which the flute would readily originate. The pipe is, in fact, found among many savages. The invention of stringed instruments, as they are more artificial, is of later origin. The instrumental music of the Greeks was confined to a few instruments, among which the flute, the cithara, the sackbut, though not precisely like those instruments among the moderns, were the most important. The violin was invented in the middle ages, and soon became the principal instrument, taking place above the flute, though the latter is of much more ancient origin, because the playing on a stringed instrument is less fatiguing, and the tone of the violin is more distinct from the human voice, and therefore better fitted to be used with it; besides, the instrument permits much more perfect execution. Until the middle of the last century, the Italian composers used no other instruments in their great pieces than violins and bass-viols; at that time, however, they began to use the hautboy and the horn; but the flute has never been much esteemed in Italy, particularly in music exclusively instrumental. These were the only wind-instruments in Italy, used in instrumental music, until the end of the last century; and even to this day the Italians use wind-instruments much less than the Germans, and particularly the French. Since Mozart, every instrument has been used which appeared adapted to answer a particular purpose. This is the cause of the fewness of the notes in the Italian, and of their great number in German, and their excess in the modern French scores. In general, symphonies and overtures, solos, duets, terzettos, quartettos, quintettos, &c., sonatas, fantasias, con-

certos for single instruments, dances, marches, &c., belong to instrumental music.

INSURANCE is a contract whereby, for a stipulated consideration, called a *premium*, one party undertakes to indemnify another against certain risks. The party undertaking to make the indemnity is called the *insurer* or *underwriter*, and the one to be indemnified the *assured* or *insured*. The instrument by which the contract is made is denominated a *policy*; the events or causes of loss insured against, *risks* or *perils*; and the thing insured, the *subject* or *insurable interest*. *Marine* insurance relates to property and risks at sea; insurance of property on shore against fire is called *fire* insurance; and the written contracts, in such cases, are often denominated *fire* policies.

There was a kind of insurance in use among the Greeks and Romans, called *bottomry* or *respondentia*, which is where the owner of a vessel or goods borrows money upon bottomry, upon the vessel, or upon respondentia on the goods, for a certain voyage, agreeing that, if the ship or goods arrive at a certain port, the money shall be repaid, and also interest, exceeding the legal rate; but, if lost by the risks specified in the bond before arriving at the port named, the lender is to lose the money loaned. This risk of losing the whole capital is the cause of the excess of interest allowed in case of the arrival of the ship or goods; and it is called *marine interest*, which ought to be equal to the common rate of interest added to the rate of premium for insuring the ship or goods for the same voyage against the same risks. This sort of contract was anciently in use, and, as the laws then gave less security, or, at least, as credit and confidence were not so widely diffused, and correspondence was less extensive among merchants, it was usual for the lender to send some person with the property, to receive repayment of the money loaned and the marine interest, at the port where the risk terminated. In modern times, it is not usual to send any person with the property, who would not be of service during the voyage; and, at its termination, some agent of the lender, at the port of arrival, if he is not there himself, looks after his interest.

The wide extension of correspondence, among merchants in all parts of the world, in modern times, gives a facility for this purpose, and renders the execution of this, as well as other commercial contracts, more economical, and at the same time more secure. But contracts of insurance, strictly so called, are of modern invention; and their importance, in relation to commerce, is scarcely inferior to that of bills of exchange. Every merchant is liable to losses and reverses, by the change of the markets. The risks of this description may, however, be calculated upon with some degree of probability; but those of fire, the perils of the seas, or capture, cannot be so well estimated; and, when they come, they would, in many cases, bring ruin upon the merchant, if it were not for the system of insurance, the object of which is to apportion the losses from these disasters among all those whose property is exposed to the same hazards. If, for instance, all persons engaged in trading were to enter into a general agreement to contribute for the losses of each other, occasioned by those casualties, in the proportions of the amounts that they should respectively have at risk, every individual would then only run the risk of the proportion of losses occurring upon the general aggregate of property at risk. But as such a general combination would be complicated, and practically inconvenient, a very simple system is devised, by means of insurance, for effecting the same object; for one person—the underwriter—agrees to take upon himself those risks for a hundred merchants, more or less, for a certain premium on each risk, calculating that the premiums on the fortunate adventurers will compensate him for the losses he may incur on those which are unfortunate, and leave him some surplus, as a compensation for his time and trouble; and a little experience will enable him to calculate the chances with very considerable accuracy. The result accordingly is, that all the persons who procure their property to be insured by him, in effect, mutually contribute for each other's losses, by the bargain of each with the common receiver of the contributions of all. This contract was subjected to a system of definite rules much earlier in Italy and France than in England; and, as the contract is the same in principle and very similar in form in different countries, the rules of construction adapted to it in one country are equally applicable in another.

Insurances on human life may now be noticed. The duration of life, over which the most healthy and the most temperate man has no certain control, must necessarily appear a matter of chance when individually considered. If, however, we regard the human species in masses, we are enabled to ascertain with considerable precision the average of life; and thus to apply a system of insurance, not to life itself, for that is, of course, dependent upon a higher power than man, but against the injurious consequences which proceed from the death of those upon whom the support of others depends. If we take ten millions of people, for instance, and ascertain the age to which each person arrived previously to his death, by dividing the total of their ages by the number of individuals, we establish the average term of the duration of life. This term varies in particular countries and under different states of society; but it is invariably found to increase with the increase of the means of comfort. The average term of life in Great Britain is thus longer, by almost one-third, than it was during the last century. The rate of mortality in 1780 was one in forty; in 1821 it was one in fifty-eight. Vaccination, and the great improvements in medical science, have doubtless contributed to this result. To establish data for determining this mean length of life has been an important object with statesmen, of late years, and forms a great branch of the science of statistics. The tables which have been constructed upon the experience of most European nations enable us, not only to determine the average term of life, but the probabilities of the number of years a person of any particular age has to live. Upon these calculations is founded the system of life-assurances and annuities; and the various corporations which grant life-assurances are enabled to conduct their operations upon a just and solid foundation, in proportion as they form their estimates upon averages equally supported by science and experience. To all persons whose income is not permanent, and who are unable to lay by a sufficiency to prevent the lamentable consequences to their children of an inadequate provision, the principle of life-assurance offers a safe and effectual remedy against the chances of mortality, which no prudent father should forego, if the annual sacrifice

be at all within his ability. We subjoin a table of the value of an annuity of 100*l.* on a single life from birth to 70 years of age.

Age.	Value. £.	s.	Age.	Value. £.	s.	Age.	Value. £.	s.
Birth.	1032	14	24	1556	0	48	1168	10

INTAGLIO. See GEM.

INTEREST is the allowance made for the loan or forbearance of a sum of money, which is lent for, or becomes due at, a certain time; this allowance being generally estimated at so much per cent. per annum, that is, so much for the use of 100*l.* for a year. Interest is either *simple* or *compound*. *Simple interest* is that which is allowed upon the principal only, for the whole time of the loan or forbearance. The money lent, or forborne, is called the *principal*; the sum paid for the use of it the *interest*. The interest of 100*l.* for one year is called the *rate per cent.*, and the sum of any principal, and its interest, together, the *amount*. *Compound interest* is that which arises from any sum or principal in a given time, by increasing the principal, at fixed periods, by the interest then due, and hence obtaining interest upon both interest and principal. The accumulation of money, when placed at compound interest, after a certain number of years, is exceedingly rapid, and in some instances appears truly astonishing.

INTERVAL; the difference in point of gravity or acuteness between any two sounds. Taking the word in its more general sense, we must allow that the possible *intervals* of sound are infinite; but we now speak only of those intervals which exist between the different tones of any established system. The ancients divided the *intervals* into simple or uncomposite, which they called *diastems*, and composite intervals, which they called *systems*. The least of all the *intervals* in the Greek music was, according to Bacchius, the enharmonic diesis, or fourth of a tone; but our scale does not notice so small a division, since all our tones concur in consonances, to which order only one of the three ancient genera, viz. the diatonic, was accommodated. Modern musicians consider the *semitone* as a simple interval, and only call those composite which consist of two or more semitones: thus from B to C is a semitone, or simple interval, but from C to D is two half tones, or a compound interval.

INTESTINE. The convoluted membraneous tube that extends from the stomach to the anus, receives the ingested food, retains it a certain time, mixes with it the bile and pancreatic juice, propels the chyle into the lacteals, and covers the fæces with mucus, is so called. The intestines are situated in the cavity of the abdomen, and are divided into the small and large, which have, besides their size, other circumstances of distinction. The small intestines are supplied internally with folds, called *valvulæ conniventes*, and have no bands on their external surface. The large intestines have no folds internally, but are supplied externally with three strong muscular bands, which run parallel upon the surface, and give the intestines a saccated appearance; they have also small fatty appendages, called *appendiculæ epiploicæ*. The first portion of the intestinal tube, for about the extent of twelve fingers' breadth, is called the *duodenum;* it lies in the epigastric region, makes three turnings, and between the first and second flexure receives, by a common opening, the pancreatic duct, and the *ductus communis choledochus*.

It is in this portion of the intestines that chylification is chiefly performed. The remaining portion of the small intestines is distinguished by an imaginary division into the *jejunum* and *ileum*. The *jejunum*, which commences where the *duodenum* ends, is situated in the umbilical region, and is mostly found empty; hence its name: it is every where covered with red vessels, and, about an hour and a half after a meal, with distended lacteals.—The *ileum* occupies the hypogastric region and the pelvis, is of a more pallid colour than the former, and terminates by a transverse opening into the large intestines, which is called the *valve of the ileum*, the *valve of the cæcum*, or the *valve of Tulpius*. The beginning of the large intestines is firmly tied down in the right iliac region, and, for the extent of about four fingers' breadth, is called the *cæcum*, having adhering to it a worm-like process, called the *processus cæci vermiformis*, or *appendicular cæci vermiformis*. The great intestine then takes the name of *colon*, ascends towards the liver, passes across the abdomen, under the stomach, to the left side, where it is contorted like the letter S, and descends to the pelvis; hence it is divided, in this course, into the *ascending portion*, the *transverse arch*, and the *sigmoid flexure*. When it has reached the pelvis, it is called the *rectum*, whence it proceeds in a straight line to the anus.

The intestinal canal is composed of three membranes or coats; a common one from the *peritoneum*, a muscular coat, and a villous coat, the *villi* being formed of the fine terminations of arteries and nerves, and the origins of lacteals and lymphatics. The intestines are attached to the body by the mesentery; the *duodenum* has also a peculiar connecting cellular substance, as have likewise the colon and rectum, by whose means the former is firmly accreted to the back, the colon to the kidneys, and the latter to the *os coccygis*, and in women to the vagina. The remaining portion of the tube is loose in the cavity of the abdomen. The arteries of this canal are branches of the *superior* and *inferior mesenteric*, and the *duodenal*. The veins evacuate their blood into the *vena portæ*. The nerves are branches of the eighth pair and intercostals. The lacteal vessels, which originate principally from the *jejunum*, proceed to the glands in the mesentery.

INTONATION, in *music*, relates both to the consonance and to the strength or weakness of sounds. Intonation not only includes the act of tuning, but the giving to the tones of the voice or instrument that occasional impulse, swell, and decrease, on which, in a great measure, all expression depends. A good intonation is one of the first qualifications in the higher walks of execution.

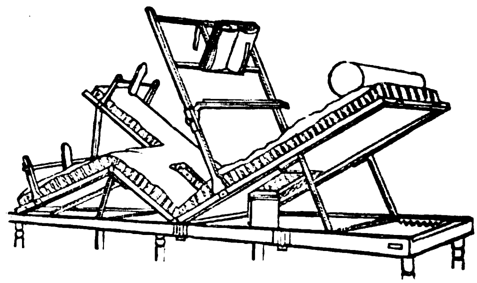
In church music, those antiphonies are called *intonations* which are first sung by the priest, and then responded by the choir or the congregation; also the short sentence, mostly taken from the bible, which the minister sings before the collect, and which is responded by the choir or community. Such are the *Gloria*, "The Lord be with you," &c.

INTOXICATION. See DRUNKENNESS and TEMPERANCE.

INTRENCHMENT; any work that fortifies a post against the attack of an enemy. The word is generally used to denote a ditch or trench with a parapet. Intrenchments are sometimes made of fascines with earth thrown over them, of gabions, hogsheads, or bags filled with earth, to cover the men from the enemy's fire.

INVALIDS; soldiers and officers, who are disabled for foreign service by wounds, disease, or age, and who are generally maintained for life in public establishments (hospitals), at the public expense. The Athenians had a law providing for the public maintenance of persons disabled in war. The Romans also made some, though small, provision for invalids. At a later period, they were taken care of in the monasteries. Philip Augustus of France first formed the plan of an hospital for invalids; but, as Pope Innocent III. would not permit this institution to be placed under the direction of the bishop, the king relinquished the plan. Louis XIV. was the first who carried this design into execution. Between 1671 and 1679, he erected a splendid hospital at Paris, in the suburb of St. Germain. A church, a department for the sick, a governor, and other officers, are attached to it. A soldier must have served ten years to be received into this hospital on account of poverty or infirmity. The invalids who mount guard are the only ones who bear arms. This institution suffered very much at the commencement of the revolution; but, during the imperial government, it was put in a better condition than ever. The architect of the hospital was Bruant. It is composed of five courts surrounded by buildings. A vast esplanade, bordered by rows of trees, and decorated with a fountain, gives the principal *façade*, towards the Seine, a noble perspective. The *hôtel* has a library of 20,000 volumes. It is capable of containing 7000 men, and is governed by a marshal of France. The church is considered a *chef-d'œuvre* of French architecture; its dome supports a lantern, which is surmounted by a cross 308 feet high. From the dome were formerly suspended 3000 colours, taken from different nations; but they were taken down and burnt by the invalids, at the time when the allies entered Paris, that they might not be retaken. Works in statuary and painting, by Lafosse, Boullongne, Coypel, Coustou, Coysevox, &c., adorn the ceilings, niches, and other parts of the buildings. Frederick the Great, in 1748, built the hospital at Berlin, with the inscription *Læso et invicto militi*. Our own hospitals at Greenwich and Chelsea are the best regulated of the kind.

INVALID BED. There are many contrivances under this name, but the one represented beneath seems the best mechanical arrangement for the purpose.



It is the invention of Mr. Earl, and consists of a strong frame supporting a jointed bedstead. The situation of the pillow points out the part of the apparatus which supports the upper portion of the body. The mattress should be either of horse-hair or wool, and nailed round its edges to the upper division of the movable frame.

Another form of bed for an invalid has been suggested by Dr. Arnott. It consists of a trough containing water, and covered with a cloth composed of cotton coated with Indian rubber. This forms one of the softest and most flexible beds that has ever been devised.

INVENTION, in *science*, is distinguished from *discovery*, as implying more creative combining power, and generally signifies the application of a discovery to a certain purpose. But the distinction is often very nice, and it is difficult, in many cases, to say which word is the more suitable. Every invention includes a discovery. Inventions owe their origin, as discoveries do, either to chance, to some happy idea suddenly striking the mind, or to patient reflection and experiment. Many inventions belong to the two former heads. Of the third class of inventions, late years afford many instances, owing to the great attention which has been paid to the natural sciences. As man, in modern times, is always inclined to consider that which is nearest him the most important, he generally considers the inventions of his age as far surpassing those of other times; but the study of history teaches us more modesty. The invention of the screw, of the wheel, of the rudder, of the double pulley, may be compared with any modern inventions in mechanical science, and could not, moreover, have been struck out at once by chance. The history of inventions is one of the most interesting branches of the historical sciences, exhibiting in a striking light the stages of progress and decline in human activity, and the great variety of motives which have actuated different ages.

INVISIBLE GIRL. This curious acoustical exhibition was contrived by a foreigner, about thirty years ago. It consisted of a hollow copper ball, to which were attached four trumpets, and which was suspended by ribands from the four corners of a frame resembling a bed-post, and having no other connection with the frame. The globe was supposed to contain the invisible being, as the voice apparently proceeded from the interior of it. If a question was asked by speaking into one of the trumpets, an answer was returned in a low female voice proceeding from all the trumpets. This effect was produced by one of the standards of the frame being

hollow, opening opposite the mouth of one of the trumpets, and communicating with a large case placed in an adjoining room, and containing the confederate.

Upon this principle also is constructed the *oracular bust*, which is thus made :—Place a bust on a pedestal in the corner of a room, and let there be two tin tubes, one going from the mouth and the other from the ear of the bust, through the pedestal and floor, to an under apartment; there may likewise be wires that go from the under jaw and the eyes of the bust, by which they may be easily moved. A person being placed in the under room, and at a given signal applying his ear to one of the tubes, will hear any question that is asked by another person above who speaks into the ear of the bust, and he may immediately reply; the sound will move through the tube, and seem to come from the mouth of the bust.

INVOICE; an account, in writing, of the particulars of merchandise, with their value, custom, charges, &c., transmitted by one merchant to another in a distant country.

INVOLUTION, in *mathematics;* the raising of a quantity from its root to any power assigned. Thus $2\times2\times2=8$. Here 8, the third power of 2, is found by involution. By continuing the process, we can obtain any power of 2, and so with other numbers.

IODINE is the name of an undecompounded principle or element in chemistry. It had escaped the observation of chemists until 1812, when a manufacturer of saltpetre, at Paris, detected it in the ashes of sea-weeds, in the following manner. In evaporating the ley from these ashes, to procure the carbonate of soda which they contain, he noticed that the metallic vessels with which he operated were powerfully corroded, and that the corrosion was increased as the liquor became more concentrated. Having at hand, one day, a bottle of sulphuric acid, he added some of it to a portion of water, and was surprised to see a rich violet vapour disengaged; this vapour was the iodine. He at once communicated the observation to M. Clément Desormes, who set about collecting some of the vapour, and, after examining its leading properties, announced it to the Royal Institute of France as a new body. Its real nature was soon after unfolded through the accurate researches of Gay-Lussac and Sir H. Davy. Its history proved singularly interesting in modifying the then prevailing theory of chemistry. Sir H. Davy had, a few years previously, promulgated the new theory of chlorine, which was still received with suspicion among chemists. The strong analogies, however, between this substance and chlorine, in their relations to combustibles,—both bodies forming compounds by uniting with them, similar to acids containing oxygen, or oxides,—were conceived to give great weight to the views of Sir H. Davy, and operated completely to overthrow the erroneous hypothesis of oxygenation invented by Lavoisier. Its investigation, therefore, may be said to form a new era in chemistry.

The physical properties of iodine are as follow :—It is a soft, friable, opaque solid, of a bluish-black colour, with a metallic lustre, usually in scales, but sometimes in distinct crystals of the form of rhomboids or rhomboidal tables, referrible to an octahedron, with a rhombic base as their primary form; its specific gravity is 4.046. It possesses an odour somewhat analogous to that of chlorine. It is a non-conductor of electricity, and possesses in an eminent degree the electrical properties of oxygen and chlorine.

Iodine enters into fusion at 225° Fahr., and boils at 347°; but, when moisture is present, it sublimes rapidly at a temperature considerably below 212°, and gives rise to a dense vapour of the usual violet hue. It is scarcely at all soluble in water, but is readily taken up by alcohol and ether, to which it imparts a reddish-brown colour. It extinguishes vegetable colours, but with less energy than chlorine. It is not inflammable. Its range of affinity for other bodies is very extensive; the most important compounds it forms with these we shall describe after alluding to its natural state and preparation. It exists most abundantly in the various species of fucus, which form the greatest part of the sea-weeds of our coast; it also occurs in the sponge, and in the coverings of many molluscous animals, and has been found in a great number of mineral waters, as those of Salz in Piedmont, Saratoga in New York, &c., and more recently has been detected in some silver ores from Mexico, and in an ore of zinc from upper Silesia. But it is from the incinerated sea-weed, or kelp, that the iodine in large quantities is obtained.

As the soap-manufacturers are in the habit of obtaining their soda from kelp, iodine may be procured, very economically, from the residuums of their operation, according to the process invented by Dr. Ure, which is as follows :—The brown iodic liquor of the soap-boiler, or the solution of kelp from which all the crystallizable ingredients have been separated by concentration, is heated to about 230° Fahr., poured into a large stone-ware basin, and saturated with diluted sulphuric acid. When cold, the liquor is filtered through woollen cloth; and to every 12 oz. (apothecaries' measure) of it are added 1000 grains of black oxide of manganese in powder. The mixture is put into a glass globe, or large matrass with a wide neck, over which a glass globe is inverted, and heat is applied, which causes the iodine to sublime copiously, and to condense in the upper vessel. As soon as the balloon becomes warm, another is substituted for it; and, when the second becomes heated, the first is again applied. The iodine is withdrawn from the globes by a little warm water, which dissolves it very sparingly; and it is purified by undergoing a second sublimation. The test made use of for the detection of iodine in any solution, when it is suspected to be present, is starch, with which iodine has the property of uniting, and of forming with it a compound, insoluble in cold water, which is recognized with certainty by its deep blue colour. The solution should be cool at the time of adding the starch; and, if the colour does not become apparent simply on the addition of the starch, a few drops of sulphuric acid should be cautiously added, when, if any iodine be present, the blue colour will make its appearance. This test is so exceedingly delicate that a liquid, containing $\frac{1}{450000}$ of its weight of iodine, receives a blue tinge from a solution of starch.

Iodine has a powerful affinity for hydrogen, which it takes from animal and vegetable substances, in the same manner as chlorine, and, uniting with it, forms hydriodic acid. The following are the methods for obtaining this acid in the gaseous and in the liquid state:—Into a flask, to which a recurved tube is fitted, dipping under a jar of mercury, are introduced eight

parts of iodine and one of phosphorus, and to the mixture a few drops of water are added; the water is immediately decomposed; the phosphorus, seizing its oxygen, forms phosphoric acid, while the hydrogen combines with the iodine. As there is not water present in sufficient quantity to dissolve the hydriodic acid, it passes over in the gaseous state, and is collected over the mercury. In contact with air, it smokes, or fumes, like muriatic acid, and, like it, reddens vegetable blues. It is distinguished, however, from that acid, by the superior affinity possessed by chlorine for hydrogen, in consequence of which, if chlorine and hydriodic gases are mingled together, the yellow colour of the former disappears, and the violet vapour of iodine makes its appearance, which proves the decomposition of the hydriodic acid by the chlorine. If the decomposition be complete, the vessel will be wholly occupied by muriatic acid gas.

To obtain the hydriodic acid in a liquid state, we have only to conduct the gas through water, until it is fully charged with it; or it may be obtained by transmitting a current of sulphuretted hydrogen gas through water in which iodine, in fine powder, is suspended. The iodine, from a greater affinity for hydrogen than the sulphur possesses, decomposes the sulphuretted hydrogen; and hence sulphur is set free, and hydriodic acid produced. The solution of hydriodic acid is easily decomposed. Thus, on exposure for a few hours to the air, the oxygen of the atmosphere forms water with the hydrogen of the acid, and liberates the iodine. Nitric and sulphuric acids likewise decompose it by yielding oxygen, the former being converted into nitrous and the latter into sulphurous acid. The free iodine becomes obvious on the application of the above-mentioned test. The compounds of hydriodic acid with the salifiable bases may be easily formed, either by direct combination, or by acting on the bases in water with iodine. Sulphurous and muriatic acids, as well as sulphuretted hydrogen, produce no change on the hydriodates, at the usual temperature of the air; but chlorine, nitric and concentrated sulphuric acid, instantly decompose them, and separate the iodine. The hydriodates of potash and soda are the most interesting of their number, because they are the chief sources of iodine in nature. The latter salt is probably the one which affords the iodine obtained from kelp; while it is believed that it is the hydriodate of potash which is most generally found in mineral springs.

Iodine forms acids by uniting with oxygen and with chlorine. When it is brought into contact with protoxide of chlorine, immediate action ensues; the chlorine of the protoxide unites with one portion of iodine, and its oxygen with another, forming two compounds,—a volatile orange-coloured matter, the chloriodic acid, and a white solid substance, which is iodic acid. Iodic acid acts powerfully on inflammable substances. With charcoal, sulphur, sugar, and similar combustibles, it forms mixtures which detonate when heated. It enters into combination with metallic oxides, giving rise to salts called *iodates*. These compounds, like the chlorates, yield pure oxygen by heat, and deflagrate when thrown on burning charcoal. Iodic acid is decomposed by sulphurous, phosphorous, and hydriodic acids, and by sulphuretted hydrogen. Iodine, in each case, is set at liberty, and may be detected, as usual, by starch. Chloriodic acid, which is also formed by simply immersing dry iodine in chlorine gas, deliquesces in the open air, and dissolves very freely in water. Its solution is very sour to the taste; and it reddens vegetable blues, but afterwards destroys them. It does not unite with alkaline bases; in which respect it wants one of the characteristics of an acid, and has hence been called by Gay-Lussac a *chloride of iodine*. Iodine unites with nitrogen, forming a dark powder, which is characterized, like chloride of nitrogen, by its explosive property. In order to form it, iodine is put into a solution of ammonia; the alkali is decomposed; its elements unite with different portions of iodine, and thus cause the formation of hydriodic acid and iodide of nitrogen. Iodine forms, with sulphur, a feeble compound, of a grayish-black colour. With phosphorus, also, it combines with great rapidity at common temperatures, attended with the emergence of heat. It manifests little disposition to combine with metallic oxides; but it has a strong attraction for the pure metals, producing compounds which are called *iodurets*, or *iodides*.

The iodides of lead, copper, bismuth, silver, and mercury, are insoluble in water, while the iodides of the very oxidizable metals are soluble in that liquid. If we mix a hydriodate with the metallic solutions, all the metals which do not decompose water will give precipitates, while those which decompose that liquid will give none. Iodine, besides being employed for philosophical illustration, is used in the arts, for pigments, dyes, and medicine.

Iolite. See Mineralogy.

Ionian Order. See Architecture.

Ipecacuanha, according to the latest authorities, is the product of two different plants, both natives of South America. The gray is the root of a species of *richardia*; the other that of the *cephælis ipecacuanha*. The two roots, however, do not differ in their medicinal properties, and they are much employed indiscriminately. Ipecacuanha was first brought to Europe towards the middle of the seventeenth century; but was not generally used till about the year 1686, when it was introduced under the patronage of Louis XIV. Its taste is bitter and acrid, covering the tongue with a kind of mucilage. It is one of the safest and mildest emetics with which we are acquainted, and is administered as a powder, in the tincture, or infused in wine. It is also less injurious, if it does not operate as an emetic, than antimony, from its not disturbing the bowels as that does.

Iridium; the name of a metal discovered in 1803, by Mr. Tennant, in the black residuum from the solution of the ore of platinum. Its name was bestowed in allusion to the rainbow (*iris*), in consequence of the changeable colour it presents while dissolving in muriatic acid. Its colour is white; it is brittle, and very difficult of fusion; specific gravity, 18.68. It is acted upon with difficulty even by the nitro-muriatic acid; but, when oxidized by digestion with it, it unites with other acids, and with the earths, particularly with alumine. It combines with sulphur, by heating a mixture of ammonia, muriate of iridium, and sulphur; the compound is a black powder, consisting of 100 iridium and 33.3 sulphur. Lead unites with this metal easily, but is separated by cupellation, leaving the iridium on the cupel, as a coarse black powder. Copper forms with it a very malleable alloy, which after cupellation, with the addition of lead, leaves a small proportion of the iridium, but much

less than in the preceding instance. Silver forms with it a perfectly malleable compound, the surface of which is merely tarnished by cupellation; yet the iridium appears to be diffused through it in fine powder only. Gold remains malleable, and little altered in colour, though alloyed with a considerable proportion; nor is it separable by cupellation. Dr. Wollaston observed that, among the grains of crude platinum, there are some scarcely distinguishable from the rest but by their insolubility in nitro-muriatic acid. They are harder, however, when tried by the file, not in the least malleable, and of the specific gravity of 19.5. These he concluded to be an ore consisting entirely of iridium and osmium.

Iron. This metal is extremely diffused. It exists in the mineral kingdom in large quantities, and under numerous forms; it is a constituent principle of vegetable matter, and is obtained from the ashes of almost every plant; it exists in the blood, and other animal products; it is even an atmospheric or meteoric production, those stony masses which at different times, and in different countries, have fallen from the atmosphere, containing iron as their principal ingredient.

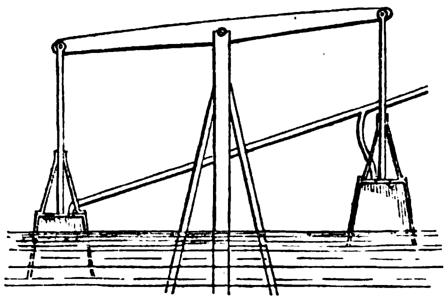
The ores from which iron is extracted are those in which it is mineralized by oxygen, of which there are many varieties, consisting of the oxide intermixed with argillaceous, calcareous, and silicious earths. It is principally from the argillaceous ore, or clay iron-stone, that iron is extracted in this country. After raising, the ores are picked, to separate, as far as possible, the considerable pieces of earthy or otherwise refractory matters, with which they may be associated. They are next submitted to a roasting, in large heaps, in the open air, to expel the sulphur and arsenic which they may contain, as well as to render them more friable and easy of further reduction to powder. The roasting is performed generally by bituminous coal. The result of the operation is, that it becomes full of fissures, friable, and loses altogether its vitreous lustre. It is now transferred to the crushing-mill, where it undergoes a further pulverization, after which it is transported to the smelting furnace, to be converted into iron. Here it passes through two distinct operations—1. the reduction of the oxide to the metallic state; 2. the separation of the earthy matters in the form of scoria. These processes consist in exposing the ore, ordinarily mixed with certain fluxes, to the action of carbon at an elevated temperature, in furnaces urged by bellows, hence called *blast-furnaces*, or sometimes *high-furnaces*. These furnaces vary in height from twelve to sixty feet, and have, externally, the shape of a four-sided pyramid, truncated at top, and terminating in a cylindrical chimney, whose internal diameter is from four to six feet. The interior body of these furnaces is usually in the circular form, except the laboratory at its bottom, where the liquid metal gathers. This, called sometimes the *crucible* or *hearth*, is a right-rectangular prism, oblong in the direction perpendicular to the blast orifices, or tuyeres of the bellows. The sides of the crucible are commonly made of a fine gritstone.

Above the crucible the boshes are placed, in the form of an inverted quadrangular pyramid, approaching to the prismastic shape; and above these stone boshes rises the conical body of the furnace, lined with fire-bricks, contracting as it ascends, like the narrow end of an egg, until it terminates in the chimney. The entire furnace is built in a very solid manner, and strengthened by bands and cross bars of iron. The bellows are usually cylindrical, and their pistons worked either by water or a steam-engine. The blast-holes, which are situated in the upper part of the crucible, are two in number, and frequently placed on opposite sides, but so angled that the currents of air do not impinge on each other. At the lower part of the crucible are openings for the discharge of the metal and scoria. These openings are kept stopped by accumulations of clay and sand upon the exterior when the furnace is in operation. The process of reduction commences by first gradually heating up the furnace, until it will bear to be filled entirely with fuel, after which, as the contents of the furnace begin to sink, alternate charges of ore mingled with flux, and of charcoal or coke, are added: the blast is let on, and the metal in the ore, parting with its oxygen, flows by degrees, and subsides to the bottom of the crucible, covered with a melted slag. The slag is occasionally allowed to flow off by removing the clay from some one of the apertures in the crucible; and when the bottom of the furnace becomes filled with the metal, which it ordinarily does after a space of nine or twelve hours, the iron itself is discharged by one of these openings, into a fosse of sand mingled with clay. As soon as the iron has flowed out, the aperture is closed again; and thus the furnace is kept in incessant activity.

The flux employed to assist the fusion of the ore, by vitrifying the earths associated in it with the oxide of iron, is limestone of the best quality. The iron which has run out from the blast-furnace is in the condition of cast-iron, or iron with a considerable portion of carbonaceous matter intermingled with its particles, and a small proportion of oxygen, from which causes it has a coarse grain, and is brittle. In converting it into bar-iron, it undergoes one or the other of the following processes, according as charcoal or coke is employed. In the former case, a furnace is made use of resembling a smith's hearth, with a sloping cavity sunk from ten to twelve inches below the blast-pipe. This cavity is filled with charcoal and scoria, and on the side opposite to the blast-pipe is laid a pig of cast-iron, well covered with hot fuel. The blast is then let in, and the pig of iron, being placed in the very focus of the heat, soon begins to melt, and, as it liquefies, runs down into the cavity below. Here, being out of the direct influence of the blast, it becomes solid, and is then taken out and replaced in its former position, the cavity being again filled with charcoal. It is thus fused a second time, and after that a third time, the whole of these three processes being usually effected in between three and four hours. As soon as the iron is become solid, it is taken out and very slightly hammered, to free it from the adhering scoria. It is then returned to the furnace, and is placed in a corner, out of the way of the blast, and well covered with charcoal, where it remains till, by further gradual cooling, it becomes sufficiently compact to bear the tilt, or trip-hammer, whose weight varies from 600 to 1200 lbs., and which is moved by water. Here it is well beaten, till the scoria are forced out, and is then divided into several pieces, which, by a repetition of heating and hammering, are drawn into bars, and in this state it is ready for sale.

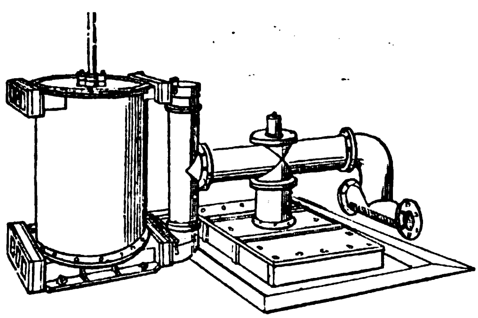
The stream of air employed in a blast-furnace is procured by various processes. The first and most

ancient is evidently that of a pair of bellows; but the friction of the leather is so great as to materially injure the working power. The apparatus represented beneath is in this respect a material improvement on the original arrangement.



A large beam is made to vibrate freely on the axis shown in the figure, and by its vibration the buckets are elevated and depressed. A flexible pipe moves with the buckets, and serves to carry the imprisoned and compressed air to the furnace. On elevating either of the buckets, the air is admitted by a valve opening inwards, which closes when it afterwards descends, and the air is thus forced along the pipe.

The piston blowing-machine is considerably employed, but requires a great deal more power than the one already described. It consists of a piston which nearly fits a case or cylinder, the latter being provided with pipes and valves above and beneath. The external appearance of the apparatus is shown in the figure. When the piston is raised it sucks air from a valve opening beneath, and, when it is depressed, air is drawn from above, and the blast proceeds from beneath.



A complete blast-machine put in operation by a band-wheel is shown at *fig.* 1, *Plate* I., Iron Manufacture.

A contrivance of great importance has lately been adopted in some of the mining districts, which is exceedingly simple, but much more effective than any which had gone before it. A series of vanes are attached to an axis, which is made to revolve with great rapidity in a box. A pipe passes from the outside of the box to the furnace, and as the vanes revolve the air is carried by its centrifugal force into the furnace, a new portion continually entering by a hole at the axis. A similar arrangement has been applied to an artificial blast for a common fireplace.

The proportion of pig-iron or cast-iron from a given quantity of ore is subject to considerable variation, from a difference in the metallic contents of different parcels of ore, and other circumstances; but the amount of bar-iron that a given weight of pig-iron is expected to yield is regulated very strictly, the workmen being expected to furnish four parts of the former for five of the latter, so that the loss does not exceed twenty per cent. The other process for the manufacture of bar-iron, and which is the one chiefly employed in this country, is executed in part in reverberatory furnaces, known by the name of *puddling-furnaces*. The operation commences with melting down the cast-iron in refinery furnaces, like the one above described. When the cast-iron is fully melted, a tap-hole is opened in the crucible, and the fine metal flows out, along with the slag, into a fosse covered with water mixed with clay, which forms a coating, to prevent the metal from sticking to the ground. The finer metal forms a plate ten feet long by three feet broad, and from two inches to two and a half thick. A great quantity of cold water is sprinkled on it, in order to make it brittle, and also to oxidize it slightly. The loss of weight in the iron, by this operation, is from twelve to seventeen per cent. It is then broken to pieces, and laid on the hearth of a reverberatory furnace, in successive portions, being heaped up towards its sides in piles which rise nearly to the roof. The middle space is left open, to give room for puddling the metal as it flows down in successive streams. When the whole is reduced, by the heat of the furnace, to a pasty state, the temperature is lowered, and a little water is sometimes thrown on the melted mass. The workman stirs about the semi-liquid metal with his puddle, during which it swells up, emits a considerable quantity of oxide of carbon, which burns with a blue flame, so that the mass appears to be on fire. The metal, as it refines, becomes less fusible, or, in the language of the workmen, it begins *to dry*. The puddling is continued till the whole charge is reduced to the state of an incoherent sand; then the temperature is gradually increased, so as to impart a red-white heat, when the particles begin to agglutinate, and the charge *works heavy*. The refining is now finished, and nothing remains but to form the metal into balls, and condense it under the rolling cylinders. The *balling-furnace* in which this melting takes place is shown in *Plate* II., *fig.* 3, Iron Manufacture. The iron is now to be passed through hard rollers. A pair of the best kind is shown at *fig.* 5, and an end view of the same at *fig.* 6. When the lump of iron has passed five or six times through the grooved rollers, it assumes an elliptic figure, and is called a *bloom*. Loose fragments of the ball, with the slag, fall down about the cylinder. The metal thus roughed down is called *mill bar-iron*. It is subjected to a second operation, which consists in welding several pieces together, whence it derives the valuable properties of ductility, uniformity, and cohesion. After welding laterally four pieces together, the mass is run through between a series of cylinders, as at first, and becomes English bar-iron.

Iron, for laminating into sheets, is treated in the refinery furnace with a charcoal, instead of a coke fire. The object of all these operations, as respects the treatment of cast-iron, is to convert it into tough iron, and thus to get rid of the slag, the oxygen, and the carbon, it contains. The first of these is separated in part by the long-continued fusion

IRON MANUFACTURE.

and the repose of the melted metal, in consequence of which the slag, being lighter than the bath, floats on its surface; but its more effectual removal is produced by the compression, in which process the earthy masses are forced through the pores of the bloom, or lump, as water exudes from a sponge. Among the different varieties of cast-iron, there are some which contain exactly the proportion of oxygen and carbon proper to form a gaseous combination. For the refinery of these, an elevated temperature, without access of air, is all that is necessary. These elements, re-acting upon one another, are dissipated in the aërial state; but there are likewise other varieties of cast-iron, in which the carbon is in excess. In this case, the free access of atmospherical air is requisite.

In order to understand how the carbon is abstracted from the interior of a mass of the liquefied metal by the oxygen of the atmosphere, which can only be in contact with the surface of the iron, we have merely to reflect upon the reverse process in the manufacture of steel, which consists in the introduction of carbon into iron. At first, an outer coat of iron, by being surrounded with charcoal powder, gets partially saturated with carbon. If, by pushing the cementing process, we wish to arrive at the complete saturation of that coat, we can succeed only by making a previous partition. The layer immediately beneath the first carries off from it a portion of its carbon; and it is not till itself is partly saturated that it suffers the outer coat to absorb its maximum dose of carbon, when it remains stationary; but an effect quite similar takes place with the second coat in reference to the third, that is, the one immediately within or beneath it. To apply these ideas to the refinery processes, the decarburation of the cast-iron is merely a restoration of the carbon to the surface, in tracing inversely the same progressive steps as had carried it into the interior during the smelting of the ore. Thus the oxygen of the air, fixing itself at first at the surface of the cast metal on the carbon which it finds there, burns it. Fresh charcoal, issuing from the interior, comes then to occupy the place of what had been dissipated, till, finally, the whole carbon is transferred from the centre to the surface, and is then converted into either carbonic acid gas, or oxide of carbon—an alternative which may fairly be allowed, since no direct experiment has hitherto proved what is the precise product of this combustion.

Malleable iron is frequently obtained directly from the ores by one fusion, when the metallic oxide is not too much contaminated with foreign substances. This mode of working, which is allowed to be vastly more economical than the one just described, on account of the saving both of time and combustibles, has for a long period been employed in Catalonia, in the Pyrennees, from which circumstance it is called the *method of the Catalonian forge*. Those ores best adapted to its treatment are the pure black oxide, red and brown oxide, and carbonate of iron, to extract the metal from which, it is sufficient to expose them to a high temperature in contact with charcoal or carbonaceous gases. The furnace employed is similar to the refiner's forge already described. The crucible is a kind of semicircular or oblong basin, eighteen inches in diameter, and eight or ten in depth, excavated in an area or small elevation of masonry, eight or ten feet long, by five or six broad, and covered in with a chimney. The tuyere stands five or six inches above the basin, and has a little inclination downwards, and the blast is given by a water blowing-machine. The first step consists in expelling the water combined with the oxide, as well as the sulphur and arsenic, when these contaminations are present. This is done, as usual, by roasting in the open air. The roasted ore is crushed to a tolerably fine powder, and thrown by the shovel-full, at intervals, upon the charcoal fire of the forge hearth, the sides and bottom of the basin being previously lined with two or three *brasques* (coats of pounded charcoal). It gradually softens and unites into lumps more or less coherent, which finally melt and accumulate in the bottom of the crucible or basin. A thin slag is occasionally let off from the upper surface of the melted iron in the basin, by means of holes which are opened and closed according to the discretion of the workmen. The melted iron preserves a pasty condition, owing to the heat communicated from above; and, when a mass of sufficient dimensions has accumulated, it is removed, put under the hammer, and forged at once. A tilt-hammer consisting of two beaters, worked by a wheel and axis furnished with teeth for raising the hammer, is shown at *fig.* 2, *Plate* I., IRON MANUFACTURE; and the remainder of the small tools employed in the foundry, at *fig.* 4, *Plate* II. A lump or bloom of malleable iron is thus produced in the space of three or four hours. The iron is generally soft, very malleable, and little steely. Four workmen are employed at one forge; and, by being relieved every six hours, they are enabled to make 86 cwt. of iron per week. In the Catalonian forges, 100 lbs. of iron are obtained from 300 lbs of ore (a mixture of sparry iron, or carbonate, and hematite) and 310 lbs. of charcoal, being a produce of 33 per cent.

The number of high furnaces in blast in England, Scotland, and Wales, at several periods, from 1740 up to 1827, have been collected from documents on which we consider every reliance may be placed:—

	Tons.
In 1740 the iron made amounted to	17,000
1788	68,000
1796	121,000
1806	250,000
1820	400,000
1827	690,000

In the year 1740, only fifty-nine furnaces were in blast; in 1778, they had increased to eighty-five; and in 1796, to 121; while the number of furnaces in blast in 1827 was 214.

An account of the number of works for blasting of iron in each mining district in Great Britain, with the average produce per week in each district, in the year 1825.

Mining Districts of	Number of Works.	Number of Furnaces. Total.	out of Blast.	in Blast.	Produce in Tons; per Week	Year.
1 South Wales	37	109	27	80	4,460	223,520
2 Staffordshire	54	108	27	80	3,503	171,735
3 Shropshire	23	49	13	36	1,723	86,320
4 Yorkshire	14	34	12	22	752	35,308
5 Scotland	9	25	8	17	645	29,200
6 Derbyshire	9	19	5	14	436	19,184
7 North Wales	9	14	6	8	303	13,100
8 All other parts of England	12	14	5	—	—	—
9 Ireland	1	2	—	2	60	3,000
Totals, 1825	168	374	103	261	11,883	581,367

There are four furnaces in South Wales, and nine in the other parts of England from which no return of produce has lately been obtained; consequently not included in the foregoing total of produce. The following is another account, derived from an authentic source, exhibiting a comparative view of the number of furnaces in and out of blast, in January 1826, and in April 1828.

	Mining Districts of	Number of Furnaces. Total	out of Blast	in Blast	Produce in Tons; per Week	Year.
January, 1826.	1 South Wales	109	27	82	4,430	230,412
	2 Staffordshire	108	27	81	3,503	182,156
	3 Shropshire	49	13	36	1,723	89,596
	4 Yorkshire	34	12	22	752	39,104
	5 Scotland	25	8	17	645	33,540
	6 Derbyshire	19	5	14	436	22,672
	7 North Wales	14	6	8	303	15,756
	Totals, January, 1826	359	99	260	11,793	613,236
April, 1828.	1 South Wales	100	11	89	5,376	279,512
	2 Staffordshire	120	25	95	4,220	219,492
	3 Shropshire	48	17	31	1,562	81,224
	4 Yorkshire	34	17	17	634	32,968
	5 Scotland	25	8	18	725	37,700
	6 Derbyshire	18	4	14	436	22,360
	7 North Wales	19	7	12	484	25,168
	8 Forest of Dean (Glo'stersh.)	2	1	1	50	2,600
	9 Duckinfield (Cheshire)	1	0	1	30	1,560
	Totals, April, 1828	367	90	278	13,512	702,624

According to the above statement, notwithstanding the progressive depreciation in the value of iron since 1825, seventeen additional furnaces were brought into blast in 1826-7, and the produce of some of the others considerably increased, so that in April 1828 the produce of 278 furnaces then in blast amounted to upwards of 700,000 tons of pig-iron; and this exclusive of four furnaces in South Wales, and nine in different parts of England, from which no return of produce had been obtained; so that the total produce probably amounted to not less than 735,000 tons. It has been estimated by some competent and high authorities that an average of 27 cwt. of pig-iron makes a ton of wrought-iron; while others estimate the average at 30 cwt. to the ton, and some even give a still greater average. Admitting the first estimate to be correct, 735,000 tons of pig is equal to 545,000 tons of wrought iron, out of which, in 1828, there was exported of wrought and unwrought iron and steel, to all parts of the world

	Tons
(Except Ireland)	100,265
And of hardwares and cutlery	12,488
Estimate of all kinds to Ireland	30,000
Do. of arms, machinery, and mill work	7,247
Making a total quantity exported of	150,000

Leaving for home consumption the enormous quantity of 395,000 tons; to which may be added about 50,000 tons of old iron, annually brought to re-manufacture, and the 12,000 tons of foreign. Admitting, however, that a ton of wrought-iron absorbs, on an average, 30cwt. of pig-iron, it will reduce the quantity of wrought from 545,000 to 490,000 tons, and the quantity left for home consumption from 395,000 to 340,000 tons.

Iron is oxidated and dissolved by the acids with facility; its saline compounds, when neutral, are in general soluble and crystallizable.

Sulphate of iron is a salt which has long been known under the name of *green vitriol*. It is economically prepared from the native sulphuret of iron, which, when calcined, and exposed for some time to air and humidity, absorbs oxygen, so that the sulphur is converted into sulphuric acid, and the iron is oxidated; the sulphate of iron, thus formed, is extracted by lixiviation and crystallization. It is obtained more pure by the direct solution of iron in diluted sulphuric acid, the acid enabling the iron to decompose the water by attracting its oxygen, and at the same time combining with the oxide. The solution is of a pale green colour, and if concentrated affords crystals of the same colour, in the form of rhomboidal prisms. This salt is soluble in six parts of cold water. Exposed to heat, it first liquefies; when the water of crystallization is dissipated, it forms a dry mass of a greenish colour; when urged by a strong heat, the greater part of its acid is expelled, partially decomposed, and a red oxide remains. Exposed to the air, it loses its transparency, and is covered with a yellowish crust; a change owing to the absorption of oxygen. This absorption takes place to a greater extent when the salt is in solution, and continues until the oxide passes to the maximum of oxidation. In this state it requires a larger quantity of acid for its saturation than the oxide in the green sulphate does; hence a portion of this more perfect oxide is precipitated, while the remaining quantity is retained in combination with the acid. The one of these salts is named the *green sulphate of iron*, the other the *red sulphate*. The latter is not crystallizable, but when its solution is evaporated it forms a mass of a yellowish-red colour. It is soluble in alcohol, and this affords a mode of separating it from the other. With re-agents, these salts afford different phenomena. The green sulphate, decomposed by the alkalies, gives precipitates of a green colour; the red sulphate affords precipitates of a yellow colour, approaching more or less to red; the former, with prussiate of potash, gives a white precipitate, the other, with the same test, a precipitate of a rich blue colour; the one is little altered by the infusion of galls, the other strikes immediately a deep purple colour.

From the strong tendency of iron to pass to a highly oxidated state, it is difficult to obtain the green sulphate perfectly pure, so as to exhibit these phenomena. The solution of iron is usually in an intermediate state of oxidation: and though Proust and some other chemists have supposed that there are only two sulphates of iron of determinate composition, one having for its base the metal at the *minimum*, the other at the *maximum* of oxidation, and that any apparent intermediate compound is merely a mixture of these, crystals of numerous shades of colour can be obtained, denoting a series of these compounds in different degrees of oxidation. The different precipitates which the compounds form with the different re-agents, the prussiate of potash, and infusion of galls, have been supposed to depend on the peculiar properties of the oxides, which are their bases: but they appear also to arise in part from the different forces of affinity with which the oxide is retained in combination with the sulphuric acid, the force being greater exerted towards the metal at a low than at a high degree of oxidation, so that the salt in the former state does not so easily form a precipitate with these re-agents. Hence, if the affinity be weakened by causes which do not change the state of oxidation, as by mere dilution with water, or by the addition of

an alkali in small proportion, the precipitation is produced by their action on the salt in even the least oxidated state.

Sulphate of iron is applied to numerous uses in the arts, more particularly in dyeing, as forming, with vegetable astringents, the basis of black dyes, and, with other colouring substances, different shades of colour. Its combination with these astringents is the basis of writing-ink.

Sulphurous acid dissolves iron, being partly decomposed, so that the combination is a sulphuretted sulphite of iron, "or rather a hypo-sulphite of iron." The pure sulphite is obtained by the direct combination of the acid with oxide of iron; it is soluble in water, but not in alcohol, and is not coloured by infusion of galls. "The hypo-sulphite, it has been ascertained, is formed also when carbonate of iron is dissolved in sulphurous acid, and the solution afterwards boiled with sulphur. If acid be added to a solution of the hypo-sulphite, sulphurous acid will be evolved, and sulphur deposited. By evaporation, the hypo-sulphite is obtained in crystals."

Nitric acid is decomposed by iron with rapidity, and the metal passes to the highest state of oxidation. When the acid is diluted, the action is more moderate, and a more perfect solution is obtained, which, however, cannot be evaporated so as to afford the nitrate crystallized, the heat that is required causing a further decomposition of the acid, and the precipitation of a sub-nitrate of iron. A similar change is produced in the solution from exposure to the air, oxygen being absorbed.

Muriatic acid dissolves iron with facility, the iron receiving oxygen from the water, and the solution being therefore attended with a disengagement of hydrogen gas. The liquor is of a pale green colour, and by evaporation affords crystals of the same colour. If oxide or rust of iron is dissolved in muriatic acid, a solution is obtained of a yellow colour, which does not crystallize on evaporation, but affords a soft deliquescent mass. In one of these salts the iron is in a low, in the other in a high state of oxidation, and they differ in their chemical properties; the former, the green muriate, is insoluble in alcohol, is little altered in its colour by infusion of galls, and, when decomposed by the alkalies, gives a green precipitate; the latter, the red muriate, is soluble in alcohol, gives a deep purple colour with galls and a blue with prussiate of potash, and affords a yellow precipitate when decomposed by the alkalies. The green is converted into the red muriate by exposure to the air, passing through various intermediate states of oxidation by absorption of oxygen. The solution of the green muriate, as well as of the green sulphate of iron, absorbs nitric oxide gas, a property the application of which to eudiometry has been already adverted to.

In oxymuriatic gas, iron wire, when heated, suffers combustion, and a product is obtained of a yellowish colour, with considerable lustre, volatile and soluble in water. With a smaller proportion of the acid, a compound is obtained, which is fusible, but not volatile. The one appears to be the red, the other the green muriate in a dry and concentrated state.

Iron is acted on by water strongly impregnated with carbonic acid, and a portion of it is dissolved. The common rust of iron contains a portion of this acid; and a carbonate is formed by decomposing sulphate of iron by carbonate of potash or soda; it is precipitated of a greenish colour, but in drying becomes brown from absorption of oxygen from the air. In the natural chalybeate waters, the iron is usually held dissolved by carbonic acid.

Phosphoric acid acts weakly on iron; but the phosphate may be formed by adding phosphate of soda to a solution of sulphate of iron; it is of a white colour, insoluble in water, and fuses into a brilliant globule by intense heat. The borate, formed by a similar process, is insoluble. The fluate is soluble, does not crystallize, but by evaporation forms a gelatinous mass. Prussic acid has a powerful affinity to oxide of iron: it forms with the red oxide the pigment, of a rich blue colour, known by the name of *Prussian blue;* and from the deepness of the colour of this combination, and the strength of affinity which the acid exerts, it affords one of the most delicate tests of iron. Gallic acid produces with the salts of iron, in the higher degrees of oxidation, a deep violet tinge, and in the state in which it is combined with tannin in the infusions of vegetable astringents, particularly of galls, is a test still more delicate and more accurate. Succinic acid forms with oxide of iron an insoluble compound, and from this property has been employed to abstract iron from other combinations, or in delicate analyses to ascertain the quantity of iron. Benzoic acid has a similar effect, and, being less expensive than succinic acid, has been employed under the form of benzoate of ammonia.

The alkalies scarcely act on iron or its oxides; in decomposing its salts, they in some cases form, when added in excess, soluble ternary compounds. The earths when melted with oxide of iron form coloured enamels.

Iron appears to exert a strong attraction for carbon. When melted from its ores in contact with the fuel, a portion of carbonaceous matter combines with it, and this, with oxygen and other ingredients, forms cast-iron. The combination of iron with carbon alone constitutes *steel,* one of the most useful forms of this valuable metal.

The usual process for forming steel is that named *cementation,* in which bars of malleable iron are imbedded in layers of charcoal-powder in a close furnace, through which flues are carried to distribute the heat: a strong fire is applied for six or eight days; the progress of the cementation is known by withdrawing a bar from the furnace: if this is sufficiently changed, the fire is extinguished, and the metal is left to cool for six or eight days. This forms *blistered-steel;* it is rendered more perfect by subjecting it to the operation of the forge-hammer, as in forging iron; or by welding it; or it is fused with the addition of a little charcoal, and cast into small bars, forming what is named *cast-steel.* These operations are performed on malleable iron; but some kinds of cast-iron, particularly the gray crude iron, can be converted into steel of an inferior quality by a similar process. Steel is also formed by fusing forged iron with charcoal.

In this operation, an increase of weight from $\frac{1}{150}$th to $\frac{1}{140}$th is gained. The more carbon is introduced, the more brittle is the steel. Bergman first clearly showed the presence of this carbonaceous matter, by ascertaining by experiment that less hydrogen is disengaged during the solution of steel in diluted sulphuric acid than during the solution of iron in the same acid; and that, during the solution of the steel, carbon is precipitated in the form of a black shining

powder, similar to plumbago. Guyton has observed that it is probably pure carbon, not charcoal, that is present in steel; and to this its great hardness may be ascribed. This has been confirmed by the experiment of converting iron into steel, by exposing it to heat with diamond. Bergman further found that some specimens of steel contain manganese and silicious earth; and Vauquelin has likewise discovered the existence of this earth, or perhaps rather its metallic base, and of phosphorus, in several kinds of steel which he analysed.

Steel is of a gray colour; when heated it assumes various brilliant colours on its surface from oxidation; its fracture is granular and brilliant, and it is susceptible of a high polish. It is more fusible than iron. It is ductile and malleable, and, when hammered, its ductility and its elasticity are increased. The property by which it is eminently distinguished is that of acquiring a great degree of hardness by being immersed in cold water when previously heated, the hardness being greater as the steel has been hotter and the water colder; it at the same time becomes more brittle and elastic, effects which evidently arise from the irregular aggregation produced by the sudden cooling. Steel, thus hardened, may have its softness and ductility restored, by again heating it, and allowing it to cool slowly. This is what is termed *tempering* of it, the requisite degree of *temper* being given by heating the metal more or less, previously to the slow cooling. The harder steel is, the more elastic it becomes, and at the same time the more brittle, and hence, for different purposes, different degrees of this quality are required.

Steel possesses a degree of hardness superior to that of any other metal; it is also possessed of the highest elasticity; and from these properties it acquires its high value.

The mineral substance known by the name of *plumbago*, or *graphite*, is a compound of iron and carbon. The proportion of iron is variable, but in general does not exceed from 3.5 to 10 in 100 parts. By exposure to a continued red heat, the carbonaceous matter is slowly consumed, being converted into carbonic acid, and oxide of iron remains. It suffers a similar change by deflagration with charcoal. It is scarcely acted on by the acids. From its softness and lubricity, plumbago is used to lessen the friction of machinery; it is added to some kinds of earthenware, to communicate a degree of tenacity, whence the composition is not so liable to crack on exposure to heat. It is rubbed on the surface of iron to prevent rusting; and it forms the best kind of crayons.

Iron has a strong attraction for sulphur, and combines with it with facility by fusion, the combination being attended with the evolution of heat and light. They also exist combined in nature, the mineral named *pyrites* being a combination of this kind. The proportions of the ingredients in the native sulphurets are usually different from those in the artificial sulphuret; in the former they are about fifty-three of sulphur and forty-seven of iron; in the latter the proportion of sulphur does not exceed thirty-seven. There exists, however, a native sulphuret named *magnetic pyrites*, similar in composition to the artificial sulphuret; and, on the other hand, the artificial sulphuret may be combined by fusion with an additional proportion of sulphur. When the proportion does not exceed thirty-seven of sulphur in 100 parts of the compound, the magnetic property remains; but, when it is so high as fifty-three, it is destroyed. These compounds are of a gray or yellow colour, frequently variegated, with a degree of lustre, the colour approaching more to yellow, and the lustre being more perfect, as the proportion of sulphur is large. They are of a crystalline texture, brittle, and fusible, and are partially decomposed by heat. The compound in which the iron predominates, when moistened and exposed to the air, absorbs oxygen, and is gradually converted into sulphate of iron. A mixture of iron-filings and sulphur moistened acts on atmospheric air in a similar manner, and suffers the same change. The alkaline sulphurets combine with iron by fusion, and also by boiling with water. Sulphuretted hydrogen, and the hydro-sulphurets, form precipitates from the salts of iron.

With phosphorus iron forms a compound which is white, brittle, and of a granular fracture. A compound of this kind, obtained from cast-iron, was once regarded as a peculiar metal, and named *siderite*. It has been considered as the cause of the cold short property of iron.

Iron combines with a number of the metals, but few of its alloys are applied to use. That with gold is hard, ductile, and malleable, but of a dull gray colour. With silver it combines imperfectly. With platina the combination is not easily effected, from the infusibility of both metals. It does not easily amalgamate with quicksilver; the combination can be produced only by indirect methods, and is imperfect. The alloy with copper is brittle, and of a gray colour. The principal alloy of any use is that with tin, this forming what is named *tinned iron*.

Iron is perhaps the most useful of the metals, possessing in its pure form the highest degree of tenacity, ductility, elasticity, and hardness, whence it is applied to all purposes where strength is required; and, though infusible, it is capable by the operation of welding of being easily fashioned and worked. Cast-iron, being fusible, can be adapted to other purposes, and derives value from its hardness, and from being less liable than forged iron to be acted on by the air. And the elasticity and hardness of steel adapt it to numerous uses for which other metals would afford very imperfect substitutes.

IRON-WOOD. This name is given to a small tree, having the foliage of a birch, and the fruit somewhat resembling that of the hop. It is remarkable for the hardness and heaviness of the wood, which, however, has not hitherto been applied to any very important uses, partly on account of its small size. The trunk usually does not exceed six inches in diameter; but the excellent qualities of the wood may, at some future day, be better appreciated. The term *hop-hornbeam*, derived from the form of the fruit, is frequently applied to the species of *ostrya*.

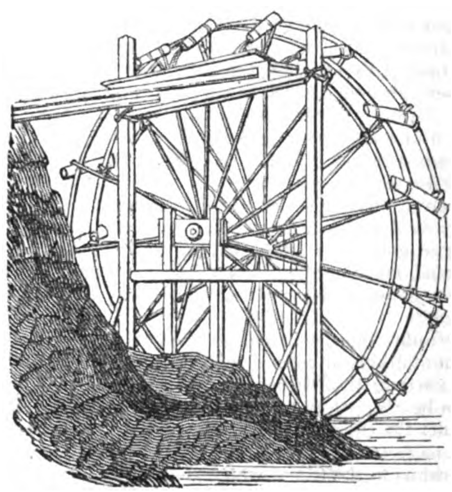
IRRATIONAL QUANTITIES are those which cannot be measured by unity or parts of unity; for example, the square root of 2, 1.4124 .... which, by continued approximation, can be obtained more and more exactly, without end, in parts of unity, but can never be exactly determined. The relation of two quantities is also called *irrational* when one cannot be exactly measured by the whole and parts of the other. The circumference and diameter of a circle stand in such an *irrational* relation to each other, because we can only find by approximation how many times the latter is contained in the former.

IRRIGATION. The fertilizing of land by artificial

streams is a subject of the greatest importance to the agriculturist. To make the matter intelligible to the reader, it will be necessary for us to point out the various processes for irrigating land which are resorted to in different parts of the globe. We may commence with the East.

In Hindostan the operation of conveying water to and from the fields is one of the most expensive and troublesome in their agricultural system, particularly in the higher districts. In the Monghere districts of Bengal, a deep well is dug in the highest part of the field, which, being ploughed, is divided into little square plots, resembling the chequers of a chess-board. Each square is surrounded with a border, four inches high, capable of containing water; while, between the chequers thus constructed, small dykes are formed for conveying a rivulet over the whole field. As soon as the water has stood a sufficient time in one square for it to imbibe moisture, it is let off into the next by opening a small outlet through the dyke. Thus one square after another is irrigated, till the whole field is gone over. The water is raised in leathern bags by two bullocks, yoked to a rope; the cattle retiring from the well, and returning to its mouth, according as the bag is meant to be raised or to descend. The rope is kept perpendicular in the pit by a pulley, over which it runs; and, from the mouth of the well thus placed, the rivulets are formed. In Patna the buckets are raised by large bamboo levers, as buckets are in this country.

Dr. Davy gives an interesting account of the prevalence of this practice at Ceylon. The cultivation in the interior of that country, he says, is of two kinds, the dry and the wet. The former consists in cutting down and grubbing up the wood on the sides of hills, where particular varieties of rice and Indian corn are afterwards sown: the latter, and by far the most general mode, is carried on wherever water can be obtained for irrigation. "Most of the operations in the cultivation of *paddy*," he states, "are connected with or have some relation to the element on which its success depends. The farmer commences with repairing the banks of the paddy-field. He then admits water in sufficient quantity to be an inch or two deep over the whole surface. After the ground has been well macerated and softened, he ploughs it, still under water. After further maceration, it is ploughed again, or merely trampled over by buffaloes, till reduced to the state of mud. Its surface is now levelled and smoothed; the water is drawn off; and the paddy, having been previously steeped in water till it has begun to germinate, is sown with the hand, and is scattered as equally as possible over the moist surface of mud. When the seed has taken root, and before the mud has had time to dry, the openings through which the water was drawn off are closed, and the field is again inundated. When the paddy is two or three inches high, it is weeded; and, where the seed has failed, the vacant spots are planted from those parts which are too thick and require thinning. The irrigation is continued till the paddy is nearly full-grown and about to ripen, when openings are made in the banks and the field is drained. As soon as ripe, the paddy is cut with reaping-hooks, and immediately carried to the threshing-floor, where the grain is trampled out by buffaloes. From the moment the seed is sown, till the period of harvest, the paddy-field, like the chenas, requires constant nightly watching to protect it from the depredations of its wild enemies. In the low country, where the cultivation of paddy is in a great measure dependent on the rainy season, and on artificial reservoirs for a further supply of water, only one crop is procured annually; but amongst the mountains, in situations where perpetual irrigation is at command, the seasons are less concerned, the farmer can sow when he pleases, and from good ground annually obtain two, and I have heard even three crops. The hilly and mountainous districts, in consequence of being well supplied with water, are thus particularly favourable for the cultivation of this important grain: and it is a most fortunate circumstance that they are so; otherwise the coolest, most salubrious, and most beautiful parts of the interior would, instead of being cultivated to a certain extent, be quite neglected and deserted. In the low country the paddy-fields are generally of a large size, and apparently quite flat; and every crop being in the same state of vegetation, or nearly so, the whole exhibits very little variety of surface. Amongst the mountains it is quite different: paddy-fields there are a succession of terraces, or flights of steps; and in each field the crop may be in different stages of growth,—in some just vegetating, in others full-grown, ripening, or ripe; there, at the same time, you may see the labourers at all their different operations,—banking, ploughing, sowing, weeding, reaping, and treading out the grain. In the low lands the labour and skill required to cultivate paddy are less than are necessary in the high lands. In cutting terraces in the sides of hills, the perseverance and industry of the mountaineer are often in a striking manner displayed. Many of his beds are actually walled up, and many of them are not four feet wide, and, though generally long, occasionally they are so short, from the nature of the ground, as well as narrow, that one would not suppose they were worth the labour of keeping in repair, and much less of making. In bringing water to his fields, and insuring them a constant supply, the judgment and skill of the cultivator are most exercised. Sometimes it is conducted two or three miles along the side of a hill, and occasionally it is even carried from one side of a mountain to another by means of wooden pipes."



The process for irrigating land with wheels em-

ployed in China is curious, and might be adopted with advantage in many situations in this country. The wheel must be of considerable size, and a running stream is of course necessary to give motion to it. At the extremity of the radial spokes are placed a number of earthen pots. These pots fill as they pass through the water, and then discharge their fluid contents into the series of troughs at the top, whence it is conveyed to the land to be fertilized.

"In *surface* irrigation," says Mr. Loudon, "the water is conveyed in a system of open channels, which require to be most numerous in such grounds as are under drilled annual crops, and least so in such as are sown in breadths, beds, or ridges, under perennial crops. This mode of watering has existed from time immemorial. The children of Israel are represented as sowing their seed and watering it with their feet; that is, as Calmet explains it, raising the water from the Nile by a machine worked by the feet, from which it was conducted in such channels as we have been describing. It is general in the south of France and Italy; but less required in Britain.

"Irrigation with a view to conveying additions to the soil (or for manuring it in fact) has long been practised, and is an evident imitation of the overflowing of alluvial lands, whether in meadow or arable. In the former case it is called irrigation or flooding, and in the latter warping. Warping is used chiefly as a mode of enriching the soil by an increase of the alluvial depositions, or warp, of rivers, during winter, where the surface is not under crop, as is common on the banks of the Ouse.

"*Subterraneous* irrigation appears to have been first practised in Lombardy, and first treated of by Professor Thouin. It consists in saturating a soil with water from below, instead of from the surface, and is effected by surrounding a piece of ground by an open drain or main, and intersecting it by covered drains communicating with this main. If the field is on a level, as in most cases where the practice is adopted in Lombardy, all that is necessary is to fill the main and keep it full till the lands have been sufficiently soaked. But, if it lie on a slope, then the lower ends of the drains must be closely stopped, and the water admitted only into the main on the upper side: this main must be kept full till the land is soaked, when the mouths of the lower drains may be opened to carry off the superfluous water. The practice is applicable either to pasture or arable lands. In Britain, subterraneous irrigation has been applied in a very simple manner to drain bogs and morasses, and to fen lands. All that is necessary is to build a sluice in the lower part of the main drain, where it quits the drained grounds, and in dry weather to shut down this sluice, so as to dam up the water and throw it back into all the minor open drains, and also the covered drains. This plan has been adopted with success in several parts of England."

"Subterraneous irrigation may be effected by a system of drains or covered gutters in the subsoil, which proceeding from a main conduit, or other supply, can be charged with water at pleasure. For grounds under the culture of annual plants, this mode would be more convenient, and for all others more economical as to the use of water, than surface irrigation. Where the under stratum is gravelly, and rests on a retentive stratum, this mode of watering may take place without drains, as it may also on perfectly flat lands, by filling to the brim, and keeping full for several days, surrounding trenches; but the beds or fields between the trenches must not be of great extent. This practice is used in Lombardy, on the alluvial lands near the embouchures of the Po. In Lincolnshire the same mode is practised by shutting up the flood-gates of the mouths of the great drains in the dry seasons, and thus damming up the water through all the ramifications of the drainage from the sea to their source. This was first suggested by Mr. Rennie and Sir Joseph Banks, after the drainage round Boston, completed about 1810. A similar plan, on a smaller scale, had been practised in Scotland, where mosses had been drained and cultivated on the surface, but where, in summer, vegetation failed from a deficiency of moisture. It was first adopted by James Smith on a farm in Ayrshire, and has subsequently been brought into notice by J. Johnstone, the first delineator and professor of Elkinton's system of draining.

"In general, in nature, the operation of water," says Sir H. Davy, "is to bring earthy substances into an extreme state of division. But, in the artificial watering of meadows, the beneficial effects depend upon many different causes, some chemical, some mechanical. Water is absolutely essential to vegetation; and when land has been covered by water in the winter, or in the beginning of spring, the moisture that has penetrated deep into the soil, and even the subsoil, becomes a source of nourishment to the roots of the plants in the summer, and prevents those bad effects that often happen in lands in their natural state, from a long continuance of dry weather. When the water used in irrigation has flowed over a calcareous country, it is generally found impregnated with carbonate of lime; and in this state it tends, in many instances, to emeliorate the soil. Common river-water also generally contains a certain portion of organizable matter, which is much greater after rains than at other times; or which exists in the largest quantity when the stream rises in a cultivated country. Even in cases when the water used for flooding is pure, and free from animal or vegetable substances, it acts by causing a more equable diffusion of nutritive matter existing in the land; and in very cold seasons it preserves the tender roots and leaves of the grass from being affected by frost. Water is of greater specific gravity at 42° Fahrenheit than at 32°, the freezing point; and hence, in a meadow irrigated in winter, the water immediately in contact with the grass is rarely below 40°, a degree of temperature not at all prejudicial to the living organs of plants. In 1804, in the month of March, the temperature in a water meadow near Hungerford was examined by a very delicate thermometer. The temperature of the air at seven in the morning was 29°. The water was frozen above the grass. The temperature of the soil below water, in which the roots of the grass were fixed, was 43°. Water may also operate usefully in warm seasons by moderating temperature, and thus retarding the over-rapid progress of vegetation. The consequence of this retardation will be a greater magnitude and improved texture of the grosser parts of plants, a more perfect and ample developement of their finer parts, and, above all, an increase in the size of their fruits and seeds. We apprehend this to be one of the principal uses of the flooding of rice-grounds in the east; for it is ascertained that the rice plant will perfect its seeds in Europe, and even in this country,

without any water beyond what is furnished by the weather, and the natural moisture of a well-constituted soil."

IRRITABILITY; the contractility of muscular fibres, or a property peculiar to muscles, by which they contract, upon the application of certain *stimuli*, without a consciousness of action. This power may be seen in the tremulous contraction of muscles when lacerated, or when entirely separated from the body in operations. Even when the body is dead, to all appearance, and the nervous power is gone, this contractile power remains till the organization yields, and begins to be dissolved. It is by this inherent power that a cut muscle contracts, and leaves a gap, that a cut artery shrinks, and grows stiff after death. This irritability of muscles is so far independent of nerves, and so little connected with feeling, which is the province of the nerves, that, upon stimulating any muscle by touching it with caustic, or irritating it with a sharp point, or driving the electric spark through it, or exciting with the metallic conductors, as those of silver or zinc, the muscle instantly contracts, although the nerve of that muscle be tied; although the nerve be cut so as to separate the muscle entirely from all connection with the system; although the muscle be separated from the body; although the creature, upon which the experiment is performed, may have lost all sense of feeling and have been long apparently dead. Thus a muscle, cut from the limb, trembles and palpitates a long time after; the heart, separated from the body, contracts when irritated: the bowels, when torn from the body, continue their peristaltic motion, so as to roll upon the table, ceasing to answer to *stimuli* only when they become stiff and cold. Even in vegetables, as in the sensitive plant, this contractile power lives. Thence comes the distinction between the *irritability* of muscles and the *sensibility* of nerves; for the irritability of muscles survives the animal, as when it is active after death; it survives the life of the part, or the feelings of the whole system, as in universal palsy, where the vital motions continue entire and perfect, and where the muscles, though not obedient to the will, are subject to irregular and violent actions; and it survives the connection with the rest of the system, as when animals very tenacious of life are cut into parts; but *sensibility*, the property of the nerves, gives the various modifications of sense, as vision, hearing, and the rest; gives also the general sense of pleasure or pain, and makes the system, according to its various conditions, feel vigorous and healthy, or weary and low.

The eye feels and the skin feels; but their appointed *stimuli* produce no motions in these parts: they are sensible, but not irritable. The heart, the intestines, the urinary bladder, and all the muscles of voluntary motion, answer to *stimuli* with a quick and forcible contraction; and yet they hardly feel the *stimuli* by which these contractions are produced, or, at least, they do not convey that feeling to the brain. There is no consciousness of present stimulus in those parts which are called into action by the impulse of the nerves, and at the command of the will; so that muscular parts have all the irritability of the system, with but little feeling, and that little owing to the nerves which enter into their substance; while nerves have all the sensibility of the system, but no motion. After every action in an irritable part, a state of rest, or cessation from motion, must take place before the irritable part can be again incited to action. If, by an act of volition, we throw any of our muscles into action, that action can be continued only for a certain space of time. The muscle becomes relaxed, notwithstanding all our endeavours to the contrary, and remains a certain time in that relaxed state before it can be again thrown into action. Each irritable part has *stimuli* which are peculiar to it, and which are intended to support its natural action: thus blood is the stimulus proper to the heart and arteries; but if, by any accident, it gets into the stomach, it produces sickness or vomiting. The urine does not irritate the tender fabric of the kidneys, ureters, or bladder, except in such a degree as to preserve their healthy action; but, if it be effused into the cellular membrane, it brings on such a violent action of the vessels of these parts as to produce gangrene. Such *stimuli* are called *habitual stimuli* of parts.

Each irritable part differs from the rest in regard to the quantity of irritability which it possesses. This law explains to us the reason of the great diversity which we observe in the action of various irritable parts; thus the muscles of voluntary motion can remain a long time in a state of action, and, if it be continued as long as possible, another considerable portion of time is required before they regain the irritability they lost; but the heart and arteries have a more short and sudden action, and their state of rest is equally so. The circular muscles of the intestines have also a quick action and short rest. The action of every stimulus is in an inverse ratio to the frequency of its application. A small quantity of spirits, taken into the stomach, increases the action of its muscular coat, and also of its various vessels, so that digestion is thereby facilitated. If the same quantity, however, be taken frequently, it loses its effect. In order to produce the same effect as at first, a larger quantity is necessary; and hence the origin of dram drinking. The more the irritability of a part is accumulated, the more that part is disposed to be acted upon. It is on this account that the activity of all animals, while in perfect health, is much livelier in the morning than at any other part of the day; for, during the night, the irritability of the whole frame, and especially that of the muscles destined for labour, viz. the muscles for voluntary action, is re-accumulated. The same law explains why digestion goes on more rapidly the first hour after food is swallowed than at any other time; and it also accounts for the great danger that accrues to a famished person upon first taking in food.

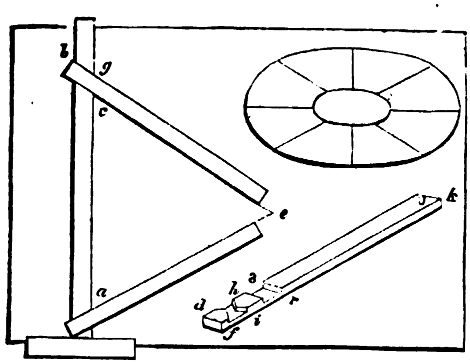
In German philosophy, *irritability, sensibility,* and *reproductivity* constitute the whole of organic life. Since the time of Schelling, *irritability* is much considered in the mental philosophy of that country. The French, treating the subject merely with reference to physiology, generally use, at present, the word *contractility* instead of *irritability*.

ISINGLASS. This substance is almost wholly gela tine, 100 grains of good dry isinglass containing rather more than ninety-eight of matter soluble in water. It is brought principally from Russia. The belluga yields the greatest quantity, being the largest and most plentiful fish in the rivers of Muscovy; but the sounds of all fresh-water fish yield more or less fine isinglass, particularly the small sorts, found in prodigious quantities in the Caspian Sea, and several hundred miles beyond Astracan, in the Wolga, Yaik,

Don, and even as far as Siberia. It is the basis of the Russian glue, which is preferred to all other kinds for strength. Isinglass receives its different shapes in the following manner. The parts of which it is composed, particularly the sounds, are taken from the fish while sweet and fresh, slit open, washed from their slimy covering, divested of a very thin membrane which envelopes the sound, and then exposed to stiffen a little in the air. In this state, they are formed into rolls about the thickness of a finger, and in length according to the intended size of the staple; a thin membrane is generally selected for the centre of the roll, round which the rest are folded alternately, and about half an inch of each extremity of the roll is turned inwards. Isinglass is best made in the summer, as frost gives it a disagreeable colour, deprives it of its weight, and impairs its gelatinous principles. Isinglass boiled in milk forms a mild, nutritious jelly, and is thus sometimes employed medicinally. This, when flavoured by the art of the cook, is the *blanc-manger* of our tables. A solution of isinglass in water, with a very small proportion of some balsam, spread on black silk, is the court-plaster of the shops. Isinglass is also used in fining liquors of the fermented kind, and in making mock-pearls, stiffening linens, silks, gauzes, &c. With brandy it forms a cement for broken porcelain and glass. It is also used to stick together the parts of some musical instruments.

Isometrical Perspective. A new process for drawing in perspective, under this title, has been introduced by Professor Farish of Cambridge. It is preferable to the common perspective on many accounts, especially for the exhibition of machinery. It is both easy and simple in its principles. It is effected by the help of a common drawing-table, and two rulers; so that there is no difficulty in giving an almost perfectly correct representation of any object adapted to this perspective, to which the artist has access, if he has a very simple knowledge of its principles and a little practice.

It is unnecessary to describe the accompanying drawing-table any further than by observing that it ought to be so contrived as to keep the paper steady on which the drawing is to be made.



There should be a ruler in the form of the letter T, to slide on one side of the drawing table. The ruler should be kept, by small prominences on the under side, from being in immediate contact with the paper, to prevent its blotting the fresh drawn lines as it slides over them; and a second ruler, by means of a groove near one end on its under side, should be made to slide on the first. The groove should be wider than the breadth of the first ruler, and so fitted that the second may at pleasure be put into either of the two positions represented in the engraving, so as to contain with the former ruler, in either position, an angle of sixty degrees. The groove should be of such a size that, when its shoulder *a* is in contact with and resting against the edges of the first ruler, the edges of the second ruler should coincide with *e*. When the shoulders *b c* rest against the edges of the first ruler, the edge of the second should lie along *a e*, the other side of the equilateral triangle. The second ruler should have a little foot at *k*, for the same purpose as the prominences on the first ruler; and both of them should have their edges divided into inches and tenths, or eighths of tenths.

It would be convenient if the second ruler had also another groove, *r s*, so formed that when the shoulders *r* and *s* are in contact with the edges of the first ruler the second should be at right angles to it. For representing circles in their proper positions, Professor Farish made use of the inner edge of rims cut out from cards into isometrical ellipses, as represented in the figure; of these he had a series of different sizes, corresponding to his wheels.

The Professor states that "by this apparatus we may represent the straight lines which lie in the three principal directions, all on the same scale. The right angles contained by such lines are always represented either by angles of sixty degrees, or the supplement of sixty degrees: and this, though it might look like an objection, will be understood on the first sight of a drawing on these principles by any person who has ever looked at a picture; for he cannot for a moment have a doubt that the angle represented is a right angle, on inspection."

And we may observe further that an angle of sixty degrees is the easiest to draw of any angle in nature. It may instantly be found by any person who has a pair of compasses, and understands the first proposition in Euclid. The representation, also, of circles and wheels, and of the manner in which they act on one another, is very simple and intelligible. The principles of this perspective, which, from the peculiar circumstance of its exhibiting the lines in the three principal dimensions on the same scale, which the Professor denominates "isometrical," will be understood from the following detail:—Suppose a cube to be the object represented, the eye placed in the diagonal of the cube produced, the paper on which the drawing is to be made to be perpendicular to that diagonal, between the eye and the object, at a due proportional distance from each, according to the scale required. Let the distance of the eye, and consequently that of the paper, be indefinitely increased, so that the size of the object may be inconsiderable in respect of it. It is manifest that all the lines drawn from any points of the object to the eye may be considered as perpendicular to the picture, which becomes, therefore, a species of orthographic projection; and the projection will have for its outline an equi-angular and equilateral hexagon, with two vertical sides, and an angle at the top and bottom. The other three lines will be radii drawn from the centre to the lowest angle, and to the two alternate angles; and all these lines and sides will be equal to each other both in the object and representation; and if any other lines parallel to any of

the three radii should exist in the object, and be represented in the picture, their representations will bear to one another, and to the rest of the sides of the cube, the same proportion which the lines represented bear to one another in the object.

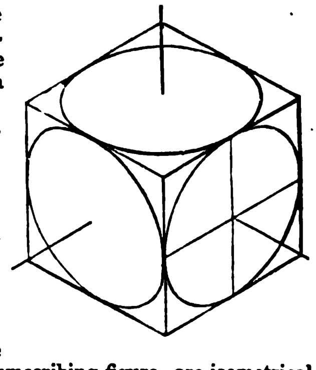
If any one of them, therefore, be so taken as to bear any required proportion to its object, as in the representation of models, the others also will bear the same proportion to their objects; that is, the lines parallel to the three radii will be reduced to a scale.

By the use of the simple apparatus already described, the representation of these lines in the objects may be drawn on the picture, and measured to a scale with the utmost facility: the point at the extremity being first found or assumed. The position of any point in the picture may be easily found by measuring its three distances; namely, first its perpendicular distance from the ***regulating horizontal plane*** (that is, the horizontal plane passing through the regulating point); secondly, the perpendicular distance of that point where the perpendicular meets the dexter line; and, thirdly, of the point where that perpendicular meets the dexter line from the regulating point; and then taking those distances reduced to the scale, first along the dexter line, secondly along the sinister line, and thirdly along the vertical line, in the picture. These three may be called the ***dexter distance*** of the point, its ***sinister distance***, and its ***altitude***. And it is manifest they need not be taken in this order, but in any other that may be more convenient to the artist, there being six ways in which this operation may be performed.

If any point in the same isometrical plane with the point required to be found be already represented in the picture, that point may be assumed as a new regulating point. If it is in the same isometrical line with the point, it is found by taking only one distance. And this last simple operation will be found in practice all that is necessary for the determination of most of the points required. Thus any parallelopiped, or any frame-work or other object with rafters, or lines lying in isometrical directions, may be most easily and accurately exhibited on any scale required. But, if it be necessary to represent lines in other directions, they will not be on the same scale, but may be exhibited, if straight lines, by finding the extremities as above, and drawing the line from one to the other; or sometimes more readily in practice by the help of an ellipse, as hereafter described.

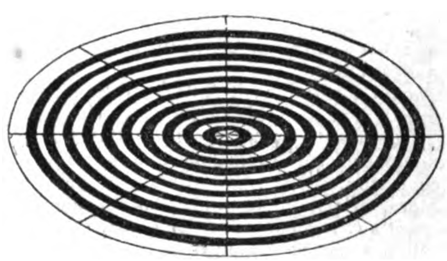
If a curved line be required, several points may be found, each being sufficient to guide the artist to that degree of exactness which is required.

The method of exhibiting the representations of any machines or objects the lines of which lie, as they generally do, in the isometrical direction, that is, parallel to the three directions of the lines of the cube, has been already shown; and likewise the mode of representing any other straight lines by finding their extremities, or curved lines by finding a number of points. But, in representing machines and models, there are not only isometrical lines, but also many wheels working into each other to be represented. These, for the most part, lie in the isometrical planes. And it is fortunate that the picture of a circle in any one of these planes is always an ellipse of the same form, whether the plane be horizontal, dexter, or sinister; yet they are easily distinguished from each other by the position in which they are placed on their axle, which is an isometrical line, always coinciding with the minor axis of the ellipse.



The fact above alluded to will be obvious from considering the figure of a cube with a circle inscribed in each of its planes, and considering these circles as wheels on an axle. The two other lines, (or spokes of the wheel) in the ellipse, which are drawn respectively through the opposite points of contact of the circle with the circumscribing figure, are isometrical lines also; for the points of contact bisect the sides of the circumscribing parallelogram, and therefore the lines are parallel to the other sides. They likewise give the true diameter of the wheels, reduced to the scale required.

The ellipse itself may be drawn by an elliptic compass, as that instrument may be properly set, if the major and minor axes are known. If it be intended to represent a wheel on an axle, care must be taken to make the minor axis lie along that axle. In the absence of the instrument, it may be drawn from the concentric ellipses annexed, which may be placed under the pa-



per, in the position above described, and seen through it if the paper be not too thick; and in this method the smaller concentric circles of the wheel may be described at the same time, as they may be seen through the picture; or, if they should not be exactly of the right size, it would be easy to describe them by hand, between the two nearest concentric ellipses; and thus also the height of the cogs of a wheel in the different parts of it may be exhibited, longer and narrower towards the extremities of the major, and shorter and wider at the extremities of the minor axis. Their width may be determined from the divisions of the ellipse. In most cases, this may be done with sufficient accuracy from the circumference of the ellipse being divided into eight equal divisions of the circle, by the two axes and two isometrical diameters, each of which parts may be subdivided by the skill of the artist; and not only the face of the wheel in front may be thus exhibited, but the parts of the back circles also which are in sight may be exhibited by pushing back the system of concentric ellipses on the minor axis, or axle, through a distance representing the breadth of the

wheel, and then tracing both the exterior and interior circles of the wheel, and of the socket on which it is fixed, as far as they are visible. Care should be taken to represent the top of the teeth, or cogs, by isometrical lines, parallel to the axle, in a face-wheel, or tending to a proper point in the axle in a bevil-wheel. And nearly in the same way may the floats of a water-wheel be correctly represented. If a series of concentric ellipses, such as have been described, be not at hand, it will still be easy for an artist to draw the ellipses with sufficient accuracy for most purposes, by drawing, through the proper point in the axle, the major and minor axes, and two isometrical diameters, thus marking eight points in the circumference to guide him.

If in any case it should become necessary to represent a circle which does not lie in an isometrical plane, we may observe that the major axis will be the same in whatever plane it lies; and it will be the picture of that diameter which is the intersection of the circle with the plane, parallel to the picture, passing through its centre; and the major axis will bear to the minor axis the proportion of radius to the sine of the inclination of the line of sight to the plane of the circle. The representation of every other line parallel and equal to any diameter of the circle may be exhibited by drawing it equal and parallel to the corresponding diameter in the ellipse.

To describe a cylinder lying in an isometrical direction, the circles at its extremities should be represented by the proper isometrical ellipse, and two lines touching both should be drawn; and in a similar way a cone, or frustum of a cone, may be described. A globe is represented by a circle whose radius is the semi-major axis of the ellipse representing a great circle.

It would not be difficult to devise rules for the representation of many other forms which might occur in objects to be represented. But the above cases are sufficient to include almost every thing which occurs in the representation of models, of machines, of philosophical instruments, and indeed of almost any regular production of art.

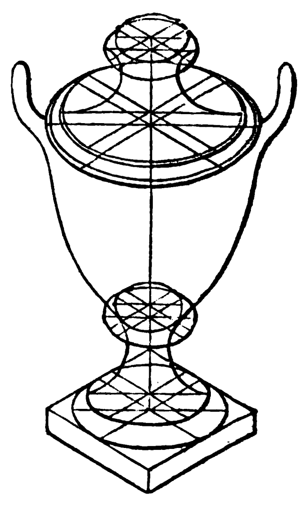
Buildings may be exhibited by this perspective as correctly, in point of measurement, as by plans and elevations, under the advantage of having the full effect of a picture.

A bridge, or any circular or Gothic arch, consisting of portions of circles lying in isometrical planes, may be represented by portions of isometrical ellipses, which will easily be adapted and drawn, upon the principles already explained by which wheels are exhibited on their axles. The centres of these circles must be found, with which the centres of the ellipses must be made to coincide, their minor axes lying along the lines drawn from those centres perpendicular to the planes of the circles.

The shaft of a pillar consists of a frustum of a cone and a cylinder united; or perhaps of a cylinder alone, or a congeries of cylinders: and we have already shown the method of exhibiting these, as well as their bases. And on the same principles the position and size of the volutes and ornaments of the capital may be found, and such guiding points as will make it easy to trace their forms. Thus the different courts and edifices of a cathedral, a college, or a palace, may be correctly depicted; and even the rooms, and internal structure, though less in the form of a picture, may be exhibited in such a way as to enable an architect, or his employer, to contemplate their situation, their ornaments, furniture, or any other circumstance belonging to their appearance; and to mark down exactly what he would have done, in such a way as could hardly be misunderstood by an attentive agent, though at a distance.

In the instances which have been given, most of the lines are isometrical: but the art is applicable to many cases where there are few or none such. It may be necessary, in many of them, to draw isometrical lines, or isometrical ellipses, by way of a guide, to determine the position of certain lines, and points, to enable the artist to describe with accuracy what he has in view: and there is scarcely any form so anomalous as to preclude the artist from taking advantage of these methods of ascertaining such lines or points in it as will give him much assistance in representing it with precision. If the intention be merely to make a picture, the guiding lines may be obliterated as soon as they have served the purpose designed, or they may be retained, in some cases, and their lengths or diameters noted down in figures, if it be wished to give ready information. And often, if the artist wishes to provide materials to enable him, at his leisure, to give accurate descriptions, or exact drawings, the rudest exhibition of such lines may completely serve his purpose, provided he notes down on the spot such measurements with accuracy, however unexact the lines may be on which they are recorded. In many cases it may be expedient to take liberties with this perspective, or with the picture, which will make it suit the purpose designed. And this will produce no confusion, provided those liberties are explained: for instance, it may be often expedient to make the scale in the vertical direction considerably larger than in the horizontal. It may in some cases be necessary to represent on paper what is hid in nature, and what has been said on the internal structure of buildings is an instance of this fact. We shall proceed to give some examples of these observations.

To give such a representation of an Etruscan vase as would enable an artist to model it exactly would be exceedingly easy. Let a vertical line be drawn to represent the axis of the vase, and let points be taken in that axis, corresponding to the centres of the principal circles of the vase, through which the horizontal isometrical lines may be drawn, representing the radii of those circles, by the help of which the isometrical ellipses representing them are easily drawn. These will become a complete guide to the artist. He may assist himself by looking at the object along the line of sight, and then, if he has any skill in drawing, he



will find no difficulty in tracing the outline from one of these to the other, with a sufficient degree of correctness. If he be unskilled in the art, of course he must be at the trouble of finding a larger number of ellipses to guide him. And, in a similar manner, any solid, formed by the revolution of a plane figure round one of its sides, may be represented.

The laying down the timbers of a ship, or making a picture of one, may be adduced as another example. Let a vertical isometrical plane be conceived to pass through its keel, and to be intersected by the perpendicular planes passing through the ribs, and by planes parallel to the decks. The isometrical lines which are the intersections of these may be measured in the ship, and represented, with their proper measures noted down, in the picture, which will afford the means of representing the ribs, and laying them down in their proper places.

If this should be designed for the purpose of constructing a ship from a given model, it might be sufficient to represent the ribs only on one side; those on the other side being the exact counterparts. If the purpose should be to make use of these lines for a drawing, they need be marked but very faintly, and the artist will have little difficulty, when guided by them, to fill up the representation by hand.

ITALIAN SCHOOL, *in the fine arts*. The art of painting was early introduced both into Italy and Germany by Greek masters; but the diversities of national character, climate, and religion, produced different results in the two countries. A glowing imagination, an easy life, an innate sense for the beautiful, enthusiastic piety, the constant sight of nature in her fairest forms, and the contemplation of the masterpieces of ancient art, occasioned painting in Italy to unfold itself with great magnificence; while in Germany the ancient painters loved rather to dwell on the inward life and character. They were poets and philosophers, who selected colours instead of words. The Italians have therefore remained inimitable in the ideal of this art, as the Greeks in statuary. The twelfth century is generally taken as the period of the beginning of the history of painting in Italy; but, even before that time, it had been the scene of the labours of Greek and Byzantine artists.

During the pontificate of Leo the Great, in the year 441, a large picture in mosaic was executed in the Basilica of St. Paul, on the road to Ostia, and the portraits of the forty-two first bishops, which are seen in the same church, date their origin from the same time. Mosaic and encaustic painting were then the prevalent mode. Painting in distemper was afterwards introduced. About the end of the sixth century, there were many paintings which were not believed to be the work of mortal hands, but were attributed to angels or blessed spirits. To this class belongs one of the most famous representations of the Saviour, in wood, at Rome, called *Archeiropoieta*, of which a sight can be obtained only with difficulty in the *sanctum sanctorum*. One of the oldest monuments of art is the celebrated Christ on the Cross, in the Trinity church at Florence, which existed there as early as 1003. About 1200, a Greek artist, Theophanes, founded a school of painting in Venice. The genuine Italian style first developed itself in Florence, and may be treated under three leading periods: 1. from Cimabue to Raphael; 2. from Raphael to the Caracci; 3. from the Caracci to the present time.

First Period. The art was first pursued with zeal in Pisa. Giunta Pisano, Guido of Sienna, Andr. Tafi, and Buffalmaco precede Cimabue, who was born at Florence, in 1240. His scholar Giotto was the friend of Dante and Petrarch, and practised with equal success historical painting, mosaic, sculpture, architecture, and portrait and miniature painting. He first attempted foreshortening and a natural disposition of drapery; but his style, nevertheless, remained dry and stiff. Boniface VIII. invited him to Rome, where he painted the still celebrated Navicella. He was followed by Gaddi, Stefano, Maso, and Simone Memmi, who painted the celebrated portraits of Petrarch and Laura. But Masaccio first dispelled the darkness of the middle ages, and a brighter dawn illumined the art.

The Florentine republic, in the beginning of the fifteenth century, had attained the summit of its splendour. Cosmo of Medici patronized all the arts and sciences; Brunelleschi then built the dome of the cathedral; Lorenzo Ghiberti cast the famous doors of the baptistery in bronze; and Donatello was to statuary what Masaccio was to painting. Masaccio's real name was Tommaso Guidi. He was born at St. Giovanni, in Val d'Arno, in the year 1402. His paintings have keeping, character, and spirit. His scholars first began to paint in oil, but only upon wooden tablets, or upon walls coated with plaster of Paris. Canvass was not used till long after. Paolo Uccelli laid the foundation for the study of perspective. Luca Signorelli, who first studied anatomy, and Domenico Ghirlandaio, who combined noble forms and expression with a knowledge of perspective, and abolished the excessive use of gilding, were distinguished in their profession. The elevated mind of Leonardo da Vinci, who was a master in all the arts and sciences, infused so much philosophy and feeling into the art that, by his instrumentality, it quickly reached maturity. From him the Florentine school acquired that grave, contemplative, and almost melancholy character, to which it originally leaned, and which it afterwards united with the boldness and gigantic energy of Michael Angelo. The Roman school already enumerated among its founders the miniature painter Oderigi, who died in 1300. He embellished manuscripts with small figures. Guido Palmerucci, Pietro Cavallini, and Gentile da Fabriano were his most distinguished successors. Almost all the painters of this time were accustomed to annex inscriptions to their pictures: the Annunciation to the Virgin Mary was their favourite subject. Perugia was the principal seat of the Roman school.

As early as the thirteenth century, there was a society of painters there. Pietro Vanucci, called *Perugino* (who was born 1446, died 1524), first introduced more grace and nobler forms into this school, whose character acquired from him something intellectual, noble, simply pious, and natural, which always remained peculiar to the Roman school. Perugino's great scholar, Raphael, soon surpassed all former masters, and banished their poverty, stiffness, and dryness of style. Taste came into Venice from the East. Andr. Murano and Vittore Carpaccio are among the earliest artists of that city. Giovanni and Gentile Bellino are the most distinguished painters of the earlier Venetian school. The former was born 1424, and

died 1514. The latter laboured some time in Constantinople under the reign of Mohammed II. They introduced the glowing colours of the East; their style was simple and pure, without rising to the ideal. Padua was the principal seat of the Venetian school. Mantegna afterwards transferred it to Mantua, and his style formed the transition to the Lombard school. Schools of painting flourished in Verona, Bassano, and Brescia. Giovanni of Udine (who was so distinguished by his faithful imitation of nature in secondary things that he painted for Raphael the garlands around his pictures in the Farnesina), Pellegrino, and Pordenone, were the most able predecessors of the two great masters of the Venetian school, Giorgione and Titian. No capital city served as the central point of the Lombard school: Bologna subsequently became the centre. Imola, Conto, Ferrara, Modena, Reggio, Parma, Mantua, and Milan, were afterwards considered the seats of this school. Galasio, who lived about 1220, Alighieri, Alghisi, Cosimo Tura, Ercole Grandi, and especially Dosso Dossi, were the principal painters of Ferrara. The last, a friend of Ariosto, possesses a remarkable grandeur of style, united with a richness of colouring which may bear comparison with that of Titian. Bramante, who was likewise a great architect, Lippo Dalmasi, and especially Francesco Raibolini, called *Francesco Francia*, were highly distinguished among the Bolognese masters. The latter, who was marked by a tender religious expression and uncommon industry, had the greatest veneration for Raphael. It is asserted that, at the sight of the St. Cecilia of this master, he was so struck with the impossibility of attaining the same perfection that he fell into a deep melancholy, and soon after died. Here also belongs the charming Innocenzo da Imola. But all these were far surpassed by the incomparable Antonio Allegri da Correggio, who, in fact, first founded the Lombard school, so distinguished for harmony of colours, expression replete with feeling, and genuine grace.

Second Period. We now come to the greatest masters of any age, who almost at the same time, as heads of the four schools, carried every branch of the art to the highest perfection. In Italy, they and their scholars are called *Cinquecentisti*, from the century in which they flourished. This period of perfection passed away rapidly, and soon required the violent restoration with which the third period commences. Next in order after Leonardo da Vinci, who in the Florentine school had settled the proportions of figures and the rules of perspective and of light and shade, may be placed his scholars, Luini, Salaino, and Melzo, besides the admirable Baccio della Porta, who is celebrated under the name of *Fra Bartolommeo*.

We now come to the most extraordinary of all masters, Michael Angelo Buonarotti (born 1474, died 1564). His gigantic mind grasped, with equal power, statuary, architecture, and painting. His fire of composition, his knowledge of anatomy, the boldness of his attitudes and foreshortenings, leave him without a rival; but, as a model, he was detrimental to the art, because his imitators necessarily fell into exaggeration and contempt of a simple style. In grandeur, his fresco painting, the Last Judgment, in the Sistine Chapel at Rome, is inimitable. Beauty was never so much his object as power and sublimity, especially since, in the former, he could not equal Raphael, while in the latter he stood alone. Dante was his favourite poet. In his later years, the erection of St. Peter's church almost entirely engrossed his thoughts. Rosso de' Rossi, Daniel of Volterra, Salviati, Angelo Bronzino, Allessandro Allori, and many others, were his scholars and imitators.

In 1580, Ludov. Cigoli and Greg. Pagani began to awaken a new spirit. They returned to nature, and sought to create a better taste in the *chiaro-oscuro*. Domenico Passignani, Cristoforo Allori, and Comodi were their followers. If we turn our attention to the Roman school, we find at its head the first of artists—Raphael da Urbino. His genius showed itself as elevated in his fresco paintings, in the *stanze* and *loggie* of the Vatican, as it appears lovely, spiritual, and original in the frescos of the Farnesina. No less superior are his oil-paintings, of which we shall only mention his *Madonnas*, celebrated throughout the world, especially the *Madonna del Sisto* (in the Dresden gallery), *the Madonna della Sedia* (in Florence), *Madonna della Pesce* (in Madrid), his St. Cecilia (in Bologna), and his last work, the Transfiguration of Christ. His scholars and successors—the bold Giulio Romano, the more gloomy Franc. Penni il Fattore, the lofty Bartolommeo Ramenghi, surnamed *Bagnacavallo*, Pierino del Vaga, Polidoro da Caravaggio, Gemigniani, Benvenuto Tisi, called *Garofolo*, and many others—were skilful masters; but they forsook the path of their great pattern, and degenerated into mannerism. Frederico Baroccio endeavoured to counteract this tendency. In spirit, he belonged to the Lombard school, as he aimed at the grace of Correggio. He possesses an uncommon degree of grace and expression. With his scholars, Francesco Vanni, Pellegrini, and the brothers Zuccheri, he infused a new life into the Roman school, though the latter produced pleasing rather than great works, and fell into mannerism. Muziano was distinguished in landscape-painting, and Nogari, Pulzone, and Facchetti in portrait-painting.

At the head of the Venetian school, we find two excellent colourists, Giorgione Barbarelli di Castelfranco and Tiziano Vercelli. The portraits of the former are celebrated for their warmth and truth. The latter was great in all the departments of art, inimitable in the disposition of his carnations, excellent as a historical and portrait painter, and the first great landscape painter. Even in extreme old age, his powers were unimpaired. Ariosto and Aretino were friends of the gay-minded Titian. He executed many works for the Spanish kings. Some of his most famous works are the altar-piece of St. Pietro Martire, his pictures of Venus, his Bacchanal, and his Children Playing, in Madrid, his *Cristo della Moneta*, &c. He first understood the art of painting with transparent colours. In groups, he selected the form of a bunch of grapes for a model. His successors—Sebastiano del Piombo, Palma Vecchio, Lorenzo Lotto, Paris Bordone, Pordenone—are distinguished, especially in colouring. Schiavone, whose *chiaro-oscuro* and richness of colour are truly remarkable; Giacomo da Ponto, called *il Bassano*, who imitated reality, even in common things, to deception, and who was the head of a whole family of painters; the ardent, inspired Robusti, called *il Tintoretto*, whom Titian, through jealousy, dismissed from his school; the fantastic, splendid Paul Veronese, who painted boldly and brilliantly with a free pencil, but neglected all propriety of costume, and

frequently mingled masks in historical paintings, and the Veronese Cagliari, were ornaments of the Venetian school. This likewise degenerated, and its mannerists were worse than those of the other schools, because they did not study the antiques and the ideal.

At the head of the Lombard school, we find the charming Antonio Allegri, called *Correggio*, whose works are full of feeling. His successors and scholars were Francesco Rondani, Gatti, Lelio Orsi, and especially Francesco Mazzola il Parmegianino. This artist possessed much ease and a peculiar grace, which frequently bordered on mannerism. Gaudenzio Ferrari, and many others, are the ornaments of the Milanese school. In landscape-painting, Lavizzario was called the *Titian of Milan*. The famous Sofonisba Angosciola, of Cremona, was highly distinguished in music and painting. As an excellent portrait-painter, she was invited to Madrid, where she painted don Carlos and the whole royal family, and gave instruction to queen Elizabeth. Van Dyke declared that he had learned more from the conversation of this woman, when she was blind from age, than he had from the study of the masters. She died in 1620. Lavinia Fontana, Artemisia Gentileschi, Maria Robusti, and Elis. Sirani were celebrated female artists of this time. Camillo and Giulio Procaccino were distinguished for strength of imagination and excellent colouring. In Bologna, we find Bagnacavallo, a distinguished artist of this period, whom we have already mentioned as one of Raphael's scholars. He flourished about 1542. Francesco Primaticcio, Niccolò dell' Abbate, Pellegrino Tibaldi, Passarotti and Fontana were very able Bolognese artists.

Third Period. It begins with the age of the three Caracci. These excellent artists endeavoured to restore a pure style, and, by the combined study of the ancient masters of nature and science, to give a new splendour to the degraded art. Their influence was powerful. The division into the four principal schools now ceases, and we find but two principal divisions—the followers of the Caracci, who are called *eclectics*, and the followers of Michael Angelo Caravaggio, who are called *naturalists*. Ludovico Caracci was the cousin of the two brothers Agostino and Annibale. Ludovico was quiet, contemplative, soft, and serious. His passionate teachers, Fontana and Tintoretto, at first denied him any talent: he studied therefore more zealously, and acquired the deepest views as an artist. Agostino united uncommon sagacity and the most extensive knowledge with a noble character. His brother Annibale, who made extraordinary progress in the art, under Ludovico's direction, became jealous of Agostino. The disputes between the two brothers never ceased, and the offended Agostino devoted himself chiefly to the art of engraving. The attacks of their enemies first united them, and they founded together a great academy. The brothers were invited to Rome to paint the gallery of the duke of Farnese. They soon disagreed, and Agostino retired, leaving the work to his brother, who completed the undertaking with honour, but was shamefully cheated of the greatest part of his pay. Deeply mortified, he sought to divert his mind by new labours and a journey to Naples; but the hostility which he there experienced hastened his death. Meanwhile, with the aid of his scholars, the quiet Ludovico finished one of the greatest works—the famous portico of St. Michael in Bosco, in Bologna, on which are represented seven fine paintings, from the legends of St. Benedict and St. Cecilia. The last of the labours of this great master was the Annunciation to Mary, represented in two colossal figures, in the cathedral of Bologna. The angel is clothed in a light dress, and, by an unhappy distribution of drapery, his right foot seems to stand where his left belongs, and *vice versâ*. Near at hand, this is not observed; but, as soon as the large scaffold was removed, Ludovico saw the fault, which gave occasion to the bitterest criticisms from his enemies. The chagrin which he suffered on this occasion brought him to the grave.

The scholars of the Caracci are numberless. The most famous endeavoured to unite the grace of Correggio with the grandeur of the Roman masters. Cesare Aretusi was distinguished for the most faithful copies of Correggio and Guido Reni, especially for the ideal beauty of his heads, the loveliness of his infant figures, and the uncommon facility of his pencil. His fresco representing Aurora, in the palace Borghese, and his fine oil-painting, the Ascension, in Munich, are well known. Francesco Albani lived in constant rivalry with Guido. He produced many large church paintings, but was most celebrated for the indescribable charm with which he represented, on a smaller scale, lovely subjects from mythology, and especially groups of Cupids. His paintings in the Verospi gallery, and his Four Elements, which he painted for the Borghese family, gained him universal reputation. The back-ground of his landscapes is excellent. All his works breathe serenity, pleasure, and grace. The third great contemporary of those already mentioned, Domenico Zampieri, called *Domenichino*, was at first little esteemed by them, on account of his great modesty and timidity. Thrice were prizes awarded by Ludovico to drawings the author of which no one could discover. At last Agostino made enquiries, and the young Domenichino timidly confessed that the drawings were his. His industry and perseverance rendered him the favourite of his master. His works evince the most thorough knowledge of art, and are rich in expression of character, in force and truth. His Communion of St. Jerome, his Martyrdom of St. Agnes, and his fresco in the Grotta Ferrata, are immortal masterpieces. He was always remarkable for his timidity. He was invited to Naples, but was there persecuted and tormented by the painters; and it is even suspected that he was poisoned.

Giovanni Lanfranco was especially distinguished for the effect of his lights. Bartol. Schidone is one of the best colourists of this school. The Bibienas, the Molas, Al. Tierini, Pietro di Cortona, Ciro Ferri also deserve mention. At the head of the naturalists, who, with a bold and often rash pencil, imitated nature without selection, stands Michael Angelo Merigi, or Amerigi da Caravaggio (born 1569). His chief opponent in Rome was D'Arpino, who stood at the head of the idealists, or rather of the mannerists. Caravaggio and his successors, Manfredi, Leonello Spada, Guercino da Cento, &c., often took common nature for a model, which they servilely imitated, thus profaning the genuine dignity of the art, though they cannot be denied strength and genius. About this time, the beginning of the seventeenth century, the *bambocciate* were introduced. Many artists, especially Michael Angelo Cerquozzi, surnamed *Delle Battaglie*, and *Delle Bambocciate*, followed this degenerate taste. Andrea Sacchi made great efforts to oppose him. His drawing was correct and grand; Raphael was

his model. His most famous scholar was Carlo Maratto (born 1625, at Camerano), whose style was noble and tasteful. The cavaliere Pietro Liberi, Andrea Celesti, the female portrait-painter Rosalba Carriera (born at Venice, 1675, died 1757), who was distinguished for her drawings in crayons, the graceful Francesco Trevisani, Pinzetta Tiepolo, and Canaletto, a painter in perspective, were the most celebrated Venetian painters of this time. Carlo Cignani (born 1628, died at Bologna, 1719), acquired a great reputation by his originality and the strength and agreeableness of his colouring. Of his scholars, Marc. Antonio Franceschini was distinguished (born 1648, died 1729), whose works are charming and full of soul.

Giuseppi Crespi, called *Spagnoletto*, deserves mention for his industry and correct style, but his pictures have unfortunately become very much defaced by time. Among the Romans, Pompeo Battoni (born 1708, died 1787) was principally distinguished, and was a rival of the celebrated Mengs. Angelica Kaufmann also deserves to be mentioned.

We must not forget the Neapolitan and the Genoese schools. Of the Neapolitans, we name Tommaso de' Stefani (born 1230), Fil. Tesauro, Simone, Colantonio de' Fiori (born 1352), Solario il Zingaro, Sabatino (born 1480), Belisario, Caracciolo, Giuseppe Ribera Spagnoletto (born 1593), Spadaro, Francesco di Maria (born 1623), Andrea Vaccaro, the great landscape-painter Salvator Rosa (born 1615), Preti, called *il Calabrese* (born 1613), and Luca Giordano (born 1632, died 1705), who was called, from the rapidity of his execution, *Luca fa Presto*. Solimena (born 1657) and Conca belong to the modern masters of this school. The Genoese can name among their artists Semino (born 1485), Luca Cambiasi (born 1527), Paggi Strozzi, called *il Prete Genovese*, Castiglione (born 1616), Biscaino, Gaulli, and Parodi. Perhaps the most distinguished of the living painters of Italy is Camoccini. This reputation, however, is not allowed him without dispute by foreign countries, and even by many artists of his native land. His style is grand, and purely historical; his drawings are even more highly esteemed than his paintings. His pieces, however, are cold, and their estimation seems to have diminished. The pencil of Grassi possesses an inimitable grace, and a true enchantment. Benvenuti, director of the academy in Florence, is the first artist there. Appiani, who died a few years ago at Milan, was particularly celebrated for the grace of his female figures; and Bossi had equal reputation in a more serious and severe style. The Florentine Sabbatelli's sketches with the pen are highly esteemed.

In the art of engraving, the Italians have acquired great eminence. Tommaso Finiguerra, who flourished 1460, was the first celebrated master of this art, which he taught to Baccio Bandini. They were succeeded by Mantegna; but Marco Antonio Raimondi, of Bologna, who lived in 1500, was the first to introduce greater freedom of style into his engravings. His copies of Raphael have always been highly valued, on account of their correctness. His manner was imitated by Bonasone, Marco di Ravenna, Di Ghisi, and others. Agostino Caracci, Parmeggiano, Carlo Maratti, and Pietro Testa, etched some excellent works. Stefano della Bella was distinguished for his small, spirited, and elegant pieces. Among the moderns, Bartolozzi deserves mention in stippled engraving. Cunego, Volpato, and Bettelini are also distinguished; but, above all, the Florentine Raphael Morghen, who carried the art of engraving to a degree of perfection never before anticipated. The labours of Morghen, and yet more those of Longhi (perhaps the most admirable of all modern engravers), of Toschi, of Anderloni, of Folo, of Palmerini, of Lasinio, of Caravaglia, Lapi, and Schiavonetti, evince an activity to which new employment and new excitement have been afforded by the eagerness of travellers to procure their works. One of the latest and best is the work of the brothers Durelli, *La Certosa di Pavia*. The painter Francesco Pirovano, whose description of Milan exceeds all others in exactness, has also given us a description of this celebrated Carthusian monastery.

As a medium between painting and sculpture, we must mention mosaic, in which many paintings have been imitated in Italy, from the wish to render the master works imperishable. There is a distinction made between the Roman mosaic executed by Tafi, Giotto, and Cavallini, and the Florentine. (See Mosaic.) Mosaic painting seems to have flourished as well in France, whither it was transplanted, as in Rome. The art of working in *scagliola* (see Scagliola) has flourished for two centuries in Tuscany. In later times, Lamberto Gori has distinguished himself in this branch. Rome is still the metropolis of the arts.

Pope Pius VII. generously supported the plans of that lover of the arts, Cardinal Gonsalvi; and the Chiaramonti museum, the most superb part of the long galleries of the Vatican, will be a lasting monument of his noble patronage. All friends of the sublime and beautiful deeply felt the accident that befel St. Paul's church, near Rome, in the conflagration of 1823. To restore it would hardly be possible. The loss of this noble Basilica is not adequately compensated by the church of St. Peter and Paul, built opposite the castle of Naples, nor by the temple of Possagno, which, before it was finished, received the ashes of its founder, the great Canova. As a monument to the embellishment of which that distinguished man contributed the last efforts of his genius, this church is a legacy highly to be esteemed by Italian artists. Sculpture and painting here again meet architecture in a sisterly embrace. Canova's death was the cause of its first solemn consecration. Notwithstanding the excellence of their master, little is to be expected from the Italians of Canova's school. The monuments which were executed or planned by Ricci for the present grand-duke of Tuscany, at Arezzo, by Pisani for the princesses of the house of Este at Reggio, and by Antonio Bosa to the memory of Winckelmann, rather depress our hopes than exalt them. The principal ground of hope of future excellence is in the love which has been generally awakened for the plastic arts. Gem engraving has been carried to a very high degree of perfection; and Bernini's labours well merit the wide reputation which they have acquired.

Italian School, *in music*; the style of music now prevalent in Italy is characterized by the predominance of melody and song to the neglect of harmony, and is in this respect distinguished from the old Italian music. Like other branches of modern art, the music of modern times sprung from religion. The history of the art, after pointing out a few imperfect glimmerings of ancient music, conducts us to Italy,

where, in the course of centuries, the ancient was first lost in the modern. Here we first find the proper choral song, the foundation of modern church music, which was at first sung in unison, chiefly in melodies derived from the old Greco-Roman music, and adapted to Christian hymns and psalms. (See MUSIC, and MUSIC, SACRED.) It seems to have had its origin when Bishop Ambrosius, in the fourth century, introduced into the western church songs and hymns adapted to the four authentic modes of the Greeks, and appointed psalmists or precentors. Gregory the Great, in the sixth century, enlarged the choral song by the plagal modes. From this time, singing-schools were multiplied, and much was written upon music. The most important inventions for the improvement of music generally we owe to the eleventh century, and particularly to the Benedictine Guido of Arezzo, who, if he did not invent the mode of writing musical notes and the use of the clef, improved and enlarged them, determined the exact relations of the tones, named the tones of the scale, and divided the scale into hexachords.

In the thirteenth century, the invention of music in measure was spread in Italy, dependent upon which was that of counterpoint and figured music. Instruments were multiplied and improved in the fourteenth and fifteenth centuries. Many popes favoured music, particularly vocal, and consecrated it by their briefs; yet the ecclesiastical ordinances restrained the independent developement of music. Much instruction was given in singing in the fifteenth century, and not entirely by monks. Music acquired the rank of a science, and vocal music in counterpoint was developed.

In the sixteenth century, we discover distinguished composers and musicians—Palestrina, composer for the chapel of Pope Clement XI., whose works possess great dignity and scientific modulation, and his successors, Felice Anerio, Nanino da Vallerano, who, together with Giovanni da Balletri, were considered as distinguished musicians; also the celebrated contrapuntist and singer, Gregorio Allegri, and the great writer upon harmony, Giuseppe Zarlino, chapel-master at Venice. Music at Rome and Venice was cultivated with the greatest zeal. Hence it went to Naples and Genoa; and Italy, Schubert says, was soon one loud-sounding concert-hall, to which all Europe resorted to hear genuine music, particularly beautiful singing. In the seventeenth century, we meet with the first profane music. The first opera was performed at Venice 1624, at first with unaccompanied recitatives and chorusses in unison; it spread so quickly that the composers of spectacles were soon unable to supply the demands of the people, and from forty to fifty new operas appeared yearly in Italy. This caused great competition among the Italian musicians. Thus the peculiar character of the Italian music, not to be changed by foreign influence, was developed the more quickly, because this species was cultivated independently, and unrestrained by the church. Already, in the middle of the seventeenth century, when the music of the theatre was continually advancing, simplicity began to give place to pomp and luxuriance, and the church style to decline. Music (says Schubert) united the profane air of the drama with the fervour of the church style, and this was the first cause of the decline of the latter.

Let us now consider the principal periods of the dramatic style. Vocal music must have been first; it was regulated by the discovery and improvement of instruments; thence arose the simple, grand church music of the fifteenth and sixteenth centuries; with it various forms of national song were developed. On the stage, the higher style of music flourished independently. Here the Italian, without much attention to the poetical part of the performance, which was, indeed, only the hasty work of a moment, followed his inclination for melody and sweet sounds, which appears even in his language.

All the southern nations show a great sensitiveness, and melody is to them as necessary as harmony to the inhabitants of the North; but to no nation so much as to the Italians, whose beautiful climate and happy organization for song made melody their chief aim in their music. On the other hand, the simplicity of melody degenerated into effeminacy and luxuriance from the time when vocal music developed itself independently, and the voice, being but little supported by instrumental music, began to be cultivated like an instrument. Poetical expression and truth gave place to mere gratification of the ears, and deep emotion to a momentary excitement: a rapid change of tones, with the avoidance of all dissonance, was principally desired. At this time music began to predominate over poetry in dramatic representations, and the musical part of the performance obstructed the improvement of the dramatic and poetic. This taste spread over other countries so much the more easily from Italian music having advanced, by rapid strides, far before that of the rest of Europe, as appears even from the predominance of Italian terms in musical language. This artificial developement of the song was promoted by the introduction of soprano singers on the stage, which destroyed the possibility of poetic truth in dramatic representation. The voice was cultivated to the highest degree by means of the numerous conservatorios and singing schools. To this was added the great encouragement and the extravagant rewards of distinguished singers; the great opportunities afforded for singing (as every place of consequence in Italy had its theatre, and many had several); besides which, music is an essential part of the service of the Catholic church, and castration was permitted *ad honorem Dei*, as a papal brief expresses it. The excessive culture of the voice must necessarily lead to the treatment of it as an instrument, to the neglect of poetical expression. Instrumental music, too, in this case, necessarily becomes subordinate. The latter should not indeed overpower the song, as is the case in much of the French and German music; but, in the Italian music, the composer is almost restricted to showing off the singer, and cannot develope the fulness and depth of harmony which depends upon the mingling of consonance and dissonance. This is the reason why the masterpieces of Mozart have never entirely satisfied the Italians. Among the best composers, since the seventeenth century, are Girolamo Frescobaldi, Francesco Foggia, Bapt. Lully, the celebrated violinist and composer Arcangelo Corelli. To the singers, of whom the most were also composers, belong Antimo Liberati, Matteo Simonelli, both singers in the chapel of the pope.

In the beginning of the eighteenth century, Ant. Caldara was distinguished. He increased the effect of vocal music by the addition of instruments, but his tyle partook much of the theatrical. There were,

besides, Brescianello, Toniri, and Marotti. In the middle of this century, Italian music, especially theatrical, flourished, particularly at Naples, Lisbon, and also in Berlin. This has been considered by some as the most brilliant period of Italian music. Among the composers of the eighteenth century are mentioned Traelta, who, through his refinements, injured the simplicity of composition; Galuppi, distinguished by simple and pleasing song, rich invention, and good harmony; Jomelli, who gave greater importance to instrumental music; Maio; Nic. Porpora, the founder of a new style of singing, distinguished for his *solfeggios* in church music; Leo; Pergolesi, whose music is always delightful, from its simple beauty; Pater Martini, at Bologna; the sweet Piccini, rival of Gluck; and Anfossi. Of a later date are Paesiello Cimarosa, the ornament of the *opera buffa*, and Zingarelli, Nasolini, Paganini, Niccolini, Pavesi, and the now much celebrated Generali and the copious Rossini. The Italian school is yet unequalled in whatever depends upon the mere improvement of the voice; but the slavish imitation of their manner leads to affectation, and the English singers should employ it no farther than they can without losing the spirit and poetical expression which all vocal music aims at.

IVORY; the substance of the tusk of the elephant. Ivory is esteemed for its beautiful cream colour, the fineness of its grain, and the high polish it is capable of receiving. That of India is apt to lose its colour and turn yellow; but the ivory of Achem and Ceylon is not chargeable with this defect. Ivory is used as a material for toys, and for panels in miniature painting, &c.

The shavings of ivory may be reduced into a jelly, of a nature similar to that of hartshorn; or, by burning in a crucible, they may be converted into a black powder, which is used in painting, under the name of *ivory-black*. Ivory may be stained or dyed; a black colour is given it by a solution of iron and a decoction of logwood; a green one by a solution of verdigris; and a red by being boiled with Brazil-wood, in lime-water.

The use of ivory was well known in very early ages: we find it employed for arms, girdles, sceptres, harnesses of horses, sword-hilts, &c. The ancients were also acquainted with the art of sculpturing in ivory, of dyeing and encrusting it. Homer refers to the extreme whiteness and beauty of ivory. The coffer of Cypselus was doubtless the most ancient monument of this kind in basso-relievo, and we meet with similar instances in the temple of Juno at Olympius, in the time of Pausanias; that is to say, 700 years after it had been built. The ancients had numerous statues of ivory, particularly in the temples of Jupiter and of Juno, at Olympius. In these statues, there was very frequently a mixture of gold. The most celebrated are stated to have been the Olympian Jupiter and the Minerva of Phidias: the former was covered with a golden drapery, and seated on a throne formed of gold, of ivory, and cedar wood, and enriched with precious stones. In his hand the god held a figure of Victory, also of ivory and gold. The Minerva was erected in the Parthenon at Athens during the first year of the eighty-seventh Olympiad—the year which commenced the Peloponnesian war. Pausanias likewise makes mention of an ivory statue of Juno on her throne, of remarkable magnificence, by Polycletes, together with numerous others.

JALAP has received its name from being principally brought from the environs of Xalapa; though the plant which produces it is abundant in other parts of Mexico, even in the immediate vicinity of Vera Cruz. It is much employed in medicine, as a very valuable purgative, and has been known in Europe since the year 1610. It is exported almost exclusively from Vera Cruz, to the amount of about 400,000 lbs. annually. The root, which is the part employed, is very large, sometimes weighing fifty pounds.

JAPANNING is the art of varnishing in colours. All substances that are dry and rigid, or not too flexible, admit of being japanned. Wood and metals require no other preparation than to have their surfaces perfectly even and clean; but leather should be securely stretched, either on frames or on boards, as its bending would crack and force off the varnish. Paper should be treated in the same manner, and have a previous strong coat of size; but it is rarely japanned till converted into *papier maché*, or wrought into such form that its flexibility is lost. The article to be japanned is first brushed over with two or three coats of seed lac varnish, to form the *priming*. It is then covered with varnish, previously mixed with a pigment of the tint desired. This is called the *ground colour*; and, if the subject is to exhibit a design, the objects are painted upon it in colours mixed with varnish, and used in the same manner as for oil-painting. The whole is then covered with additional coats of transparent varnish, and all that remains to be done is to dry and polish it. Japanning requires to be executed in warm apartments, and the articles are warmed before the varnish is applied to them. One coat of varnish also must be dry before another is laid on. Ovens are employed to hasten the drying of the work. The same pigments which are employed in oil or water answer also in varnish. For painting figures, shell lac varnish is considered best, and easiest to work; it is therefore employed in most cases where its colour permits. For the lightest colours, mastic varnish is employed, unless the fineness of the work admits the use of copal dissolved in alcohol.

JAUNDICE is a disease of which the distinguishing peculiarity is that the whole skin becomes yellow. It proceeds from some disease about the liver, or its communication with the bowels. The internal symptoms are those of all disorders of the digestive organs, except that the water is dark and loaded with bile, while the bowels appear to be deprived of it. The yellow colour is first perceptible in the whiter parts of the body, as the white of the eye, &c., and soon overspreads the whole body. There is often an extreme itching and pricking over the whole skin. After the disease has continued long, the colour of the skin acquires a deeper and darker tint, till the disease becomes, at last, what is vulgarly called the *black jaundice*. This appearance arises from the bile being retained, from various causes, in the liver and gall-bladder, and thus being absorbed and circulated with the blood. It may be produced by obstacles to the passage of the bile of various kinds, and is often suddenly induced by a violent fit of passion, or more slowly by long continuance of melancholy and painful emotions. It is a very common figure of speech to say that "a person views a thing or a person with jaundiced eyes;" but this is founded in a mistake; for it is not true that jaundice communicates such a colour to the transparent part of the

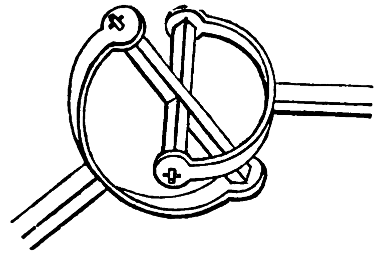
eye as to affect the colour of objects. The above phrase is therefore inappropriate.

Jelly includes every translucent juice so far thickened as to coagulate, when cold, into a trembling mass; as the juices of acid or mucilaginous fruit, currants, &c., which, by the addition of one part of sugar to two parts of juice, and by boiling, have obtained a proper consistence; also a concentrated decoction of Iceland moss, made agreeable to the taste by the addition of sugar or liquorice; also strong decoctions of the horns, bones, or extremities of animals, boiled to such a degree as to be stiff and firm when cold, without the addition of any sugar.

The jellies of fruits are cooling, saponaceous, and acescent, and therefore are good as medicines in all disorders of the *primæ viæ*, arising from alkalescent juices, especially when not given alone, but diluted with water. On the contrary, the jellies made from animal substances are all alkalescent, and are therefore good in all cases in which an acidity of the humours prevails. The alkalescent quality of these is however, in a great measure, taken off, by adding lemon-juice and sugar-lemon to them. There was formerly a sort of jellies much in use, called *compound jellies;* these had the restorative medicinal drugs added to them, but they are now scarcely ever heard of. Animal jelly is soluble in water, glutinous, becomes fluid by heat, coagulates in the cold, combines with oils and resins, is decomposed by corrosive alkali, and gives out ammonia; when it is treated with nitric acid, it yields oxalic acid, and, under dry distillation, yields the products obtainable from all animal substances, and can be changed into a perfectly dry substance by evaporation.

Jet. The colour of jet is a pure and deep black, sometimes with a tinge of brown. It occurs in opaque, compact masses, so solid and hard that they are susceptible of being turned on a lathe and highly polished. Its fracture is conchoidal or undulated, shining or even splendent, and it has a resinous lustre; its specific gravity, from 1.25 to 1.30. By friction, it acquires a weak electricity, even when not insulated. It sometimes presents the form of branches of trees, and exhibits traces of a ligneous texture. It burns with flame, often a little greenish, but it does not melt, like solid bitumen. It exhales, while burning, a strong and sometimes aromatic odour, sensibly different from that of coal or bitumen. It most frequently occurs in detached masses of a moderate size, in beds of sandstone, marl, limestone, and secondary trap. Jet is sometimes employed for fuel, but is more frequently cut and polished, for ornamental purposes, buttons, bracelets, snuff-boxes, &c. Some mineralogists consider it intermediate between coal and bituminous wood.

Joint, in *mechanics;* the connecting point of any movable machine. The various joints employed in the human frame are all of the most perfect kind, though they differ considerably in their structure. The mechanic has however copied but two, the *hinge*, and the *ball and socket*. The hinge-joint is used for doors, and those places generally which require motion but in one direction. The ball and socket, on the contrary, admits of a variety of positions. The expense attendant on constructing the latter is very considerable, and to obviate this inconvenience the *Hook's-joint* represented in the accompanying engraving may be employed. It was originally invented by Dr. Hook, and is found very useful in communicating a rotatory motion from the principal axis of a machine to the more distant wheels it is intended to put in operation.



It consists of two semicircles, joined by a metal cross; and, if either of the semicircles be turned, a similar motion is communicated to the other. The same species of universal joint is employed to support a compass at sea. It is then called a *jimbel-box*.

Joint-Stock Companies. Where any branch of business requires a greater capital to prosecute it with advantage than can ordinarily be furnished by an individual or by a number of individuals actually engaged in conducting it, or where the business is attended with great risks, and may, as events turn out, be very profitable, or result in great losses, as in the case of insurance, it is desirable that the law should give facility to the combination of the contributions of numerous persons, in great or small amounts, to make up the requisite capital. The first and most obvious combination for the purposes of business is that of copartnerships, whereby each of the members renders himself answerable, *in solido*, or absolutely and to the full extent, on all contracts made by the company. This is a sort of association existing in all places; but, if the business to be conducted be of the descriptions above mentioned, the copartnership is not a convenient mode of association, since the capital contributed by many must necessarily be managed by a few; and therefore, if each member is liable, *in solido*, on the contracts of the company, the fortune of each is put in jeopardy by ever so small a contribution to the joint stock. This must operate, of course, to discourage useful undertakings on a large scale, and, even if it did not, it might still be very important to provide for associations with a limited liability of the individual members, since the ruin of any individual will necessarily affect others to a greater or less extent.

The shocks, and individual derangements and reverses, which are necessarily incident to enterprises of industry and trade, make it very desirable to secure, by some modes of association, an apportionment of risks, losses, and gains among a great number. This is done by means of private corporations, joint-stock companies, and limited copartnerships.

Journal, in *navigation;* a sort of diary or daily register of the ship's course and distance, the winds and weather, together with a general account of whatever is material to be remarked in the period of a sea voyage, such as the shifting, reducing, or enlarging the quantity of sail, the condition of the ship and her crew, the discovery of other ships or fleets, lands shoals, breakers, soundings, &c.

Journeyman, formed from the French *journée* (a day's work), anciently signified a person who wrought with another by the day; but it is now used to designate any mechanic who works for another in his em-

ployment, whether by the month, year, or any other term. It is applied only to mechanics in their own occupations.

JUGERUM; a Roman measure; a piece of ground which could be ploughed in one day by a yoke of oxen; a Roman acre, 240 feet long, 120 feet broad (28,800 square feet). It was the unit of field-measure, and divided into ½ *jugerum* = 14,400 Roman square feet; ⅛ *jugerum* = 3600. *Actus minimus* was a strip 4 feet wide and 120 feet long = 480 Roman square feet. Two *jugera* were called *hæredium;* 100 *hæredia* made one *centuria*, and four *centuriæ* (= 800 *jugera*) one *saltus*. In the time of the kings, two *jugera* were reckoned a sufficient allowance for a father of a family; at a later period, seven; 376 B. C., fifty; but, even at a still later period, it was considered dishonourable for a senator to possess more than 500 *jugera*.

JULY; the seventh month in our calendar, which, in the Roman year, bore the name of *Quintilis*, as the fifth in the computation of Romulus, even after Numa had prefixed January and February. Marc Antony effected a change in its name, in honour of Julius Cæsar, who was born IV. *Idus Quintilis*, and thenceforward, by a decree of the senate, it was called *Julius*.

JUNE; the sixth month in our calendar. Vossius gives three etymologies of the name—one from *Juno;* another from *jungo* (to join), referring to the union between the Romans and Sabines, under Romulus and Titus Tatius; a third from *juniores* (the young men), Romulus having been said to have assigned the month of May to the elders and that of June to the young men, when he divided the people into these two great classes, the former to serve in counsel, the latter in war. These origins are more fully explained by Ovid. The name has also been traced to Junius Brutus, the first consul.

JUNIPER. The berries of this plant are made use of to impart their peculiar flavour to spirit, constituting *gin*. They are also used by brewers, to give pungency to the lighter kinds of beer. In some parts of Europe, they are roasted, ground, and used as a substitute for coffee. They are also used in Sweden and in Germany as a conserve, and as a culinary spice, and especially to give flavour to sour-crout. Like all plants of the terebinthinate class, they have a decidedly diuretic property, and they are much used as diuretic medicines. The oil of juniper, if mixed with nut-oil, forms an excellent varnish for pictures, woodwork, and iron, which it preserves from rust. From the bark exudes a resinous gum, known by the name of *gum sandarach*. It is in small yellow pieces, very brittle and inflammable, and of a pungent aromatic taste. When finely powdered and sifted, it constitutes the substance so well known under the name of *pounce*. It is also used by painters in the preparation of varnish, especially of the kind termed *vernix*.

JURY-MAST; a temporary or occasional mast, erected in a ship in the place of one that has been carried away by tempest, battle, &c. Jury-masts are sometimes erected in a new ship, to navigate her down a river, or to a neighbouring port, where her proper masts are prepared for her.

KALEIDOSCOPE; an instrument for creating and exhibiting an infinite variety of beautiful forms, pleasing the eye by an ever-varying succession of splendid tints and symmetrical figures, and enabling the observer to render permanent such as may appear appropriate for any branch of the ornamental arts. This instrument, the invention of Doctor Brewster, in its most common form consists of a tin tube, containing two reflecting surfaces, inclined to each other at any angle which is an aliquot part of 360°. The reflecting surfaces may be two plates of glass, plain or quicksilvered, or two metallic surfaces, from which the light suffers total reflection. The plates should vary in length, according to the focal distance of the eye: five, six, seven, eight, nine, and ten inches, will, in general, be most convenient; or they may be made only one, two, three, or four inches long, provided distinct vision is obtained at one end, by placing at the other an eye-glass, whose focal length is equal to the length of the reflecting planes. The inclination of the reflector that is in general most pleasing is 18°, 20°, or 22½°, or the 20th, 18th and 16th part of a circle; but the planes may be set at any required angle, either by a metallic, a paper, or cloth joint, or any other simple contrivance. When the two planes are put together, with their straightest and smoothest edge in contact, they will have the form of a book opened at one side. When the instrument is thus constructed, it may be covered up either with paper or leather, or placed in a cylindrical or any other tube, so that the triangular aperture may be left completely open, and also a small aperture at the opposite extremity of the tube. If the eye be placed at the aperture, it will perceive a brilliant circle of light, divided into as many sectors as the number of times that the angle of the reflectors is contained in 360°. If this angle be 18°, the number of sectors will be 20; and, whatever be the form of the aperture, the luminous space seen through the instrument will be a figure produced by the arrangement of twenty of these apertures round the joint as a centre, in consequence of the successive reflections between the polished surfaces. Hence it follows that if any object, however ugly or irregular in itself, be placed before the aperture, the part of it that can be seen through the aperture will be seen also in every sector, and every image of the object will coalesce into a form mathematically symmetrical, and highly pleasing to the eye. If the object be put in motion, the combination of images will likewise be put in motion, and new forms, perfectly different, but equally symmetrical, will successively present themselves, sometimes vanishing in the centre, sometimes emerging from it, and sometimes playing around in double and opposite oscillations. When the object is tinged with different colours, the most beautiful tints are developed in succession, and the whole figure delights the eye by the perfection of its forms and the brilliancy of its colouring. The eye-glass placed immediately against the end of the mirrors, as well as another glass similarly situated at the other end, is of common transparent glass. The tube is continued a little beyond this second glass, and, at its termination, is closed by a ground glass, which can be put on and off. In the vacant space thus formed, beads, pieces of coloured glass, and other small bright objects, are put. The changes produced in their position, by turning the tube, give rise to the different figures.

A very beautiful instrument may be constructed by combining the kaleidoscope with a movable pendulum. The kaleidoscope should be fixed in such a direction as to present the open end to the light, and, instead of loose objects, some twisted glass of different colours must be attached to the pendulum.

As the latter vibrates before the instrument the most brilliant and symmetrical figures are formed.

KEDGE, or KEDGER; a small anchor, used to keep a ship steady, and clear from her bower-anchor, while she rides in a harbour or river, particularly at the turn of the tide, when she might otherwise drive over her principal anchor, and entangle the stock or flukes with her slack cable, so as to loosen it from the ground. The kedge-anchors are also used to transport a ship, or remove her from one part of a harbour to another, being carried out from her in the long-boat, and let go by means of ropes fastened to these anchors. They are also generally furnished with an iron stock, which is easily displaced for the convenience of stowing.

KEEL; the principal piece of timber in a ship, which is usually first laid on the blocks in building. By comparing the frame of a ship to the skeleton of the human body, the keel appears as the back-bone, and the timbers as the ribs. The keel supports and unites the whole fabric, since the stem and stern-posts, which are elevated on its ends, are, in some measure, a continuation of the keel, and serve to connect and enclose the extremities of the sides by transoms, as the keel forms and unites the bottom by timbers. The keel is generally composed of several thick pieces placed lengthways, which, after being scarfed together, are bolted and clinched upon the upper side.

False keel; a strong, thick piece of timber, bolted to the bottom of the keel, which is very useful in preserving its lower side. The false keel is provided when the thick pieces which form the real keel cannot be procured large enough to give a sufficient depth thereto. In large ships of war, the false keel is composed of two pieces, called the *upper* and *lower* false keels. The lowest plank in a ship's bottom, called the *garboard streak*, has its inner edge let into a groove or channel, cut longitudinally on the side of the keel: the depth of this channel is therefore regulated by the thickness of the garboard streak.

Sliding Keels are found very advantageous. They are attached by timbers to the bottom of the vessel, and may be raised or depressed at pleasure. When a vessel constructed in this way enters shallow water the keel is raised: but when navigating the ocean, and carrying a press of sail, the keel is depressed, and the vessel thus rendered more stable.

KEELSON, or KELSON; a piece of timber forming the interior or counter part of the keel, being laid upon the middle of the floor-timbers, immediately over the keel, and serving to bind and unite the former to the latter, by means of long bolts driven from without, and clinched on the upper side of the keelson. The keelson, like the keel, is composed of several pieces scarfed together; and, in order to fit with more security upon the floor-timbers and crotchets, it is notched about an inch and a half deep, opposite to each of those pieces, thereby scored down upon them to that depth, where it is secured by spike-nails. The pieces of which it is formed are only half the breadth and thickness of those of the keel.

KEEP, in the *military art;* a kind of strong tower, which was built in the centre of a castle or fort, to which the besieged retreated, and made their last efforts of defence. It was also called the *donjon* or *dungeon.*

KEEPING, in *painting*, is a technical term, which signifies the peculiar management of colouring and *chiaro-oscuro*, so as to produce a proper degree of *relievo* in different objects, according to their relative position and importance. This may be effected either by shade or colour, either by throwing a shadow across the inferior objects, or by tinting them with a colour less bright than that given to others, and, in very skilful hands, it may even be done by the directly reverse practice. As the objects recede in the ground plane, the hue of the atmosphere, intermixing with their *proper* or *local* colour, as it is termed, will assist in their keeping. On keeping, *relievo* entirely depends; for, if the lights, shadows, and half tints be not kept in their exact relative proportions of depths, no rotundity can be effected, and without due opposition of light, shade, and colours, no apparent separation of objects can take place. Raphael has, in two instances, totally failed of proper keeping—in the Transfiguration, and the Miraculous Draught of Fishes.

KELP, in *commerce;* the ashes of sea-weeds or *fuci*. The sea-weed is cut close to the rocks, during the summer season, and afterwards spread out upon the shore to dry, care being taken to turn it occasionally, to prevent fermentation. It is then stacked for a few weeks, and sheltered from the rain, till it becomes covered with a white saline efflorescence, and is now ready for burning. This is usually accomplished in a round pit, lined with brick or stone; but the more approved form for a kiln is oblong, about two feet wide, from eight to eighteen long, and from two to three deep: the bottom of this is covered with brush, upon which a little dried sea-weed is scattered, and fire is applied at one extremity; the sea-weed is then thrown on gradually, as fast as the combustion reaches the surface, and, should there be much wind, it will be necessary to protect it by covering the sides with sods. After the whole is burnt, the mass gradually softens, beginning at the sides, when it should be slowly stirred up with a heated iron bar, and incorporated, till it acquires a semifluid consistence. This part of the process requires considerable dexterity; and, if the mass continue dry, a little common salt should be thrown on, which acts as a flux. When cold, it is broken up, and is then ready for sale.

Notwithstanding that kelp contains but two or three per cent. of carbonate of soda, while Spanish barilla often contains twenty or thirty, the manufacture of this article has increased prodigiously on the northern coasts of Great Britain and the neighbouring islands. Farms in the Orkneys which formerly rented for 40*l.* a year have now risen to 300*l.*, on account of their kelp shores; and so much importance is attached to this branch of business that, along sandy shores, stones have been placed within the flood-mark, which, in a short time, become covered with seaweed. Many thousand tons are thus manufactured annually, and are sold in the various ports of Great Britain. The uses of soda are, in general, the same with those of potash; but there are certain branches of manufactures to which it is indispensable, as to the making of plate and crown glass, and all hard soaps. Both alkalies are consumed in immense quantities by soap-boilers, bleachers, and glass-makers; but it is said that in France the use of potash has very much diminished since the culture of barilla has been introduced. The barilla obtained in France from the *salicornia annua* yields fourteen or fifteen per cent. of soda; while that from *salsola tragus* yields only from three to eight per cent. The Spanish barilla is the most esteemed, particularly that from Alicant. It is

obtained from the *salsola sativa*, which is carefully cultivated in light, low soils, embanked on the side next the sea, and furnished with flood-gates, through which the salt water is occasionally admitted. So anxious are the Spaniards to monopolize this trade that the exportation of the seed is prohibited under pain of death. Carbonate of soda is also found abundantly in a mineral state in many countries, as in Hungary, the southern parts of Siberia, Persia, China, North Africa, and the environs of Smyrna; but the native salt has not hitherto become important as an article of commerce.

KETCH; a vessel equipped with two masts, viz. the main-mast and the mizzen-mast, and usually from 100 to 250 tons burden. Ketches are likewise used as bomb-vessels, and are therefore furnished with all the apparatus necessary for a vigorous bombardment.

Bomb-ketches are built remarkably strong, as they are fitted with guns of a much larger caliber than any other vessel of war; and, indeed, this reinforcement is absolutely necessary to sustain the violent shock produced by the discharge of their mortars, which would otherwise, in a very short time, shatter them to pieces.

KETCHUP, or CATSUP. Doctor Kitchiner, in his *Apicius Redivivus*, devotes ten pages to different varieties of receipts for this sauce. There we may become acquainted with the composition and virtues of numerous catsups, whether they be walnut, mushroom, quintessence of mushroom, quintessence of oysters, cockle, muscle, tomato, white cucumber, or pudding. "Mushroom gravy," says the doctor, "approaches the flavour of meat gravy more than any other vegetable juice, and is the best substitute for it in meagre soups and *extempore* gravies." Again, "What is commonly called *catsup* is generally an injudicious composition of so many different tastes that the flavour of the mushroom is overpowered by a farrago of garlic, shallot, anchovy, mustard, horseradish, lemon-peel, beer, wine, and spices. Ready-made catsup is little better than a decoction of spice, and salt and water, with the grosser part of the mushrooms beaten up into a pulp."

KEY, or KEY NOTE, in *music*; a certain fundamental note or tone, to which the whole of a movement has a certain relation or bearing, to which all its modulations are referred and accommodated, and in which it both begins and ends. There are but two species of keys; one of the major, and one of the minor mode, all the keys in which we employ sharps or flats being deduced from the natural keys of C major and A minor, of which they are mere transpositions.

KEYS of an organ; movable projecting levers in the front of an organ, so placed as to conveniently receive the fingers of the performer, and which, by a connected movement with the valves or pallets, admit or exclude the wind from the pipes. See ORGAN.

KEY-STONE of an arch or vault; that placed at the top or vertex of an arch, to bind the two sweeps together. This, in the Tuscan and Doric orders, is only a plain stone, projecting a little; in the Ionic, it is cut and waved somewhat like consoles; and, in the Corinthian and Composite orders, it is a console, enriched with sculpture.

KIDNEY; one of the abdominal viscera, consisting of two voluminous glands, the office of which is to secrete the urine from the blood. One of these glands lies on the right, and the other on the left, of the vertebral column (or back bone). They are both contained in a fatty, cellular substance (suet), and are situated behind the *peritonæum*, and before the diaphragm and the *quadratus lumborum*. They are penetrated with blood-vessels and nerves, are of a reddish colour, and more consistent than the other glands. An external cellular membrane, and an internal fibrous membrane, envelope each kidney, which is divided into the cortical substance and the tubulous substance. The former constitutes the exterior part of the kidney, and extends between the cones formed by the latter: it secretes the urine, that is, separates its elements from the blood, and combines them; while the latter pours it into the pelvis, a membranous bag situated at the middle of the kidney, from which it is conveyed by the ureter, a membranous tube, into the bladder. The kidneys are not mere filters or sieves, as was anciently supposed, and as some modern physiologists have maintained; they are true glands, that is, a vascular nervous apparatus, having a particular action for the production of a peculiar fluid. The kidneys are subject to an inflammation, called *nephritis*, and to a nervous pain, called *nephralgia*. The centre of the kidney sometimes contains stones, gravel, or sand, which are also found in the cortical and tubulous substances adjoining, and occasion the most excruciating pain. Diseases of the kidneys are generally occasioned by excess in eating and drinking, or violent riding, or much walking. Temperance, vegetable diet, warm bathing, &c., are preventives.

KING AT ARMS, in *heraldry*; an officer, formerly of great authority, whose business is to direct the heralds, preside at their chapters, and have the jurisdiction of armoury. The origin of the title is doubtful.

KNEE, in *anatomy*; the hinge-joint which unites the *os femoris* with the *tibia*.

KNEE, in *naval architecture*; a crooked piece of timber, having two branches or arms, and generally used to connect the beams of a ship with her sides or timbers. The branches of the knees form an angle of greater or smaller extent, according to the mutual situation of the pieces which they are designed to unite. One branch is securely bolted to one of the deck-beams, and the other in the same manner strongly attached to a corresponding timber in the ship's side. By connecting the beams and timbers into one compact frame, they contribute greatly to the strength and solidity of the ship, and enable her to resist the effects of a turbulent sea. In fixing these pieces, it is occasionally necessary to give an oblique direction to the vertical or side branch, in order to avoid the range of an adjacent gun-port, or because the knee may be so shaped as to require this disposition, it being sometimes difficult to procure so great a variety of knees as may be necessary in the construction of a number of ships of war.

KNIGHT, in *chess*. The move of this piece has given rise to an interesting problem, in regard to the various modes by which the chess-board may be covered by the knight. The path of the knight over the board is of two kinds, terminable and interminable. It is interminable whenever the concluding move of a series is made in a square which lies within reach by the knight of that from which he originally set out, and is terminable in every other instance. Euler, in the Memoirs of the Academy of

Berlin, for 1759, has given a method of filling up all the squares setting out from one of the corners. He has likewise given an interminable route, and has explained the method by which the routes may be varied, so as to end upon any square. Solutions of the same problem have also been given by Montmort, Demoivre, and Mairan.

LA, in *music;* the syllable by which Guido denotes the last sound of each hexachord. If it begins in C, it answers to our A; if in G, to E; and, if in F, to D.

Laboratory; a place fitted up for the researches of the chemist. It bears the same relation to the science of chemistry as an observatory does to that of astronomy. Although the simple observation of nature is sufficient to teach us the properties of numerous compounds, and to enable us to develope, in part, those forces which produce chemical changes, still the science of chemistry must ever have remained exceedingly defective in facts, and faulty in theory, but for the light derived from experiment. It is by means of artificial fixtures and processes that the chemist obtains the elements in a state of freedom, and recombines them so as to produce, in many instances, not only their original compounds, but such as are altogether new. It is no exaggeration to say that nine-tenths of the facts of the science, and a majority of the arts depending upon it, have been derived from the laboratory. The constructions which first received this name consisted of under-ground apartments, secluded from light and the wholesome air of day—a situation it is impossible to account for, except upon the supposition that it was copied from the alchemists, who are known to have preferred such places for the purpose of secrecy. The inconveniences attending these situations, from the want of light and facilities for ventilation, as well as from the prevalence of moisture, caused them gradually to be exchanged for apartments above ground; and although, for a time, an unnecessarily gloomy and mysterious aspect was imparted to them, from their being built of stone or brick, and but imperfectly lighted, they have at length come to resemble, in their general appearance, other structures intended for the cultivation of science.

A building devoted to this purpose in connection with a scientific institution may now be described. It should be but one story in height, in order to facilitate access to the apartments, and to render more easy the bringing in of heavy articles, as wood, water, coals, and carboys, and, at the same time, to allow of openings in the roof for sky-lights and for ventilation. In some laboratories, the theatre and working-room are united in the same apartment; in others, they are separated by a partition. The advantage of the former construction is, that the furnace operations before a class are rendered more easy; but the disadvantages are, that the size of the room renders it an inconvenient place for private researches, especially in the winter, and the seats are continually subjected to the dust and litter of ordinary operations. We shall therefore treat of a laboratory in which these apartments are distinct.

The building may vary in length from fifty to eighty feet, and in breadth from twenty-five to fifty feet. It should be well pierced with windows laterally, and also with sky-lights and openings in the roof. The lecture-room should occupy two-thirds of the length of the building; and the partition which separates it from the working-room and other apartments must contain the flues that are requisite for the furnaces of the whole establishment: these may be spread over the wall on both sides, and finally be carried out of the roof in one general chimney. The floor, from eight to twelve feet in advance of this wall, should be paved with stone, or brick; in front of which, and immediately before the seats for the class, a table, with occasional breaks for passages, gasometers, and a pneumatic cistern, should extend quite across the room, from side to side. At the two extreme ends of the table, cupboards should be erected against the wall, with glass doors, for the reception of the jars of the pneumatic cistern, measures, retorts, flasks, receivers, and the bottles and vials containing the chemicals employed for demonstration. The table should be abundantly provided with drawers of different sizes, in some places extending quite down to the floor, for the reception of substances employed in a course of demonstrations, and which it is not necessary to keep in vials and bottles, such as the common metals and many earthy and metallic salts; they are also required for the numerous tools, knives, files, gimlets, forceps, and other indispensable articles, as corks, valves or glass plates, stirrers, strings, bladders, tow, matches, sand, tapers, glass, metallic, and earthen tubes, stop-cocks, &c.

Two or three portable furnaces, of different sizes and shapes, may have a place near the wall for ordinary furnace operations; and a recess in the wall, centrally placed, and about four feet from the floor (similar in shape to a common fire-place), should be provided, with a strong draft, for those experiments which are attended with dangerous exhalations.

The seats may be arranged as is usual in other lecture-rooms. The floor room upon the other side of the partition may be divided, lengthwise of the building, into two apartments, separated by a narrow space-way, one of the rooms having double the dimensions of the other; the larger being the working-room; the smaller, an apartment for receiving delicate articles of apparatus, as balances, electrical machines, air-pump, &c., and which would be liable to injury if exposed to the attacks of the damp and corrosive vapours that are continually floating about in the other rooms. The entry should communicate with the theatre by a door: a double door, also, connecting the working-room and the lecture-room. The whole floor of the working-room is best paved with brick or stone.

The first fixture of importance in this room is the general working furnace. Its use is partly domestic, partly chemical; for it is intended to warm and air the place, occasionally to heat water, as well as to supply the means of raising a crucible to ignition, or of affording a high temperature to flasks and evaporating basins, through the agency of a sand-bath. It should be built with a table top. The fire-place itself should be constructed of brick-work, with iron front and fittings; and the flue, being carried horizontally for three or four feet, may afterwards be carried off to, and connected with, the main flue existing in the wall. The fire-place and horizonal flue should be covered with a large plate of cast iron, of from two to three feet in width, which may be formed, in the middle, over the heated part, into sand-baths; a round movable one over the fire itself, and a long fixed one over the flue. The sand-baths supply every gradation of heat, from dull redness, if required, down to a temperature of 100° or lower, whilst on each side of them exists a

level surface, which answers every purpose of an ordinary table, and supplies extraordinary facilities to experiments going on in the sand-bath or furnace. This furnace may be advantageously placed directly against the wall which separates the working-room from the theatre. A large, projecting, wooden hood should be suspended over the sand-bath, to receive the fumes evolved during the digestions and solutions made upon it, and to conduct them away into the chimney. (For a particular description of this furnace, see Faraday *On Chemical Manipulations*.) Close by may be placed another furnace for heating a large copper boiler, intended to supply the laboratory with hot water; the boiler should also be fitted with a head, worm, and refrigerator, in order to provide an occasional supply of distilled water. The tables should be as extensive as the room will allow, and be so placed as to admit of ready access; hence a large one, placed towards the middle of the room, and in such a situation as to be well lighted, is very useful. It should be made strong, and furnished with drawers, unless it be closed in with doors, so as to form cupboards. To protect it from corrosive fluids, as acids and alkalies, it should be covered with sheet lead. In a corner, and as much out of the way as possible, a sink of stone, or of strong woodwork lined with lead, must be provided. It must be supplied with water, if possible, from a cistern or aqueduct, since an unlimited supply of water is demanded in a laboratory. A place in its immediate neighbourhood is to be appropriated to the cleansing accompaniments of a sink, such as pails, pans, sponges, brooms, brushes, &c.

Between the table and the working furnace may be placed the pneumatic cistern, which should be of larger dimensions than that employed in the theatre. If the surface of water be nineteen inches by twenty-eight, and a well be formed at one end of fourteen inches by ten, and twelve inches in depth, so as to leave a continuation of shelf surface, on three sides of the well, of two inches and a half in width, it will be found sufficiently large for almost any purpose. It should have shelf room sufficient to hold several jars of gas at once. It should be filled with water until it is an inch and a quarter or an inch and a half above the shelf, and should be provided with a stop-cock, by which the water may be drawn off when it has become acidified or dirty. Such a trough is best made of japanned copper, and supported in a wooden frame, so as to stand about thirty-nine inches from the floor; or it may be made of wood, and lined with sheet lead. Unless the establishment is very extensive, one mercurial cistern will answer for both rooms; it may be shaped out of marble or soap-stone, or be made of cast iron, and mounted upon a firm frame fitted with rollers. Cupboards are very useful; and at least two large ones, with shelves, ought to be provided, in order to preserve chemical preparations, and the neater sort of apparatus, from the dust and dirt which are constantly moving and settling in the laboratory. All parts of the walls within reach should be fitted up with shelves, in a firm manner, to receive bottles and jars; also a tube-rack should be provided, to hold pieces of glass tube, from one to three feet long. A part of the wall should be furnished with long spikes, to hold retort and flask rings, large bent tubes, siphons, coils of wire, iron tongs for holding flasks, &c.

Among other indispensable furniture may be enumerated the following articles: one or two large wooden blocks, to serve as bases on which to put heavy mortars; an anvil, or spike, with its foot-block; a vice affixed to a side table; hammers; cold chisels; a screw-driver; saws; cutting chisels; gimlets; brad-awls; half-round, flat, and small three-square files; forceps; a trowel; a soldering-iron, with its appendages; a glue pot; nails; screws; spatulas of silver, ivory, steel, and wood; corkscrew; shears; blow-pipes; scratching diamond, &c. A number of filtering stands, supports for retorts and flasks, and wooden forms for holding glass evaporating basins, flasks, and receivers, should be provided; also a great variety of common, kitchen, open furnaces. The cellar beneath the working-room should contain the more bulky articles, and such as do not receive injury from a slight degree of moisture, as lute-sand, charcoal, bricks, carboys of acid, voltaic troughs, &c. Doctor Henry recommends that the painting of that part of the laboratory furniture which is exposed to the action of acids be done with the sulphate of lead.

Laboratory, in *military affairs*, signifies that place where all sorts of fireworks are prepared, both for actual service and for experiments, viz. quick-matches, fuzes, port-fire, grape-shot, case-shot, carcasses and grenades, cartridges, shells filled, and fuzes fixed, wads, &c., &c.

LABOUR, in *physiology*, is the act by which a female of the genus *mammalia* brings one of her own species into the world. When the fœtus has remained its due time in the womb, and is in a condition to carry on a separate existence, it is extruded from its place of confinement, in order to live the life which belongs to its species, independently of the mother. The womb having reached its maximum of growth, with the increasing size of the fœtus, its peculiar irritability excites in it the power of contraction; it thereby narrows the space within, and pushes out the mature fœtus. The period of gestation is very different in different animals, but, in each particular species, it is fixed with much precision.

In the womb, the corporeal frame of man commences existence as an embryo, after further developement appears as a fœtus, then as an immature, and finally a mature child. With its growth and increasing size, the membranes which envelope it enlarge, the womb also expanding to give room for it. At the end of the thirty-ninth or the beginning of the fortieth week, the child has reached its perfect state, and is capable of living separate from the mother; hence follows, in course, its separation from her, i. e. the *birth*. Contractions of the womb gradually come on, which are called, from the painful sensations accompanying them, *labour-pains*. These are of two kinds: first, the preliminary pangs, which begin the labour, do not last long, are not violent, and produce the feeling of a disagreeable straining or pressure. When the pregnant female is attacked by these, she is often unable to move from her place till the pang is over, after which she may be free from pain for some hours. Then follow the true labour-pains; these always last longer, return sooner, and are more violent. The contractions of the womb take place in the same order as the enlargement had previously done, the upper part of it first contracting, while the mouth of the womb enlarges, and grows thin, and the vagina becomes loose and distensible. By this means the fœtus, as the space

within the womb is gradually narrowed, descends with a turning motion towards the opening; the fluid contained in the membranes enveloping the fœtus, as the part making the greatest resistance, is forced out, and forms a bladder, which contributes much to the gradual enlargement of the opening of the womb. It is therefore injurious to the delivery if hasty or ignorant midwives break the membranes too soon. By repeated and violent throes, the membranes at length burst, and discharge their contents, and, some time after, the head of the child appears. As the skull-bones have not yet acquired their perfect form and substance, but are attached at the crown of the head only by a strong membrane, and may be brought nearer together, the head, by the pressure which it undergoes, may be somewhat diminished in size, and squeezed into a more oblong form, so as to pass through the opening of the matrix and the pelvis, in which it is contained, and, finally, through the external parts of generation; and, when this is done, the rest of the body soon follows. The act of birth or delivery is accordingly, in general, not an unnatural, dangerous, and diseased state of the system, as many timid females imagine. It is a natural process of developement, which is no more a disease than the cutting of the teeth, or the coming on of puberty, although, like them, it may give rise to important changes in the body, and to various diseases. It is true that the process of child-birth requires a violent exertion of nature, but this is facilitated by many preparatives and helps adapted to the purpose.

If the birth succeeds in the way described, it is called a *natural birth*. For this, it is requisite that the pelvis should be properly formed, and that the opening should permit a free passage to the perfect fœtus; that the growth and the size of the fœtus should be proportioned to the pelvis, especially that the head should have the size designed by nature, proportioned to the diameter of the pelvis; also, that there should be a proper situation of the womb, in regard to the axis of the pelvis, and a proper position of the fœtus, namely, the head down, the back of the head in front, and towards the opening of the womb, so as to appear first at birth; and, finally, that the external parts of generation should be in a natural state.

An easy birth takes place without any excessive strainings, and in due season. A difficult birth proceeds naturally, but is joined with great efforts and pangs, and occupies a long time—over six or eight hours. The cause of it is sometimes the stiffness of the fibres of the mother, her advanced years, the disproportionate size of the child's head, or malformation in the parent. Nature, however, finishes even these births; and women in labour ought not to be immediately dejected and impatient, on account of these difficulties. An *unnatural* (or properly an *irregular*) birth is one in which one or more of the above-mentioned requisites to a natural birth are wanting. An *artificial* birth is that which is accomplished by the help of art, with instruments, or the hands of the midwife.

Premature birth is one which happens some weeks before the usual time, namely, after the seventh and before the end of the ninth month. Though nature has assigned the period of forty weeks for the full maturing of the fœtus, it sometimes attains, some weeks before this period has elapsed, such a growth that it may be preserved alive. That it has not reached its mature state is determined by various indications. Such a child, for instance, does not cry like full-grown infants, but only utters a faint sound, sleeps constantly, and must be kept constantly warm, otherwise its hands and feet immediately become chilled. Besides this, in a premature child—more or less, according as it is more or less premature—the skin over the whole body is red, often, indeed, blue, covered with a fine, long, woolly hair, especially on the sides of the face and on the back; the fontanel of the head is large; the skull-bones are easily moved; the face looks old and wrinkled; the eyes are generally closed; the nails on the fingers and toes tender, soft, and short—hardly a line in length; the weight of such a child is under six, often under five pounds. The birth is called *untimely* when the fœtus is separated from the womb before the seventh month. Such children can rarely be kept alive; there are instances, however, of five months' children living. A curious remark is made by some writers, that a seven months' child is more likely to live than one born a month later. *Late* birth is a birth after the usual period of forty weeks. As this reckoning of the time from pregnancy to birth is founded, for the most part, solely on the evidence of the mother, there is much room for mistake or deception. The question is one of much interest in medical jurisprudence, as the enquiry often arises whether a child, born more than forty weeks after the death of the reputed father, is to be considered legitimate or not. The importance of the question, and the uncertainty of the proof, have occasioned a great variety of opinions among medical writers. Most of them doubt the truth of the mother's assertions about such a delayed birth, and give as their reason that nature confines herself to the fixed period of pregnancy; that grief, sickness, &c., cannot hinder the growth of the fœtus, &c. Others maintain, on the contrary, that nature binds herself to no fixed rules; that various causes may delay the growth of the child, &c. Abortion and miscarriage take place when a fœtus is brought forth so immature that it cannot live. They happen from the beginning of pregnancy to the seventh month, but most frequently in the third month. The occasions, especially in those of a susceptible or sanguine temperament, are violent shocks of body or mind by blows, falling, dancing, cramp, passion, &c.

LABOUR AND LABOURERS. The two great sources of income, in all communities, are labour and capital. The means of production are the land, utensils, stock, and all which constitutes capital, and the labourers who use this capital. In this general division of the means of production, the term *labour* is used in its broadest sense; for the labour of the mind, or that of the artist, which depends more upon skill than muscular exertion, is to be included in the general estimate of the productive power, if a price or market value is put upon its products in the general estimate. Nor should we, in estimating the general productive capacity, confine ourselves to the species of labour which results in the production of articles of necessity or convenience merely; since, in the products consumed by any community, it is not practicable to draw a distinction between articles of mere utility and those of taste, utility and luxury being combined in a great part of the things used or consumed by a people, whatever may be its stage of civilization and refinement. The land, and the greater part of the utensils of production, are estimated, it is true, in a great degree, and in many instances

wholly, by their mere utility for production. But it is otherwise with respect to the products intended not merely as the means of producing others, but as ultimate objects of use or consumption. Dwellings, furniture, clothing, food, all combine, in different degrees and proportions, both luxury and utility.

The quantity of wool and cotton worn and used by two persons in different ranks of life, and of different means of consumption, may be the same, and answer equally well as a protection of the person against the climate; and yet that used by one, owing to the better quality of the material, and the greater labour bestowed in fabricating it, may cost three or ten times as much as that used by the other; and yet something is paid to taste and luxury even by this latter.

The abstract utility of any article is of difficult estimation, and, though it is a proper subject of enquiry and speculation, still, in estimating the productive power of labour, in comparison with capital, the more practical rule seems to be, to take the estimate put upon it by the community itself. If, for instance, the labour of a sculptor is, in the estimation of a community, worth that of twenty day-labourers, the distribution of the annual products of the labour and capital of that community will be governed by this rule of comparison, and the sculptor will be able to consume as much in value as the twenty common labourers. Hence the proportion of the income of labour and capital will vary in different communities, according to the different arts or kinds of production encouraged. To take the same examples, though the labour of a sculptor may be equal in value, as estimated by a community, to that of twenty labourers—and the same may be equally true of the painter—yet the capital or stock required for each of these twenty labourers may be (and, if they are employed in agriculture, will be) greater than is required for either of those artists. The proportion, then, of the value of the whole capital of a community to that of the whole estimated annual value of the labour of all sorts, performed by its members, will depend upon the kind of arts pursued, so that the proportions will not be uniform in different communities. The estimated annual market value of the labour will, however, in any community, be greater in proportion to its capital than it would at first view appear to be. It has been estimated to be nearly one-fifth, exceeding or falling short of that ratio according to the circumstances and pursuits of a community; that is, supposing the capital to be stationary, the value of the whole capital, including lands, buildings, animals, furniture, utensils, and every vendible thing whatsoever, is consumed and reproduced every five years. It is evident, then, what a rapid change may be made in the wealth of a community, either for the better or the worse, by an impulse or check to its industry, or a general tendency to economy or prodigality in consumption.

The arts and employments and habits of a people are every thing in respect to their prosperity; and the actual amount of their present capital is of less importance, since, if it be too small, that is, if the people are in want of a sufficient stock to employ themselves to the greatest advantage, industry and economy may very soon supply the deficiency. The aggregate annual products of the same labour and capital are greater in one country than another. This is a distinction of great importance, which is overlooked in some economical speculations, or which, at least, has not always its just weight. The fact is, perhaps, too obvious to need proof or illustration, If, for instance, the people of one country have better lands, domestic animals, roads, utensils, or are more skilful and ingenious than those of another, the same amount of manual labour bestowed upon corresponding materials, with corresponding instruments of production, will produce greater results. The wages of labour, and the interest of money, may both, therefore, be higher in one country than in another. It does not follow, then, that, if the condition of the mere labourer be better in one country than in another, that of the capitalist will necessarily be worse. To ascertain the condition of these two classes, possessing the productive capacity and means of a community, we first enquire into the aggregate productiveness of capital and industry, and next into the distribution of the aggregate products between the two classes. And, in examining into the condition of the members of a community, the next enquiry relates to the proportionate share of each industrious class in the whole portion of the aggregate products allotted to industry, as distinguished from that which is allotted to capital. This distribution among the labouring classes themselves of the products of their labour will, of course, depend upon the estimation in which the various kinds of labour are held; and its effect on their condition will also depend very materially upon the arrangements, improvements, and facilities possessed by the community, to render their labour effective; for the compensation to labourers, individually, may be small, and yet the expense of the whole class of the community to which they belong very great. To take a familiar instance, if, from the thinness of the population, or other causes, the receivers and distributors of the articles of production and consumption among the people, that is, the retail dealers, can transact but a small amount of business each, though the earnings of each one may be small, their aggregate compensation must be large.

In countries half civilized, and in which the arrangements and facilities for exchange are rude and imperfect, the usual profits of trade are at an enormous rate per cent.; and yet the wealth of these traders will be very trifling, in comparison with that of the merchants and traders of a more civilized, improved, and populous community, though the per centage of profit of these latter may be much lower. The same distinction will hold good in respect to every other pursuit and employment in a community: the proportion of the whole products awarded to any one class may not correspond at all to the individual advantage or disadvantage of the members of that class, in their pursuits, in comparison with that of those of any other class. The compensation of any one class of a community, in comparison to any other, will evidently depend upon the course taken by the taste and luxury of the community; for we may assume it as a general doctrine, that when the taste and passions of a community lead to a large consumption of the articles produced by any class, or if the services of its members are considered particularly beneficial, these members will be liberally compensated. If, for instance, as is, or at least has been, the fact in some countries, the inhabitants suppose that their future welfare does not depend so much upon their own characters and conduct as upon the prayers and good offices of their spiritual guides,

they will deem it impossible to reward these spiritual guides too liberally, seeing they have the salvation of the rest at their disposal. The same principle will hold true in respect to any other class: in proportion as its employment goes along with the tastes and passions of the community will its members be rewarded for their labours. The effect will not however necessarily extend itself to all the members of the class.

Suppose, for example, that the taste and vanity of a people appear very much in their apparel and personal ornaments: it will not follow that all clothmakers, tailors, jewellers, hatters, and shoemakers will have the highest wages in the community; but the result will be that a high price will be paid for excellence of material or superiority of skill in the manufacture of those articles. The moment, therefore, in which civilization commences—and some degree of it is co-eval with the existence of every society—excellence in some arts or employments will meet with extraordinary rewards. As arts and civilization advance, the objects of fashion and taste will be multiplied, and with them the kinds and varieties of excellence of materials or skill which will be esteemed of extraordinary value. The effect necessarily is to produce a comparative depression in the value of all ordinary products and unskilful labour. Accordingly, the ordinary labourers, in all the arts, become by degrees a distinct class. In a refined community, abounding in arts, this class necessarily becomes numerous, and the condition of its members is a subject of solicitude to the philanthropist, and of interest to the economist and statesman. The security and welfare of the whole community will depend very materially upon the character and condition of this part of the population. The greater the distance between this class and the rest—the more effectually they are set off from the others—the more unnatural and distorted will be the state of society, and the more frequent will be scenes of disorder and vice. It is one of the first and most important maxims of policy and economy, then, to sustain the members of this class, not by giving them the control and management of affairs, for which of course they are not the best fitted,—but by using all possible means, whether by legislation or social influence, to give them education, good habits, and good morals, to inspire and maintain in them a respect for themselves, and secure to them the respect of others.

Labour-saving Machines. Montesquieu somewhere regrets the introduction of water-mills for grinding corn, instead of the hand-mills formerly in use, as it threw a great many labourers out of employment, besides diverting the water from the purposes of irrigation. Upon this principle of throwing labourers out of employment, the English weavers were opposed to the use of power-looms. It is not remarkable that labourers themselves, who, for a time, feel the inconveniences of the introduction of any improvement, should oppose its introduction; but it is singular that any man of enlarged and philosophical views should fall into such a notion. Nobody certainly would think it a misfortune to a community that, in consequence of some improvement in agriculture, the same labour would produce a greater quantity of grain; on the contrary, every one consents to the praise bestowed by Johnson upon the man who makes two blades of grass grow where only one grew before. And an improvement in machinery, whereby the same labour will produce twice the quantity of cloth, is precisely the same in its general effects upon the condition of the community as an improvement in agriculture. But, in a case of improvement in machinery, the effect is more apparent and more sudden, as it will spread rapidly, and accordingly the inconvenience to the labourers is in fact greater, though it can last only for a time. However, the circumstance that its effect in discharging labourers is only temporary, though it shows that the inconvenience to the community is very limited, while its advantages are permanent, yet affords no great consolation to the labourers themselves, if the population is dense and employment difficult to be obtained, since, while this temporary effect is passing off, they may starve. To avoid producing distress and consequent disorder, labour-saving machinery, therefore, should be introduced gradually among a community of labourers, like those of this country, to whom it is ordinarily difficult to find full employment, and who, if unemployed, are immediately reduced to distress.

Labyrinth, with the ancients, a building containing such a number of chambers and galleries, one running into the other, as to make it very difficult for a stranger to find his way through it. The Egyptian labyrinth, the most celebrated of all, was situated in Central Egypt, above Lake Mœris, not far from Crocodilopolis, in the country now called *Fejoom*. According to some writers, it was built by the Dodecarchs (650 B. C.); according to others, by Psammetichus, or by Ismandes, who is also said to have been buried there. In all probability, it was a sepulchre. The building, half above and half below the ground, was one of the finest in the world, and is reported to have contained 3000 rooms, the arrangement of which seems to have been symbolic of the zodiac and solar system. All these rooms were encircled by a common wall and by columns; but the passages were so intricate that no stranger could find the way without a guide. It is said that, in the lower rooms, the coffins of the builders of this immense fabric, and of the sacred crocodiles, were deposited, and that the upper rooms excelled, in splendour and art, all human works. At present, only 150 rooms are reported to be accessible: the others are dark, and choked with rubbish. Respecting the interior construction and the destination of the labyrinth of Crete we know still less. The ancient writers consider this subterranean cavern to have been built by Dædalus, in imitation of that of Egypt, but on a smaller scale, by order of Minos, who confined there the Minotaur. According to others, it was a temple of the latter. The labyrinth at Clusium was erected by king Porsenna, probably for his own sepulchre. It was a square building of stone, fifty feet in height and thirty on each side. At each corner stood a pyramid, and also one in the centre, each 150 feet high, and at the base 75 feet wide. These edifices were not built for the purpose of making people lose their way; this was merely an accidental peculiarity, on account of which every confused mass of things, difficult to be disentangled, has been called a *labyrinth*.

Lac, Lak, Laak, and Lak'h, are different ways of spelling the vulgar derivatives from the Sanscrit words *lákshà* and *laksha*, i. e. one hundred thousand; a name given by the Hindoos to the *coccus lacca* and *gum-lac*, for which they have six different terms. The gum-lac is probably discharged by the coccus,

as a defence for its eggs, which are deposited on the bihar tree. Four kinds are known—stick-lac, seed-lac, lump-lac, and shell-lac. The first is the gum before its separation from the twigs which it incrusts; and the best is of a red purplish colour: the second is the gum in a granulated form, stripped from the twigs, and perhaps boiled, by which a portion of the colour is lost: the third is the seed-lac, melted into cakes: and the fourth, the common form in which it is known in Europe, is the purified gum: the best is amber-coloured and transparent. In the East it is much used for trinkets. It is the basis of the best sealing-wax. It forms varnishes, furnishes a brilliant red dye, and, mixed with thrice its weight of fine sand, is made into polishing stones.

Lac, in its original meaning, is applied to the computation of money in the East Indies. Thus a *lac* of rupees is 100,000, which, supposing them to be *sicca* or standard, are equal to 12,500*l*.

Lace is a species of net-work, made of silk, thread, or cotton, upon which, in old times, patterns were embroidered by the needle, after its construction: they are now, for the most part, formed during the knitting itself. The best laces are made at Mechlin, Brussels, Antwerp, Ghent, and Valenciennes. Lace made by machinery is largely manufactured at Nottingham.

The invention of lace-knitting is attributed by Beckmann to Barbara, wife of Christopher Uttman of St. Annaberg, in 1561. Paulus Jenisius, in his history of that town, states as follows: *Hoc anno* (1561) *filum album retortum in varias formas Phrygio opere duci cœpit;* and there are many other authorities for the name of the workwoman. It may be, however, that she introduced the manufacture, rather than invented it. Lace worked by the needle is of far older date. It is found richly and abundantly in church furniture of great antiquity, and is supposed to have been originally made in Italy, particularly at Genoa and Venice. The *Opus Phrygianum*, to which allusions are made by Plautus and Pliny is considered by Beckmann to have been no more than needle-work; and so the expressions of the latter writer are understood by Holland: "As for embroderie itself, and needle-worke, it was the Phrygians' invention, and hereupon embroderers in Latine bee called *Phrygiones*." *Point-lace* is that embroidered by the needle, and, from the great labour required, is therefore most expensive. In the lace knit by hand, as many threads are employed as the pattern and breadth require. These are wound upon the requisite number of bobbins (made of bone, whence the name *bone-lace*), which are thrown over and under each other in various ways, so that the threads twine round pins stuck in the holes of the pattern (a stiff parchment stretched on a cushion or pillow), and by these means produce the openings which give the desired figure. In that made by machinery, the meshes are all formed by a continuation of a single thread. The coarsest is called *Mechlin-net*, the finest *bobbin-net*, from the employment of bobbins. Lace made by the loom is generally known as *British* lace.

Mr. Babbage gives the following curious account of lace made by the *phælena pardilla* or caterpillar. It was contrived by a gentleman of Munich. He makes a paste of the leaves of the plant which is the usual food of the species of caterpillar he employs, and spreads it thinly over a stone or other flat substance. He then, with a camel-hair pencil dipped in olive oil, draws upon the coating of paste the pattern he wishes the insects to leave open. This stone is then placed in an inclined position, and a number of caterpillars are placed at the bottom. A peculiar species is chosen, which spins a strong web; and the animals, commencing at the bottom, eat and spin their way up to the top, carefully avoiding every part touched by the oil, but devouring all the rest of the paste. The extreme lightness of these veils, combined with some strength, is truly surprising. One of them, measuring twenty-six inches and a half by seventeen inches, weighed only 1.51 grain, a degree of lightness which will appear more strongly by contrast with other fabrics. One square yard of the substance of which these veils are made weighs $4\frac{1}{3}$ grains, whilst one square yard of silk gauze weighs 137 grains, and one square yard of the finest patent net weighs $262\frac{1}{2}$ grains. The ladies' coloured muslin dresses mentioned in the table subjoined cost ten shillings per dress, and each weighs six ounces; the cotton from which they are made weighing nearly six ounces and two-ninths, avoirdupois weight.

Weight of one square yard of each of the following Articles.

DESCRIPTION OF GOODS.	Value per yard measure.	Weight finished of one square yard.	Weight of cotton used in making one square yard.
	s. d.	Troy Grains.	Troy Grains.
Caterpillar Veils	. . . .	$4\frac{1}{3}$	. . . .
Silk Gauze 3-4ths wide	1 0	$137\frac{1}{4}$	. . . .
Finest Patent Net	. . . .	$262\frac{1}{2}$	. . . .
Fine Cambric Muslin	. . . .	$551\frac{1}{2}$	. . . .
6-4ths Jaconet Muslin	2 0	613	670
Ladies' coloured Muslin Dresses	3 0	788	875
6-4ths Cambric	1 2	972	1069
9-8ths Calico	0 9	988	1085
½ yard Nankeen	0 8	2240	2432

Lactometer. This is an ingenious little instrument, and very valuable, as it offers a ready mode for ascertaining the quality and purity of milk. In the dairy, it likewise enables the farmer to judge of the value of his cows from the quality of the milk. From the high price at which it is vended by mathematical instrument makers, it is, however, little known, and the principle of its construction is still less appreciated. It is constructed on the principle of the separation of cream from the milk, and the means to determine the proportion; this will at once suggest its nature. Upon a graduated tube, of the length of ten inches, or any other proportion, is described a scale containing ten equal parts. The three upper divisions are again to be subdivided into ten equal parts, and we shall thus have the scale containing one hundred and numbered in thirty equal parts. To ascertain the quality of any sample, it is only necessary to fill the tube with milk to the first point; after standing three hours, the whole of the cream will separate and float to the top; the mark to which this descends will indicate the per-centage of cream, and, in consequence, the proportionate quality of the milk. Milk seldom yields above twenty-five per cent. of cream;—that vended in the metropolis rarely affords more than seven.

Lamp. The invention of lamps is ascribed to the Egyptians. At the festivals in honour of Minerva, at Sais in Lower Egypt, great numbers of lamps

were kept burning. They were known even in the times of Moses and Job. The Egyptians were also the first who placed burning lamps in the tombs with their dead, as an emblem of the immortality of the soul. From Egypt, the use of lamps was carried to Greece, where they were also consecrated to Minerva, the goddess of learning, as indicative of the nightly studies of the scholar. From Greece, the use of lamps passed to the Romans. The first person who is known to have published a collection of ancient lamps is Fortunio Liceto, an Italian, whose chief design appears to have been to prove the possibility of the existence of inextinguishable, or rather perpetually-burning, lamps. Pietro Santo Bartoli, a countryman of his, afterwards published at Rome, in the year 1691, the collection of Bellori; but these engravings are exceedingly ill executed and unfaithful. Passeri, however, another Italian, published, at the suggestion of the academy of Pesaro, a collection of 322 lamps, which he possessed in his museum. The above-mentioned collections, however, have been much surpassed in beauty and interest by that of Portici. The sixth hall of that museum is entirely filled with lamps and candelabras discovered in the houses of Pompeii and Herculaneum. Representations of these were published in 1792, in ninety-three copper-plates, exclusive of vignettes. They form the ninth volume of the *Antiquities of Herculaneum*. We find there represented and explained upwards of 200 lamps and candelabras of bronze and terracotta.

The ancients appear to have very early acquired the practice of using lamps. The use of oil was not perhaps known to the Romans in very remote ages, although the Greeks unquestionably were acquainted with it, as appears from several passages in Herodotus. We find, indeed, the figure of the lamp sculptured and engraved on many of the most ancient Greek vases. It is with a lamp that Mercury, as depicted on one of these, lights Jupiter, who is represented scaling with a ladder the chamber of Alcmena. Baked earth was the substance of which the earliest lamps were composed, but subsequently we find them of various metals—of bronze more particularly. A few ancient lamps of iron are also extant; but these are rare, either because that metal was little used for the purpose, or on account of its more ready destruction in the ground. There are four specimens in the museum of the king of Naples, at Portici, where there is likewise one specimen of a lamp of glass. It is entirely solid, and in one single piece. Pausanias mentions a golden lamp in the temple of Minerva, and St. Augustine speaks of lamps of silver. No antique of either kind, however, has reached modern times. The testimony of Pliny, St. Augustine, and others, has led to the belief that the ancients had perpetual lamps, and Liceto composed a work to establish this supposition. Different authors mention instances of lamps which in modern times have been found burning in ancient sepulchres, but were extinguished as soon as the external air was admitted. The most famous instance is that of the tomb of Tulliola, daughter of Cicero, discovered in 1540. None of these instances, however, can be considered as proved. The idea probably arose from the inflammation of the hydrogen gas contained in these caverns, when explorers entered them with torches.

The lamps or candlesticks made use of by the Jews, in their own houses, were generally put into a very high stand on the ground. The lamps supposed to have been used by the foolish virgins, &c., in the gospel, were of a different kind. According to critics and antiquaries, they were a sort of torches made of iron or potter's earth, wrapped about with old linen, and moistened, from time to time, with oil. (*Matt.* xxv. 1, 2.) The lamps of Gideon's soldiers were of the same kind. The candlestick, with seven branches, placed in the sanctuary by Moses, and those which Solomon afterwards prepared for the temple, are said to have been crystal lamps filled with oil, and fixed upon the branches. Among the Romans, also, it was customary to have the lamp either depending from the ceiling or placed on a stand in the room, since the use of tables was not common to them, and their attitude, in studying, as well as at their repasts, was a half-recumbent one, holding their scroll or tablets before them on their knees. These stands were often highly ornamented. The most common form of them was a tripod with lion's feet, from which sprung sometimes the shaft of a column, according to one of the orders of architecture, the disc placed to receive the lamp forming the capital. These vessels were generally ornamented with mythological or allegorical subjects, and their shape varied greatly. Sometimes it was a simple disc with a hole in the circumference through which to pass the wick, and another in the middle to pour the oil into. At other times, they represented the appearance of a boat. Occasionally their extremity terminated in two or three divisions, according to the number of beaks; but it would be endless to attempt to pursue these details. Inscriptions were likewise often placed upon them.

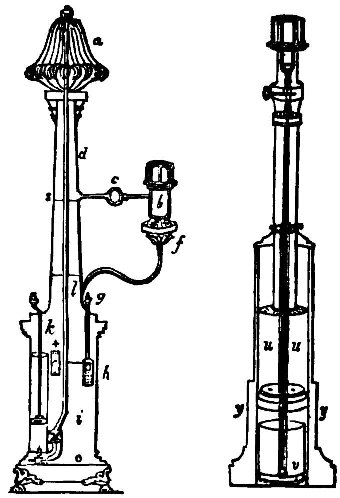
Public illuminations on occasions of national rejoicing were common to the Romans. On the birth-days of their princes, on great religious solemnities, &c., they suspended lamps at the windows. Juvenal and Persius both make mention of this usage. Various motives have been assigned for the ancient practice of placing lamps in sepulchres. One of the most ingenious, and perhaps the most satisfactory, is that it was allegorical of the cessation of mortal life—of the separation of the soul, which the ancients regarded as an emanation of fire. On some sepulchral lamps we find sculptured the figure of a butterfly, in allusion no doubt to the equally cheerful and elegant imagination of the escape of the spirit, in a more aërial semblance, from its chrysalis state. The early Christians adopted, in their monuments, this pagan usage, together with many others, and the lamp has been found in the tombs of saints and martyrs, and of distinguished men who embraced Christianity. In these instances it was no doubt meant still more to be illustrative of that divine flame by which they were inspired, and whose inward light guided them through the many savage persecutions suffered by the primitive followers of our holy faith. The shapes of ancient lamps, as well as many other ancient utensils, have been imitated with much success by Mr. Wedgwood.

The best lamps now in use are those invented by Argand, at Geneva, in 1784. The principle on which the superiority of the Argand lamp depends is the admission of a larger quantity of air to the flame than can be done in the common way. This is accomplished by making the wick of a circular form, by which means a current of air rushes through the cylinder on which it is placed with great force; and, along with

that which has access to the outside, excites the flame to such a degree that the smoke is entirely consumed. Thus both the light and heat are prodigiously increased, the combustion being exceedingly augmented by the quantity of air admitted to the flame; and what, in common lamps, is dissipated in smoke, is here converted into a brilliant flame. This lamp is now very much in use, and is applied, not only to the ordinary purposes of illumination, but also to that of a lamp-furnace for chemical operations, in which it is found to exceed every other contrivance yet invented. It consists of two parts, viz. a reservoir for the oil, and the lamp itself. The Argand burner is constructed by forming a hollow cylindrical cavity, which receives oil from the main body of the lamp, and, at the same time, transmits air through its axis, or central hollow. In this cavity is placed a circular wick, attached, at bottom, to a movable ring. This ring is capable of being elevated or depressed by means of a rack and pinion, or more commonly by a screw; so that the height of the wick may be varied to regulate the size of the flame. On the outside is placed a glass chimney, which is capable of transmitting a current of air, on the same principles as a common smoke flue. When this lamp is lighted, the combustion is vivid, and the light intense, owing to the free and rapid supply of air. The flame does not waver, and the smoke is wholly consumed. The brilliancy of the light will be still further increased if air be made to impinge laterally against the flame. This is done either by contracting the glass chimney near the blaze, so as to direct the air inwards, or by placing a metallic button over the blaze, so as to spread the internal current outward. The Argand lamps are called, in France, *lampes à Quinquet*, or, more briefly, *Quinquets*, from an artist of the name of *Quinquet*, in Paris, with whom Argand was connected. To avoid the shade occasioned in common lamps by the reservoir for the oil being under the flame, various contrivances have been introduced, in which the reservoir is placed at a distance from the flame.

In the *astral* and *sinumbral* lamps, the principle of which was invented by Count Rumford, the oil is contained in a large horizontal ring, having a burner in the centre, communicating with the ring by two or more tubes placed like rays. The ring is placed a little below the level of the flame, and from its large surface affords a supply of oil for many hours. A small aperture is left for the admission or escape of air, in the upper part of the ring. When these lamps overflow, it is usually because the ring is not kept perfectly horizontal, or else because the air-hole is obstructed—a circumstance which may even happen from filling the lamp too high with oil.

It is necessary to observe that there are two principles that govern the advantageous production of artificial light: the most material one is the proper supply of oxygen to the hydrogen and carbon of the decomposed fuel; the other to keep up a flow of oil as near the flame as possible, to prevent the wick being incrusted by the gluten of which oils are in part composed. These two principles must be considered essential in the formation of a lamp; and, therefore, cannot be departed from, without occasioning a waste of fuel. The lamps now to be described, which are a late invention, are intended to bring these principles into action. The air is regulated, in its passage to the wick, so that the flame may be supplied in proportion to its bulk, and also that the inner and outer currents of air acting on the Argand burner may be so proportioned that the flame may itself become a perfect cylinder. In these lamps the oil is always kept in close contact with the flame, and is so abundant that a part of it is even allowed to pass over the mouth of the burner, to the reservoir. By a contrivance which will be understood on a reference to the engravings, this oil is returned to the wick for combustion.



The first of these, or right-hand figure, is called a pressure lamp, the oil being forced up to the burner by a movable weight, which is required rather to overbalance the column of oil when it extends to the full height of the burner. The weight *v* is attached to a circular disc. This disc is surrounded with a leather packing, which works close to the sides of the cylinder *u u*. The passage of the oil is thus confined to the pipe which leads to the burner, over which the disc and the weight work. In the construction of this lamp there are three pipes; the centre pipe conveys the oil from under the weight to the burner; the one over that brings the oil not consumed by the wick to the top of the disc, that it may again pass under the weight; the third, or outer pipe, gives the power of raising the weight, to put it again in action, after it had pressed all the oil from under it, and thus enables it to take through a valve in its centre a fresh supply. The quantity of oil forced to the burner is regulated by a key, which can be raised as required. *y y* is the ornamental case of the oil cylinder.

The left-hand figure in the diagram is called a pump-lamp, the oil being raised from the reservoir *i* in its base, through the pipe *l*, to the reservoir *a d*, by the small pump *k*. The quantity of oil supplied to the burner, *b*, is regulated by the key *c*. As it is intended that the supply of oil should exceed the consumption of the wick, means have been taken to convey the surplus through the pipe *f* to the reservoir *i*. The flooring *s* separates the upper reservoir from the lower part of the lamp. *h* is a float to show by raising the rod *g* when the lower reservoir is full; *o* is an aperture to let out the foul oil when necessary; + is an air-valve.

LAMP-BLACK. See CARBON.

LANCE; a weapon consisting of a long shaft, with a sharp point, much used, particularly before the invention of fire-arms. It was common among the Greeks and Romans. The Macedonian phalanx was armed with it, and it was the chief weapon of the Roman infantry: the javelin, or *pilum*, was but secondary. The lance is found among almost all uncivilized tribes: it was the chief weapon in the middle ages,

and is now considered one of the most effective arms of cavalry.

The lance of the knight, in the middle ages, was of a peculiar form. Near the lower end, it was very thick, with a deep opening, in which the arm was placed when the lance was put in rest, preparatory to a charge. Immediately in front of the opening, the lance was from a foot to a foot and a half in diameter, and sloped off towards the upper end, which was from half an inch to three-quarters in diameter. From this weapon the small bands, of which the cavalry of the middle ages consisted, took their name. A *lance* denoted a man at arms (horseman completely armed) with four or five attendants. Among the French, in the fifteenth century, these attendants consisted of three archers, one *coutillier* (so named from the long broad dirk in his belt), and one page or valet.

The introduction of fire-arms gradually led to the disuse of the lance in the West of Europe, though it continued among the Turks, Albanians, Tartars, Cossacks, Poles, Russians, and other Sclavonic tribes, among whom it was borne by light-armed cavalry, on fleet horses. Frederick the Great, seeing the advantageous use made of this weapon by the Poles, gave it to a portion of his cavalry, and afterwards formed an entire regiment of lancers. The Austrians followed, and soon established three regiments of *Uhlans*, as they were termed. After the partition of Poland, many Poles entered the French service, and a body of Polish lancers was established. The war with Russia, in which the efficiency of the lance in the hands of the Cossacks, particularly in 1812, was strikingly manifested, brought this weapon into still more repute, and the Prussians formed three regiments of *Uhlans*. The French lancers were formed in 1813, to cope with the Cossacks. Almost all the armies of Europe now have regiments of lancers: those of the British were found of the greatest service at the battle of Waterloo. To use the lance with effect, however, requires much practice.

The lances now in use among the European cavalry have a shaft of ash or beech wood, eight, twelve, or even sixteen feet long, with a steel point, eight or ten inches long, and, to prevent this being hewn off, the shaft is guarded by two strips of iron, a foot and a half to two feet long, below which an iron ball is sometimes placed to prevent the lance-point from penetrating too far. The other end has an iron cap, to prevent its splitting. The point has a small flag, intended by its waving to frighten the horses of the enemy. When not in use, the lance is carried in a leathern shoe, by the right stirrup, dependent by a leathern thong on the right arm. In use, it is carried under the right arm. This weapon requires a practised horseman. (See Pike.)

Land, in *nautical* language, makes part of several compound terms: thus *laying the land* denotes that motion of a ship which increases its distance from the coast, so as to make it appear lower or smaller on account of the intermediate convexity of the sea.—*Raising the land* is produced by the motion of the vessel towards it.—*Land is shut in* signifies that another part of land hinders the sight of that the ship came from.—*Land to;* or so far from shore that it can be only just discerned.—*To set the land;* that is, to see by the compass how it bears.

Land-Breeze; a current of air which, in many parts within the tropics, particularly in the West Indies, regularly sets from the land towards the sea during the night, and this even on opposite points of the coast.—*Land-locked* is said of a harbour which is environed by land on all sides, so as to exclude the prospect of the sea, unless over some intervening land.—*To make the land* is to discover it after having been out of sight of it for some time.

Land-Mark; any mountain, rock, steeple, or the like, near the sea-side, which serves to direct ships passing by how to steer, so as to avoid certain dangers, rocks, shoals, whirlpools, &c.

Landscape-Painting. See Painting.

Laniard, or Lanniers; a short piece of rope or line, fastened to several machines in a ship, and serving to secure them in a particular place, or to manage them more conveniently: such are the laniards of the gun-ports, the laniards of the buoy, the laniard of the cat-hook, &c. The principal laniards used in a ship are those employed to extend the shrouds and stays of the mast by their communication with the dead-eyes and hearts, so as to form a sort of mechanical power, resembling that of a tackle.

Lantern; a common contrivance to carry a lamp or candle in, being a kind of cover usually made of tin, with sashes of some transparent matter, as glass, horn, &c., to transmit the light. Theopompus, a Greek comic poet, and Empedocles of Agrigentum, are the first who have spoken of this kind of illumination. In the *Antiquités d'Herculaneum*, vol. vii., will be found represented a collection of ancient lanterns, one of which, of a round form, was discovered in one of the great roads of Herculaneum in 1760, and another, 1764, at Pompeii, in the vestibule of a house, by the side of a human skeleton. The use to which these instruments were put was various. A modern author has stated, without sufficient proof however, that the games of the circus, at Rome, and the sacred games in Greece, were celebrated by this kind of light. Plutarch expressly says that they were used in augury. It is more certain still that they were common among the military, and were always carried before any troops who had to march by night. These were borne upon the top of a pike, and were constructed of a fashion to throw light only behind them.

Dark Lantern; one with only a single opening, which may also be closed up when the light is to be entirely hidden, or opened when there is occasion for its assistance to discover some object.

Magic Lantern, or *laterna megalographica;* an instrument used to magnify paintings on glass, and throw their images upon a white screen, in a darkened chamber. On the fore part of the lantern there is a thick double-convex lens, or a plane-convex (usually called a *bull's eye*), of short focus. The lantern is closed on every side, so that no light can come out of it but what passes through the lens. In the direction of this lens, there is a tube fixed to the lantern, which has a lateral aperture from side to side; through this a glass slider, with small painted images, is moved in an inverted position. The fore part of the tube contains another sliding tube, which carries a double-convex lens. The effect of those parts is as follows:—The thick lens, in the side of the lantern, throws a good deal of light from the candle upon the image; and, to increase that light still more, a reflector is very often, but not always, placed in such lanterns; and, the flame being in the focus of the reflector, the light proceeds in parallel lines from the reflector to the lens. The image, being thus well

illuminated, sends forth rays from every point, which, by passing through the lens belonging to the sliding tube, are conveyed to a focus upon the wall, and form the large images.

The *Phantasmagoria* is like the magic lantern, only, instead of the figures being on transparent glass, all the glass is opaque, except the figure only, which being painted in transparent colours, the light shines through it, and no light can fall on the screen but what passes through the figure. The screen is very thin silk, between the spectators and the lantern, and, by moving the instrument backwards or forwards, the figures seem to recede or approach.

Laocoon, a priest of Neptune (according to some, of Apollo), at Troy, after the pretended retreat of the Greeks, was sacrificing a bull to Neptune, on the shore, when two enormous serpents appeared swimming from the island of Tenedos, and advanced towards the altar. The people fled; but Laocoon and his sons fell victims to the monsters. The sons were first attacked, and then the father, who attempted to defend them. Wreathing themselves round him, the serpents raised their heads high above him, while, in his agony, he endeavoured to extricate himself from their folds. They then hastened to the temple of Pallas, where, placing themselves at the foot of the goddess, they hid themselves under her shield. The people saw, in this omen, Laocoon's punishment for his impiety in having pierced with his spear the wooden horse which was consecrated to Minerva.

We allude to the above fabulous account to illustrate the design of one of the finest works of ancient art. It forms a group of superlative excellence, and may in this respect have a place with the "Punishment of Dirce," described in our article **Grouping**.

The principal figure is very properly placed in the centre, thus giving the pyramidal form to the whole group. Agony of the most intense kind is depicted in the countenance and convulsed body of Laocoon, who is attempting to untwine the serpents from his body. Their many knotted wreaths have also extended to the sons, who with uplifted hands and imploring eyes appear to solicit that aid from their parent which he is unable to afford.

The only fault of this group, as a work of art, is its complexity, the twining of the serpents prevents the eye from following the general outline of the figures, each of which would form a good subject for the artist.

Lapidary, in the preparation of gems for sculpture, an artificer who cuts precious stones. This art is of great antiquity. There are various machines employed in the cutting of precious stones, according to their quality. The diamond, which is extremely hard, is cut in a wheel of soft metal turned by a mill, with diamond dust, tempered with olive-oil, which also serves to polish it.

Lapidolite. See **Mica**.

Lapis Lazuli. This superb mineral, which has been seen regularly crystallized only in a few instances, occurs massive, of a rich azure-blue colour. It consists, by one analysis, of 46 silex, 28 lime, 14.5 alumine, 3 oxide of iron, 6.5 sulphate of lime, and 2 water; but a later and more interesting research has given 34 silex, 33 alumine, 3 sulphur, and 22 soda. The finest specimens are brought from China, Persia, and Great Bucharia. It is much esteemed for ornamental purposes, especially for inlaid work. The most splendid exhibition of this rare substance is made in the celebrated marble palace built by Catherine, at St. Petersburg, for her favourite Orlof, in which, according to Patrin, there are entire apartments inlayed with lapis lazuli. The ancients were in the habit of engraving upon it, of whose works several specimens are to be seen in the royal library at Paris. But its chief value consists in its affording the very precious pigment called *ultramarine*.

Laquering; the laying on metals coloured or transparent varnishes, to produce the appearance of a different colour in the metal, or to preserve it from rust. Thus laquered brass appears gilt, and tin is made yellow. Seed-lac is the chief composition for laquers, but turpentine makes a cheaper laquer.

Larboard; a name given by seamen to the left side of a ship, when the spectator's face is turned in the direction of the head.

Larboard-Tack is when a ship is close-hauled, with the wind blowing on her larboard side.

Lavender, a delightfully fragrant plant, native of the south of Europe, and now commonly cultivated in our gardens. All the labiate plants are aromatic and stimulating, but these properties are more powerful in this plant than in any other of the tribe, especially when it grows in a warm and sunny exposure. Indeed, in such situations, it sometimes contains one-fourth of its weight in camphor. To the abundance of this plant is attributed the superiority of the honey in certain parts of Europe. The volatile oil, distilled water, and tincture of lavender, are much employed in officinal preparations, and as perfumes. The flowers yield by far the greatest proportion of oil.

Lazaretto; a public building, hospital, or pest-house, for the reception of those afflicted with contagious distempers. It is more particularly applied to buildings in which quarantine is performed.

Lead is a metal very anciently known; it is often mentioned by Moses. Its alchemical name was *Saturnus*. It has a bluish-grey colour, and, when recently cut, a strong metallic lustre; but it soon tarnishes from exposure to the air; specific gravity, 11.358. It is soft, flexible, and inelastic. It is malleable and ductile. In tenacity, it is inferior to all ductile metals. It soils paper and the fingers, imparts a slight taste, and emits, by friction, a peculiar smell.

It is a good conductor of heat, melts at 612° Fahr., and, when cooled, slowly crystallizes in quadrangular pyramids. It is but slowly affected by the atmosphere at common temperatures; but, when maintained in a state of fusion, it absorbs oxygen rapidly, and is converted into a dull grey dross or powder. When this dross is heated to a low ignition, it becomes of a dull yellow colour, and is called *common massicot;* and, by a higher heat and longer exposure to the air, it assumes a deeper yellow, and is then called *massicot.* This is the *protoxide of lead,* and consists, in 112 parts, of 104 lead and eight oxygen. It is insoluble in water, melts on ignition, and is unchanged by heat in close vessels. When it contains about four per cent. of carbonic acid, it is called *litharge.* It unites with acids, and is the base of the salts of lead.

If the protoxide, or metallic lead, be subjected, during forty-eight hours, to the heat of a reverberatory furnace, it passes to the condition of red oxide, or what is commonly called minium, or red lead. This is regarded by Doctor Thomson as a mixture of the protoxide and deutoxide of lead. After the protoxide is separated by acetic acid, the *deutoxide,* of a dark red colour, remains. Its composition is, in 116 parts, 104 lead, 12 oxygen. The *peroxide of lead* is formed by passing chlorine gas through a solution of acetate of lead. Its colour is brown. Heated moderately, especially with the addition of sulphuric acid, it gives out oxygen, and becomes deutoxide; and at a cherry-red heat it passes to the state of the protoxide: 120 parts contain 104 of lead. Lead forms a compound with chlorine. The union is effected by exposing the metal in thin plates to the action of chlorine gas, or, more easily, by adding muriatic acid, or a solution of common salt, to the acetate or nitrate of lead dissolved in water. This *chloride* fuses at a temperature below redness, and forms, as it cools, a semi-transparent, horny mass, sometimes called *horn lead,* or *plumbum corneum.* It bears a full red heat in close vessels without subliming.

The pigment called *mineral* or patent yellow is a compound of the chloride and protoxide of lead. It is prepared for the purposes of the arts by the action of moistened sea-salt on litharge, by which means a portion of the protoxide is converted into chloride of lead. It is a paint little used, however, in consequence of the preference given to the chrome yellow. An *iodide of lead* is easily formed by mingling a solution of hydriodic acid, or hydriodate of potassa, with the acetate or nitrate of lead dissolved in water. It is of a rich yellow colour, and is deposited from boiling water on cooling in crystalline grains of a brilliant lustre. Lead combines with sulphur. The *sulphuret* may be made by simply heating lead and sulphur together, or by the action of sulphuretted hydrogen on a salt of lead. It is an abundant natural product, and is known under the name of *galena* in mineralogy.

The *phosphuret of lead* is formed by dropping phosphorus into melted lead contained in a crucible, or by heating equal parts of lead filings and phosphoric glass with one-eighth of charcoal powder. As respects the *uses* of metallic lead and the oxides, it is well known that the former is much employed in the arts, particularly for buildings and cisterns. For the first of these uses it has many advantages. It is easily worked into any shape, on account of its great softness, and is sufficiently malleable to fold two edges over each other, so as to make it water-tight, without soldering. This is a very great advantage, since, when pieces are soldered together, the expansion and contraction, by a change of temperature, soon cause a rupture. Although it is in very general use for water cisterns, pumps, and pipes for conveying water, serious objections have, from time to time, been urged against its employment for this purpose. It has been found that, in pure water, it is oxidized with considerable rapidity, carbonate of lead being formed by the action of the oxygen and carbonic acid of the air. But if the water, as is the case with the majority of springs, contains a small proportion of saline matter, especially if a sulphate is present, which never fails to precipitate lead from any of its solutions, the liability of the water to be prejudiced by the lead is very small. And, in other cases, there can be no danger in delivering water through aqueducts of lead, provided they are constantly kept full of water, so as always to exclude the air.

Great mischief has been produced by the use of lead in dairies. If the milk run into the slightest acidity, some lead will be dissolved, and injurious consequences will follow if it be taken into the stomach. In the granulation of lead for shot, a small portion of arsenic is added. The proportion is about two per cent. of the white or yellow arsenic. The compound is heated red-hot for three hours in an iron-pot, protected by a tight cover, when the contents are let fall into a reservoir of water, from a height of 10 to 150 feet, as the shot are to be coarser or finer. One part of tin and two of lead form an alloy fusible at 350° Fahr., which is used by tinmen under the name of *soft solder.* Lead also forms an imperfect alloy with copper. The metal used for common brass-cocks is an alloy of these two metals. The union of these two metals, however, is exceedingly slight; for, upon exposing the alloy to a heat no greater than that in which lead melts, the lead almost entirely runs off of itself. This process is called *eliquation.* Of the *oxides,* the mixture of the protoxide and deutoxide which forms the red-lead is of considerable importance as a pigment. Its manufacture in Germany is conducted as follows: 180lbs. of lead are calcined for eight hours upon the hearth of a cupola furnace, and constantly stirred; it is then left in the furnace for sixteen hours, and only stirred at intervals. This calcined lead, or massicot, is ground in a mill with water, washed on tables, and, being dried, is put into stone-pots, of such a size that thirty-two pounds fill them somewhat more than one quarter full. Several of these pots are laid horizontally in the colour furnace, so that the flame may go quite round them, and a piece of brick is put before the opening of each pot. A fire is kept up in this furnace for about forty-eight hours, and the matter in the pots stirred every half-hour. The process being over, the red-lead is passed through a sieve. In this operation, 100lbs. of lead generally increase ten pounds in weight. Red-lead is also made from litharge, by heating it in pots in a reverberatory furnace.

The *salts of lead* have the protoxide, as has before been remarked, for their base, and are readily distinguished by the following general characters:— 1. The salts which dissolve in water usually give colourless solutions, which have an astringent, sweetish taste; 2. placed on charcoal, they all yield, by the blow-pipe, a button of lead; 3. ferroprussiate of potash occasions in their solutions a white precipitate; 4. sulphuretted hydrogen and hydrosulphurets produce

a black precipitate; 5. a plate of zinc, a white precipitate, or metallic leaf.

Most of the acids attack lead. The sulphuric does not act upon it unless it be concentrated and boiling. Sulphurous acid gas escapes during this process, and the acid is decomposed. When the distillation is carried on to dryness, a saline white mass is produced, a small portion of which is soluble in water, and is the *sulphate of lead;* it affords crystals. The residue of the white mass is an insoluble sulphate of lead. It consists of five acid and fourteen protoxide of lead. Nitric acid acts strongly on lead. The *nitrate* solution yields by evaporation tetrahedral crystals, which are white, opaque, and of a specific gravity of four. They consist of 6.75 acid, and fourteen protoxide. A *subnitrate* may be formed by boiling in water equal weights of the nitrate and protoxide; also by boiling a solution of ten parts of the nitrate with 7.8 of metallic lead. Acetic acid dissolves lead and its oxides, though probably the access of air may be necessary to the solution of the metal itself by this acid.

White lead, or *ceruse*, is made by rolling leaden plates spirally up, so as to leave the space of about an inch between each coil, and placing them vertically in earthen pots, at the bottom of which is some good vinegar. The pots are covered and exposed for a length of time to a gentle heat in a sand-bath, or by bedding them in dung. The vapour of the vinegar, assisted by the tendency of the lead to combine with the oxygen which is present, corrodes the lead, and converts the external portion into a white substance, which comes off in flakes when the lead is uncoiled. The plates are thus treated repeatedly, until they are corroded through.

There is a new patent for the manufacture of white lead, which should here be noticed. It is proposed to take a quantity of sulphuret of lead or lead ore, say half a ton, and having broken it, by pounding or rolling, into a powder, then burn or roast it at a temperature below that which would melt the metal. After the ore has become cold, it is to be pulverised again, and reduced to the finest powder, and then well washed in water, taking off the lighter particles, which float, and pounding the coarser again, until the whole is reduced as fine as possible.

This powder is now to be dried in pans, by exposure to the air, or in a suitable stove; and, when perfectly dry, about two hundred weight of salt-petre is to be mixed with it, and the whole placed in a retort, to undergo a sort of distillation.

The retort to be employed is a cylindrical vessel of iron, lined with lead, placed erect within another as a jacket, and fastened together by flanges, forming a steam-tight joint, and leaving a space between, all round and at bottom, for the passage of steam, by which the retort is to be heated.

In this vessel, the materials above prepared are to be placed, and to be constantly agitated during the operation, by means of a perpendicular shaft with arms, which is introduced into the cylinder, and may be turned round by hand, or by any other convenient means.

Above the cylinder there is a vat, or cistern, intended to contain about two hundred weight of sulphuric acid, of a specific gravity of from 1.400 to 1.740. From this vat two pipes descend, one leading to the top of the cylinder, which admits the acid through a stop-cock, the other to the bottom, through the latter of which, by means of a force-pump, the acid is gradually injected into the cylinder at the lower part.

Steam from a boiler under considerable pressure is now admitted into the chamber surrounding the containing cylinder, for the purpose of heating the materials within. This operation is to be continued for several hours, the stirrer being continually turned, for the purpose of bringing all the particles of the material under the action of the acid and the heated vapour.

The top of the cylindrical vessel is of course to be closed, having an aperture with stuffing, through which the upper end of the spindle or shaft of the stirrer passes; but a tube is introduced into the top, for the purpose of carrying off the vapour arising within the vessel to a condenser, or into a chimney, or away into the open air, at a distance from the workmen. A hole is likewise made in the top with a stopper, by which small quantities of the material can be occasionally withdrawn, by a ladle, for the purpose of ascertaining the progress of the operation within.

The pulverised ore, having been thus operated upon for several hours, is afterwards allowed to remain in the retort for two or three days, or under some circumstances for a longer time, occasionally stirring it up, and drawing off the acid. It is then removed and washed in water in order to discharge the acid; and when this is done, and the material dried, a similar quantity of salt-petre is again mixed with it in the retort, and the operation performed in a fresh quantity of acid as before.

The material being a second time withdrawn from the retort, it is to be thoroughly washed in warm water, until every appearance of acid has become completely removed, after which, being dried, and then ground in water, in the way white lead is usually treated, it becomes fit for use.

The patentee proposes to employ sulphuric acid in the retort, but in the second operation he sometimes uses nitric acid, and, under certain circumstances, other acids. He has described a particular formed vessel to be used as a retort, but has not exhibited any figure, as the vessel may be variously constructed without deviating from the general principle. Steam, under great pressure, is proposed and most approved as the heating material; but fire may be applied directly to the under part of the vessel, and effect the same object.

Thus a variety of changes may be made in the modes of conducting the operation, all of which come within the contemplation of the patentee, and are claimed by him under the present patent.

Ceruse is the only white used in oil paintings. Commonly, it is adulterated with a mixture of chalk in the shops. It may be dissolved without difficulty in the acetic acid, and affords a crystallizable salt, called *sugar of lead*, from its sweet taste. This, like all the preparations of lead, is a deadly poison. The common sugar of lead is an acetate; and *Goulard's extract*, made by boiling litharge in vinegar, a *subacetate*. The power of this salt, as a coagulator of mucus, is superior to that of the other. If a plate of zinc be suspended, by a thread, in a solution of acetate of lead, the lead will be revived, and form an *arbor Saturni*. The acetate, or sugar of lead, is usually crystallized in needles, which have a silky appearance. They are flat four-sided prisms, with pointed summits; specific gravity, 2.345. It is soluble in three times and

a half its weight of cold water, and in somewhat less of boiling water.

Acetate and subacetate of lead in solutions have been used as external applications to inflamed surfaces, scrofulous sores, and as eye-washes. In some extreme cases of hemorrhage from the lungs and bowels, the former salt has been prescribed, but rarely, and in minute doses, as a corrugant or astringent. The colic of the painters shows the very deleterious operation of this metal when introduced into the system in the minutest quantities at a time. A course of sulphuretted hydrogen waters, laxatives (of which sulphur, castor-oil, Epsom-salts, or calomel, should be preferred), a mercurial course, the hot sea-bath, and electricity, are the appropriate remedies. Dealers in wines have occasionally sweetened their acid wines with litharge, or its salts. This nefarious adulteration is at once detected by the use of sulphuretted hydrogen water, which will throw down the lead in the state of a dark brown sulphuret. Burgundy wine, and all such as contain tartar, will not hold lead in solution, in consequence of the insolubility of the tartrate. The proper counter-poison for a dangerous dose of sugar of lead is solution of Epsom or Glauber salt, liberally swallowed; either of which medicines instantly converts the poisonous acetate of lead into the inert sulphate. Sugar has been found to neutralize the poisonous action of acetate of lead, and therefore may be regarded as an excellent antidote to it.

League; a measure of length, containing more or fewer geometrical paces, according to the different usages and customs of countries. A sea league contains 3000 geometrical paces, or three English miles. The French league sometimes contains the same measure, and, in some parts of France, it consists of 3500 paces. The mean or common league consists of 2400 paces, and the little league of 2000. Twenty common Spanish leagues make a degree, or 69½ English statute miles. The German league (*meile*) contains four English geographical miles. The Persian league is also equal to four such miles, being very near to what Herodotus calls the length of the Persian *parasang*, which contains 30 *stadia*, eight of which make a mile. See Mile.

Leech; a genus of molluscous animals, which have an oblong body, a mouth surrounded by a lip, and a disc at the posterior extremity, by both of which they can affix themselves to bodies. In the mouth are three small jaws, tongues, or plaits of skin, by which they are enabled to extract the blood of other animals, that forming their principal nourishment. Leeches are hermaphrodites, and some species are viviparous. They occur in ponds and streams, in almost all countries. They derive their principal interest from the use made of them as a remedial agent. There are several of the species which are capable of being thus used, though it is commonly supposed that only two sorts are proper. The employment of leeches in France may be judged of from the circumstance that the hospitals of Paris require an annual supply of several hundred thousands. In Philadelphia, in America, the supply required is from 150,000 to 200,000. The leech, when forcibly pulled away whilst sucking, is very apt to leave the teeth, or plaits of skin, spoken of above, in the wound, occasioning pain and inflammation of the part; the leech is also rendered incapable of again biting. The most certain method of inducing these animals to bite is to cleanse the skin thoroughly: the leeches should be exposed to the air for a short time previous to their application, as by this means they will bite more freely. If they are voracious, they may be applied to the part by being held lightly in the fingers, or they may be placed in a cup which is to be inverted over the part from which the blood is to be drawn. They should not be disturbed whilst sucking, nor the patient be exposed to too great warmth, or they will fall off; this they should always be permitted to do of their own accord. They are made to disgorge, by putting them in a weak solution of common salt; and, if they have not been injured, they may be used five or six times. They are taken either by hand or by means of a gauze net. In keeping them, great care should be taken to renew the water frequently, and not to place too many in the same reservoir, but to remove speedily all that may die. Notwithstanding every precaution that can be taken, they will sometimes perish in great numbers, apparently from an epidemic disease. It appears that, in such cases, the use of charcoal is the best preventive: for this purpose, the bottom of the reservoir is to be strewed with small pieces of this substance, kept down by moss. In 1821, France is said to have exported 1,500,000, and, in 1829, 33,650,000 leeches. The greater part of the leeches employed in this country are brought from Holland.

Leeward, to, denotes towards that part of the horizon which lies under the lee, or whither the wind blows.

Legato; a word used in opposition to *staccato*, and implying that the notes of the movement or passage to which it is affixed are to be performed in a close, smooth, and gliding manner, holding each note till the next is struck.

Leghorn Plat. This name is given to a peculiar species of manufactured straw of great durability and beauty.

During the last war the importation of hats, and similar articles, manufactured of the fine straw grown for that purpose, and known by the name of Leghorn plat, was almost entirely put an end to. The natural consequence was an extraordinary degree of encouragement of our home manufactures of platted straw, by the wives and children of the agricultural labourers of Bedfordshire, Hertfordshire, and Buckinghamshire. At the conclusion of the war this branch of trade fell into the usual channels, and bonnets and hats of genuine Leghorn plat soon found their way again into our market.

The Leghorn straw, being much more slender than the English, may be used whole for the finest articles, by which means the plat is rendered more even, pliable, and durable, than that of equal fineness made from split straw. It is also much superior in colour. To which we may add that the Leghorn plat admits of being joined by knitting the adjacent edges together, instead of overlapping and sewing them, as is the case with English plat.

The process of platting straw in the Italian manner may easily be explained. The ears are cut off the straw, and the straws sized as to length and thickness, and also colour. Thirteen straws are then taken and tied together at one end; they are then divided into a right angle, placing six straws on the left side, and seven on the right. The seventh or outermost on the right is to be turned down by the finger and thumb of the right hand, and brought up under two straws, over two, and under two, and thus

seven straws will be placed again on the right side of the angle; and so on alternately, doubling and platting the outermost seventh straw from side to side, until it becomes too short to cross over so as to double on the other side of the angle; then another straw is to be taken, and put under the short end, at the point of the angle in the middle of the plat; and, by another straw coming under and over the joined one from both sides of the angle, in the operation of platting, it will become fastened, the short end being then left out underneath the plat, and the newly fastened straw taking its place on that side of the angle to which the short straw was directed; and thus the platting is continued, until a piece of about twenty yards long is completed. The short ends which are left out are then cut off with scissars.

Legion; a division of the Roman army. Under Romulus it was composed of 1000 foot and 100 horse, selected from each of the three tribes. The body thus selected (hence the name *legio*) amounted, therefore, to 3300 men. In the time of Polybius, a legion consisted of 4200 men, and it was finally increased to 6200 foot. All the soldiers of a legion were Roman citizens: no slaves were admitted, except in cases of the most pressing necessity; nor any citizen under seventeen years old, except in peculiar circumstances of danger. There was commonly an equal number of auxiliaries attached to each legion, so that, in the later periods of Roman history, we must understand by a legion a corps of 9000 or 10,000 men. The foot of each legion, when it consisted of 3000 men, were divided into ten cohorts, and each cohort into three companies (*manipuli*) of 100 each, hence called *centuriæ*. When the legion was enlarged, the same division was still retained, with the difference that each *manipulus* was now divided into two *centuriæ*, and each *centuria* into ten *decuriæ*.

The commander of a legion was styled the *legatus*. Sometimes, instead of a legate, six military tribunes were appointed from each, who commanded in succession, each for the space of a month, under the direction of the consul. The principal standard of a legion was a silver eagle: and the legions were named from their commander (as the *Claudian legion*), or from the place where they were stationed, or from some deity, or from birds, or from some remarkable event. In the time of Augustus the army consisted of twenty-five legions. *Legion* is also used, proverbially, to signify a large and indefinite number of persons or things. This term was revived in the time of Napoleon, and has since been commonly applied to a body of troops of an indefinite number, and usually of different kinds. Such legions are mostly formed at the beginning of a war, and dissolved at the close. Of this sort were the English-German legion, and the Russian-German legion, in the last war for the independence of Europe. The French national guards were divided into legions and cohorts. After the dissolution of the army raised by Napoleon in 1815, the remains of which had retired beyond the Loire, the new French army was divided into legions, which were named from the departments. This arrangement, however, was abolished towards the close of the year 1820.

Legion of Honour; an order instituted by Napoleon, while consul, May 19, 1802, for military and civil merit. The proposition produced much debate in the legislative body, and passed after a strong opposition. It was the object of Napoleon to kindle a spirit of ambition, the most necessary national element for the support of wars, of which he foresaw that it would be necessary for him to wage many; and for this purpose the institution was admirably calculated. At the same time it cannot be denied that, abstractly considered, it is to be regretted that a nation which had just declared itself so loudly for liberty should appear so eager for ribands—an invention of those very times against which the revolution was directed. Moreau, who was altogether opposed to Napoleon, ridiculed the institution. The cross of the legion of honour was given to all who had previously received a military weapon as a mark of honour, and to a great number of new members. Its effect upon the soldiers was very great. After Napoleon's assumption of the imperial dignity, the statutes received some modifications. The oath was originally as follows: "I swear, on my honour, to devote myself to the service of the republic, to the preservation of the integrity of its territory, to the defence of its government, its laws, and the property by them consecrated; to oppose, by every means which justice, reason, and the laws authorise, all acts tending to re-establish the feudal system, or to revive the titles and distinctions belonging to it; finally, to contribute to the utmost of my power to the maintenance of liberty and equality."

After Napoleon became emperor, the form of the oath was somewhat changed. The members swore to devote themselves to the service of the empire, to the preservation of the integrity of the French territory, to the defence of the emperor, to the support of the laws, and of the property which they had made sacred; to combat, by all the means which justice, reason, and the laws authorised, every attempt to re-establish the feudal *régime*, and to concur, with all their might, in maintaining liberty and equality.

The decoration consisted of a star containing the portrait of Napoleon, surrounded by a wreath of oak and laurel, with the legend *Napoléon, empereur et roi;* on the reverse was the French eagle with a thunderbolt in his talons, and the legend *Honneur et patrie.* The star of the *légionnaires* was of silver, that of the officers of gold, and was suspended from a red riband with a white margin. The order consisted of grand-crosses (*grand aigle*), who wore the cross on a broad riband hanging over the left shoulder, and a star on the left side of the breast; of grand-officers, who wore the cross in the button-hole, and a star, somewhat smaller, on the left side; of commanders, who wore the cross round the neck; of officers, who wore the gold cross with a bow in the button-hole; and of legionaries, who wore the silver cross with a simple riband in the button-hole. The legion was composed of sixteen cohorts, each of which had its seat in a different city, and contained 407 members; the whole number was, therefore, at first, 6512. Each cohort had a chancellor, treasurer, and chief; the whole order a grand-chancellor and grand-treasurer. The pension of a grand-officer was 5000 francs annually; of a commander, 2000; of an officer, 1000; of a legionary, 250 francs. There was also an institution for the education of the daughters of members of the legion of honour at Ecouen, under the care of Madame Campan.

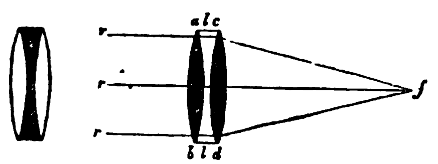
After the restoration of the Bourbons, the order underwent essential changes. The head of Henry IV. was substituted for that of Napoleon, with the

legend *Roi de France et de Navarre*; and, on the reverse, the *fleur-de-lis* took the place of the eagle. The grand-crosses were limited to 80, the grand-officers to 160, the commanders to 400, the officers to 2000: the number of the legionaries was left unlimited. New members received no pensions, whilst those of the old members exceeded the prescribed sum; but, on the death of the old members, the new ones were to receive their pensions. Foreign members received no pensions. It was evident that the legion of honour was coldly treated by the Bourbons, who restored the old orders. The members created during the hundred days were, of course, not acknowledged by the Bourbons; but, in 1831, Gen. Lamarque obtained their acknowledgment, by a spirited speech in the chamber of deputies, for which they sent him a sword with an inscription. Military honours are paid to the members of the legion, as they are also to the bearers of the *croix de Juillet*, which has been granted to 1528 persons who distinguished themselves during the struggle of July, 1830. This cross takes precedence of that of the legion of honour.

Lemma, in *mathematics*, denotes a preliminary proposition, laid down in order to clear the way for some following demonstration, and prefixed either to theorems, in order to render their demonstration less perplexed and intricate, or to problems, to make their solution more easy and short.

Lemonade; a drink made of water, sugar, and the juice of lemons. Prepared in this simple way, it is a very grateful beverage in warm weather, or to feverish patients. The taste is more agreeable, if the sugar is rubbed with the peel of the lemon, so as to imbibe the oil contained therein; but the lemonade is thus rendered stimulant rather than cooling, and many persons suffer from headach in consequence. Cream of tartar is frequently used instead of lemon-juice.

Lens, in *dioptrics*, properly signifies a small ground glass, which either collects the rays of light into a point, in their passage through it, or makes them diverge, according to the laws of refraction. Lenses have various figures, that is, are terminated by various surfaces, from which they acquire various names. Some are plane on one side, and convex on the other; others convex on both sides: both of which are ordinarily called *convex lenses*, though, when we speak accurately, the former is called *plano-convex*. Again, some are plane on one side, and concave on the other; and others are concave on both sides; which are both usually ranked among the concave lenses, though, when properly distinguished, the former is called a *plano-concave*. Others, again, are concave on one side, and convex on the other, which have the name *meniscus*. In every lens, terminated in any of the forementioned manners, a right line, perpendicular to the two surfaces, is called the *axis of the lens*, which axis, when both surfaces are spherical, passes through both their centres; but, if one of them be plane, it falls perpendicularly upon that, and goes through the centre of the other.



The effect of a convex lens is to converge the rays of light which pass through it, of which an example is given in the preceding engraving.

In the old optical arrangement for refracting light it was common to employ a lens of considerable thickness. When the focus was short, a plano-convex "lump" was usually resorted to, and this rude apparatus is still used in the magic lantern. In the foregoing wood-cut two double convex lenses, *a b*, *c d*, supply the place of the *lump*, and a slight intervening space, *l l*, is left between them. The horizontal rays *r*, *r*, *r*, impinging on the convex surfaces, are thus refracted, and form a focal point at *f*.

In the same diagram we give the combination of lenses which are termed *achromatic*, from their power of transmitting the light in a purely colourless state. The common lens partly decomposes the rays which pass through it, owing to their possessing different degrees of refrangibility; but by judiciously combining three lenses in the same frame, each of which possesses a different degree of density, the light is transmitted without colour. See Optics.

Leprosy; a name given to several different diseases. The elephantiasis is sometimes called *leprosy of the Arabs*. The *leprosy of the Jews* is distinguished by white, cutaneous spots, composed of smaller spots, which appear sometimes in one place and sometimes in another, and are covered with a rough scaly matter. It appears to have been the *leuce* of the Greek writers. The *Greek leprosy* is characterized by hard, insensible tubercles, which appear upon the skin, and are accompanied by a progressive insensibility and the loss of the voice. It is endemic in Egypt, Java, and some parts of Norway and Sweden. The use of unhealthy articles of food seems to be one of its causes. It is hereditary and contagious. It was introduced into western Europe in the time of the crusades, but has gradually disappeared. The tubercles which characterize leprosy appear in different parts of the skin: they are hard, rough, and numerous, and cause the loss of the hair at the places where they appear. They finally terminate in ulcers, which penetrate even to the bone, producing a caries. They also cause the separation of parts of the body, the toes and fingers, for example, dropping off. These symptoms are accompanied with a languor in the motions, a dulness of the senses, a change of the voice, offensive breath, and lethargy.

There are three sorts of leprosy—the squamous, or scaly; the crustaceous, in which the skin is covered with crusts; and the tuberculous. The remedy recommended for this disgusting disease is light food, such as vegetables, soups, milk: sulphur baths, sudorific drinks, and mercury, are sometimes prescribed. But all remedies are too frequently unavailing. In the middle ages, leprosy, under all the forms of disease to which this term has been applied, seems to have been very common and general. It should, however, be observed that almost all cutaneous disorders were considered as of a leprous nature, and treated as such. From the sixth to the fifteenth century, these loathsome disorders attracted the attention of lawgivers and of the benevolent, and we find numerous ordinances relating to lepers, affecting their civil rights, and great numbers of lazar-houses in all the countries of Europe. In the historians of those times, therefore, we are to consider the word *leprosy* as used indiscriminately for all cutaneous diseases; and we may well be astonished and shocked to find that all such patients were treated somewhat

after the manner prescribed in Leviticus for the Jewish leprosy. They were, in fact, treated as civilly dead: their funeral obsequies were performed, and masses said for the benefit of their souls. Their marriage ties were dissolved; but a leper might enter into a new connexion with a person who was also afflicted with the disease. They were allowed to enter the cities at certain seasons, but were required to give notice of their approach by sounding a rattle. The consequences of such a treatment may be easily imagined. The improved condition of the lower classes, in food, clothing, and manner of living in general, and the advancement of medical science, have contributed to eradicate this loathsome and disgusting malady.

Levee; an embankment on the margin of a river, to confine it within its natural channel. The lower part of Louisiana, which has been formed by encroachments upon the sea, is subject to be inundated by the Mississippi and its various branches, for a distance of more than 300 miles. In order to protect the rich lands on these rivers, mounds are thrown up, of clay, cypress logs, and green turf, sometimes to the height of fifteen feet, with a breadth of thirty feet at the base. These, in the language of that part of the country, are called *levées*. They extend for hundreds of miles; and, when the rivers are full, cultivated fields, covered with rich crops and studded with villages, are seen lying far below the river courses. The giving way of these *levées*, sometimes occasioned by a sudden and violent pressure of the water and sometimes by accidental perforations, is called a *crevasse*, or disruption.

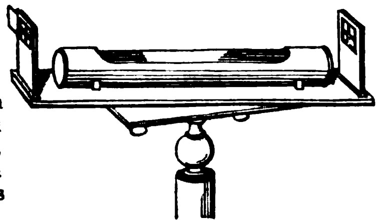
Levee-en-masse (universal rising); a military expression for the rising of a whole people, including all capable of bearing arms who are not otherwise engaged in the regular service. When animated by patriotic feelings, it is the most formidable obstacle which an enemy can encounter; and it is unconquerable, if favoured by the nature of the ground, because almost every advantage is on the side of the people. They fight on their own soil; they know the ground; they find support and assistance in every house, from every woman and child; they fight for their own hearths; they enclose the enemy on all sides, and can destroy whatever may be useful to him, cut off his communications, pursue, annoy, disturb, assail, harass him incessantly, so that he can effect nothing except getting possession of the strong places. It is called *Landsturm* (landstorm), in German, in distinction from the *Landwehr* (militia). This distinction was first made in 1796, when the peasants of Bavaria and Franconia fell upon the rear of the flying French, under Jourdan, with much success. The *Landsturm* was yet more effective in 1799, and, in 1813, the governments of Northern Germany called it forth in every part of the country. It consisted of every male person, capable of bearing arms of any sort, whom age or other reasons exempted from the militia service. Orders were issued to turn every thing into weapons, to defend the country by every means, and to injure the enemy in all possible ways, by destroying provisions and wells, attacking stragglers, intercepting couriers, and escorting prisoners. The *Landsturm* was useful at the siege of several fortresses. Its organization was founded on municipal divisions.

Napoleon ordered the *levée-en-masse* when the allies entered France, and it threatened to become dangerous to them; but the capture of Paris put an end to the war. We all know how effectual the *levée-en-masse* was in Spain, where even women took part in it, and in the Tyrol, under Hofer. The French national guard, with its different classes, might be considered a *levée-en-masse*, organized on a gigantic plan. The chief difference between a *levée-en-masse* and militia is, that, in the former, all persons are comprised not included in the latter; that they do not march far from home; and that their service is more irregular, and even owes its strength, in some measure, to this irregularity.

Level; a mathematical instrument, used for drawing a line parallel to the horizon, and continuing it at pleasure, and, by this means, for finding the true level, or the difference of ascent or descent between several places, for conveying water, draining fens, placing the surfaces of floors, &c., level, and for various other purposes in architecture, agriculture, hydraulics, surveying, &c. There is a great variety of instruments for this purpose, differently constructed, constituted of different metals, according to the particular purposes to which they are applied; as the carpenter's level, mason's level, balance level, mercurial levels, surveying and spiral levels; but, however their construction may vary, they may all be referred to the following three classes: 1. those in which the vertical line is determined by a suspended plumb-line or a balance-weight, and the horizontal position is shown by a line perpendicular to it; 2. those which determine a level line by the surface of a fluid; 3. spirit levels, which point out the horizontal direction by a bubble of air floating in a fluid contained in a glass tube.

1. Those of the first kind, depending upon the plumb-line, are very common, but not very accurate. The simplest form is that of two rulers united in the form of the letter L; they must be exactly perpendicular to each other; then, if a plumb-line be suspended from the top of the vertical ruler, and the edge thereof be made to coincide with the plumb-line, the other ruler must be horizontal. This, when applied to the top of a wall, a beam, or a floor, will show whether it is horizontal. Sometimes the instrument is formed like the letter A, the plumb-line being suspended from the vertex, and the two legs set on the surface to be levelled. The line hangs opposite to a mark made on the middle of the cross ruler when the feet are on the same level. At other times the horizontal piece crosses the perpendicular at its foot, and the plumb, suspended from the top of the perpendicular, is received in an opening at their junction. 2. The *water level* shows the horizontal line by means of a surface of water or other fluid, founded on the principle that water always places itself horizontally. The most simple kind, made of a long wooden trough, which is filled with water, shows on its surface the line of level. This is the ancient *chorobates*. The water level is also made with two cups fitted to the two ends of a straight pipe, an inch in diameter, and four feet long. The water communicates from one cup to the other; and, this pipe being movable on its stand by a ball and socket, when the two cups are seen to be equally full of water, their two surfaces mark the line of level. This instrument, instead of cups, may also be made with two short cylinders of glass, three or four inches long, fastened to each extremity of the pipe with wax or mastich. The pipe, filled with coloured water, shows

itself through the cylinders, by means of which the line of level is determined, the height of the water, with respect to the centre of the earth, being always the same in both cylinders. This level, though very simple, is yet very commodious for levelling small distances. 3. The *spirit* or *air level* shows the exact level, by means of a bubble of air, enclosed, with some fluid, in a glass tube of an indeterminate length and thickness, and having its two ends hermetically sealed. When the bubble fixes itself at a mark in the middle of the tube, the case in which it is fixed is then level. When it is not level, the bubble will rise to one end. This glass tube may be set in another of brass, having an aperture in the middle, where the bubble may be observed. The liquor with which the tube is filled is oil of tartar, which is not liable to freeze, as common water, nor to rarefaction and condensation, as spirit of wine is. A level which owes its operation to the tendency which all fluids have to a state of equilibrium is shown beneath. To make this level applicable to surveying, it is provided with apertures and cross wires, along which the sight is directed.



Lever, in *mechanics*; an inflexible right line, rod, or beam, supported, at a single point, on a fulcrum or prop, and used for the raising of weights, being either void of weight itself, or at least having such a weight as may be commodiously counterbalanced. The lever is the first of those called *mechanical powers*, or *simple machines*, as being, of all others, the most simple; and is chiefly applied for raising weights to small heights. (See Mechanics.)

Ley, or Lees; a term usually applied to any alkaline solution made by levigating ashes that contain an alkali. Soap-lees is an alkali used by soap-boilers, or potash or soda in solution, and made caustic by lime. Lees of wines are the refuse, or sediment, deposited from wine standing quiet.

Leyden Phial, in *electricity*, is a glass phial or jar, coated both within and without with tin-foil, or some other conducting substance, which may be charged, and employed in a variety of useful and entertaining experiments. Glass of any other shape, so coated and used, has also received the same denomination. A vacuum produced in such a jar, &c., has been named the *Leyden vacuum*. (See Electricity.)

Li (called also *caxa*); the common copper coin in China, with a square hole in the middle, and an inscription on one side. The copper is alloyed with lead, and the coin, which is cast, is very brittle. Ten lis make one candareen, 100 a mas, 1000 a liang, or tale.

Libra; the Roman pound unit for weighing. The ancient Romans reckoned money also by pounds, and a libra of silver was worth about three pounds sterling. This word passed over to the various nations of Latin descent or mixture.

Libration of the Earth is sometimes used to denote the parallelism of the earth's axis in every part of its revolution round the sun.

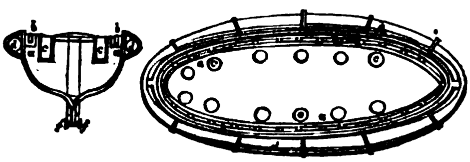
Libration of the Moon. Very nearly the same face of the moon is always turned towards the earth, it being subject to only a small change within certain limits, those spots which lie near the edge appearing and disappearing by turns; this is called its *libration*. The moon turns about its axis in the same direction in which it revolves in its orbit. Now the angular velocity about its axis is uniform, and it turns about its axis in the same time in which it makes a complete revolution in its orbit; if, therefore, the angular motion about the earth were also uniform, the same face of the moon would always be turned towards the earth; for, if the moon had no rotation on her axis, when she is on opposite sides of the earth she would show different faces; but if, after she has made half a revolution in her orbit, she has also turned half round her axis, then the face which would otherwise have been shown will be turned behind, and the same face will appear. Thus, if the moon's angular velocity about her axis were always equal to her angular velocity in her orbit about the earth, the same side of the moon would be always towards the earth; but, as the moon's angular velocity about her axis is uniform, and her angular velocity in her orbit is not uniform, these angular velocities cannot continue always equal, and therefore the moon will sometimes show a little more of her eastern parts, and sometimes a little more of her western parts. This is called a *libration in longitude*. Also the moon's axis is not perpendicular to the plane of her orbit, and therefore, at opposite points of her orbit, her opposite poles are turned towards the earth; thus her poles appear and disappear by turns. This is called a *libration in latitude*. Hence nearly one-half of the moon is never visible at the earth, and therefore nearly one-half of its inhabitants, if it has any, never see the earth, and nearly the other half never lose sight of it. Also, the time of its rotation about its axis being a month, the length of the lunar days and nights will be about a fortnight each. It is a very extraordinary circumstance that the time of the moon's revolution about her axis should be equal to that in her orbit.

Lieutenant. This word, like *captain* and many others, has received gradually a much narrower meaning than it had originally. Its true meaning is a *deputy*, a *substitute*, from the French *lieu* (place, post) and *tenant* (holder). A *lieutenant général du royaume* is a person invested with almost all the powers of the sovereign. Such was the Count d'Artois (afterwards Charles X.) before Louis XVIII. entered France, in 1814. The Duke of Orleans, before he accepted the crown as Louis-Philip, was appointed to the same office by the chamber of deputies. *Lieutenant-general* was formerly the title of a commanding general, but at present it signifies the degree above major-general. *Lieutenant-colonel* is the officer between the colonel and major. *Lieutenant*, in military language, signifies the officer next below a captain. There are first lieutenants, and second or *sous-lieutenants*, with different pay. A lieutenant in the navy is the second officer next in command to the captain of a ship. According to the new organization of the French navy, of 1831, there are *lieutenants de vaisseau* and *lieutenants de frégate*, formerly called *enseignes de vaisseau*. The latter can command only in the absence of the former. In this country, the *lord-lieutenant* of a county has the authority to call out the militia in case of invasion or rebellion. The governor of Ireland is also called *lord-lieutenant of Ireland*. In some English colonies,

jointly under a *governor-general*, the chief magistrate of each separate colony is called *lieutenant-governor*.

Life-boat, a buoyant vessel, employed when the weather is tempestuous to save the crews of shipwrecked vessels. The latest improvements in the construction of life-boats have become the subject of a patent granted to Lieut. Cook, R. N. The improvements described under this patent consist, first, in covering the deck of the boat with a water-tight canvass envelope, secured by water-tight joints all round its edges, and having bags formed in it, which descend below the deck, to contain the legs of the persons sitting in the boat.

Secondly, in the application of buoyant fenders placed all round the outside of the gunwale of the boat, which protect the boat when going alongside of a wreck, and also serve to keep the boat buoyant, in case she should have her bottom stove in. Thirdly, in improvements in the ballasting of a boat, with long bars of metal placed on each side of the keel, resting upon pins or bolts, and suspended by chains; these bars of ballast can be let go to relieve the boat of the weight in case she should fill with water. Fourthly, in the construction of the hooks or holdfasts of the ropes, by which the sails are made fast, or other ropes used in the boat, and are so contrived that they can be let go at a moment's notice, in case of a sudden squall coming on.



The accompanying wood-cut is a plan of a boat, showing some of the patentee's improvements. Beside it is a transverse section; *a a* is a shelf, placed all round the inside of the boat, or it may form part of the deck. The water-proof covering extends over the inside of the boat like a deck, and is jointed to the shelf water-tight at *b b*, by forming a channel in a groove all round in the shelf; the edges of the water-proof covering are introduced into the groove, and firmly secured by rods of wood or metal fastening into the groove by screw bolts or otherwise; *c, c*, are bags formed in the covering to contain the legs of the persons sitting in the boat.

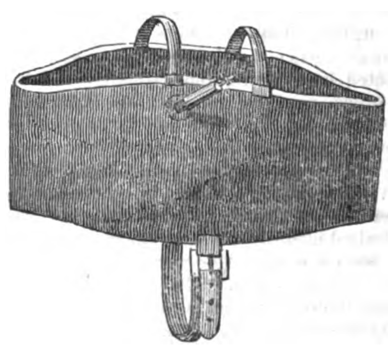
In order to let out any water which may remain on the deck or covering, holes are made in the sides of the boat through the gunwale, usually stopped tight by screw plugs, but which can be removed and replaced as required; *d, d*, are the buoyant fenders, which are formed of strong water-proof canvass, and filled with cork cuttings, shavings, or any other light material, extending round all the sides of the boat, and are firmly secured to it by lashings. Bars of metal, forming additional ballast to the boat, are shown at *f, f;* these bars rest upon bolts, projecting on both sides of the keel of the boat, and are kept in that situation by collars formed upon the bolts. In case of the boat becoming swamped, these bars can be removed by chains attached to their ends, and let fall away, thereby relieving the boat of their weight.

Life-Preservers. A variety of contrivances under this title have been brought before the public, two or three of which may advantageously have a place in this article. We may commence with Mr. Murray's apparatus, which he calls an "Invention of an effective and unfailing method for forming an instantaneous communication with the shore in shipwreck, and illuminating the scene in a dark and tempestuous night." The apparatus which Mr. Murray suggests is, "an arrow of peculiar construction, about eighteen inches long, weighing about six ounces and a half, and having a cord attached to it, which is shot from a common blunderbuss, or a three-pounder swivel, from the shore to the vessel." This arrow is barbed with iron, so as to fix itself in what it strikes. The cord thus conveyed on board is strong enough to bear the weight of a rope, which can thus be drawn to the vessel, and the necessary communication will be effected. There is a further contrivance, of a combustible substance, which, when necessary, can be attached to the arrow, and which, catching fire by the action of the air, during the arrow's flight, to use the author's phrase, "illuminates the scene." It is evident that this may be used in many situations where Captain Manby's apparatus is impracticable, and is besides not subject to the mischance that frequently defeats the success of his apparatus, the snapping of the rope.

The efficacy of this invention has been established by a variety of experiments, in the course of which it was found practicable to throw a line 170 yards against a strong gale of wind—and, with a steady aim, whatever was the direction of the wind.

The immense practical utility of such an invention is shown from several considerations. The loss of life by shipwreck, on the British coast, is more considerable than is generally supposed. It has been computed that in twenty years prior to 1812 more than 800 persons perished on the coast of Norfolk alone, exclusive of the crews of vessels known to have been totally lost. By far the greater number of shipwrecks take place at distances from the shore of from 50 to 100 yards, and therefore within the reach of the arrow.

Life-Preserver for Water. The most simple apparatus for the above purpose is that invented by Mr. Daniel and represented beneath:



The body of the machine, which is double throughout, is made of pliable water-proof leather, large enough to admit of its encircling the body of the wearer, whose head is to pass betwixt the two fixed straps, which rest upon the shoulders; the arms of the wearer pass through the spaces on the outside of the strap, one on each side, admitting the machine under them to encircle the body like a large hollow belt. The strap on the lower part of the machine is attached to the back of it, and by passing betwixt

the thighs of the wearer, holds the machine sufficiently firm to the body, without too much pressure under the arms. The machine, being thus fixed, is inflated by the wearer blowing in from his lungs, through a small stop-cock, a sufficient quantity of air to fill it, which air is retained by afterwards closing the aperture. When filled with air, it will displace a sufficient quantity of water to prevent four persons from sinking beneath the surface.

The inventor recommends this life-preserver to be prepared as follows: viz. to select sound German horse-hides, and to cut a piece six feet long and two feet six inches wide, which is first to be curried, and then rendered water-proof by any good varnish.

The leather is to be nailed on a board, and the varnish applied upon it; it is then to be placed in an oven several times, the varnish being each time repeated, till the leather is completely covered; it is then cut in the form of a jacket, as above described, and neatly and firmly stitched; the seams and stitches are afterwards to be perfectly secured by the following black elastic varnish:

Gum-asphaltum, two pounds; amber, half a pound; gum-benzoin, six ounces; linseed-oil, two pounds; spirits of turpentine, eight pounds; and lamp-black, half a pound; united together in an earthen vessel with a gentle heat.

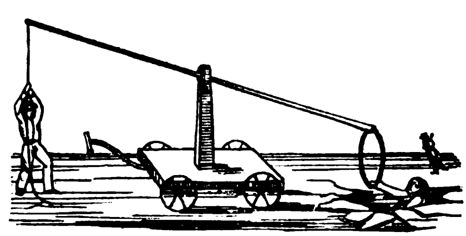
The machine, when properly made, resembles a broad belt, or circular girdle, composed of two folds of pliable leather attached together, and perfectly impervious to water. When used, the wearer introduces his head and arms within the circle, the stop-cock in front; the two fixed straps rest one upon each shoulder, to prevent the belt from sinking down; the lower strap is then brought between the thighs, and buckled in front, which prevents the machine from being forced back. The machine is then inflated by application of the mouth to the stop-cock in front, and, when properly filled, the turning of the cock retains the air in the machine, and expands it so much as to displace a quantity of water amply sufficient, not only to sustain the wearer, but a further weight, if necessary, buoyant in the water.

A great number of cases have occurred by which the efficacy of this life-preserver has been fully manifested. Among others the following may be adverted to:—The Alert privateer struck on a rock near the Western Isles, and went to pieces in five minutes. Thirteen of the crew saved themselves by clinging to pieces of the wreck; but the rest, consisting of sixty-four foremast men, and all the officers except the surgeon, perished. The surgeon, though unable to swim, supported himself amidst waves running mountains high by one of these life-preservers, with which he happened to have provided himself, until the arrival of a Portuguese boat, which put off to his assistance, and took him up about a mile from the shore.

Another instance of the utility of this life-preserver may be adduced. Two gentlemen and two ladies, in a pleasure-boat, set sail from Yarmouth about four o'clock in the afternoon, with a view to reach the city of Norwich, a distance of thirty miles, that evening: the wind blew hard at south-west. One of the life-preservers was taken on board, though without the smallest fear that any occasion for its use would occur; and it was with a view to amusement rather than otherwise jocosely filled as they went along, by one of the gentlemen. The precaution proved most fortunate; for, on tacking to enter Norwich river, at a part of the water called Braydon, two miles over, a sudden gust overset the boat, and plunged the whole company into the water, which was extremely rough. The gentleman with the machine having reached the other, who, inexpert at swimming, could scarcely support himself, directed him to lay hold of the collar of his coat, over which the machine was fixed. This being done, he proceeded to the ladies, whose clothes kept them buoyant, though in a state of fainting when he reached them; and, taking one of them under each arm, the violence of the wind drifted all four upon Burgh Marshes, where the boat had already been thrown. Here, after procuring such refreshment and assistance as they required, they again set sail in their own boat, and arrived at Norwich by eleven o'clock the same night.

It would be useless to multiply testimonies of this nature, as those adduced very clearly show the services which this very simple machine is capable of rendering, in cases of the greatest peril from shipwreck. At seaports, and wherever accidents on water are likely to occur, nothing has yet been devised better calculated for general utility; and it is highly desirable that the plan should be adopted of keeping one or more of these life-preservers in known and convenient situations. Sadler, the celebrated aëronaut, was provided with one of them, which he considered a necessary part of his apparatus in his aërial voyages, and which enabled him to contemplate, without being appalled, the circumstance of being compelled to descend even upon the sea, a disaster which actually occurred near the mouth of the river Mersey, Liverpool, while accomplishing the adventurous excursion in his balloon from Ireland to England.

Life-Preserver for Ice. The number of fatal accidents which have occurred from the fracture of this brittle material, even when help was within a few yards of the sufferers, renders it necessary that some simple plan should be adopted for opening a communication without endangering the life of the assistant. A cheap machine for this purpose is shown beneath:



It consists of a lever, supported by a movable frame, which may readily be transported to any required point. At one extremity of the lever is attached a large hoop, which may be raised by a slight force at the opposite end. The great advantage of this plan is, that the person who renders assistance does so without endangering himself; and the hoop, being drawn nearly in a perpendicular direction, prevents the person who is immersed from being wounded by the edge of the ice.

Ligament, in *anatomy;* a strong, compact substance, serving to join two bones together. A ligament is more flexible than a cartilage, not easily ruptured or torn, and does not yield, or at least yields very little, when pulled.

Ligature, in *surgery,* is a cord, band, or string; or the binding any part of the body with a cord, band, fillet, &c., whether of leather, linen, or any other matter. Ligatures are used to extend or replace bones that are broken or dislocated; to tie the patients down in lithotomy and amputations; to tie upon the veins in phlebotomy, on the arteries in amputations or in large wounds; to secure the splints that are applied to fractures; to tie up the processes of the *peritoneum,* with the spermatic vessels, in castration; and, lastly, in taking off warts or other excrescences by ligature. The term *ligature* is also used to signify a kind of bandage or fillet, tied round the neck, arm, leg, or other part of the bodies of men or beasts, to divert or drive off some disease.

Ligatures, among printers, are types consisting of two letters or characters joined together; as *ff, fi, fl.* The old editions of Greek authors are extremely full of ligatures; the ligatures of Stephens are by much the most beautiful.

Light is that imponderable body which renders objects perceptible to our sense of seeing. It is one of the most interesting subjects that fall under the contemplation of the philosopher: at the same time it must be acknowledged to be one that is as little understood, and upon which opinions are as much divided, as any of the most abstruse subjects of philosophical enquiry. Some consider light as a fluid *per se;* while others consider it merely as a principle, and attribute it to a sort of pression or vibration propagated from the luminous body through a subtile ethereal medium. The ancients believed it to be propagated from the sun and other luminous bodies instantaneously; but the observations of the moderns have shown that this was an erroneous hypothesis, and that light, like any other projectile, occupies a certain time in passing from one part of space to another, though the velocity of its motion is truly astonishing, as has been manifested in various ways. And, first, from the eclipses of Jupiter's satellites; it was observed by Reaumur that the eclipses of those satellites happen sometimes sooner and sometimes later than the times given by the tables of them, and that the observation was before or after the computed times, according as the earth was nearer to or farther from Jupiter than the mean distance. Hence it was concluded that this circumstance depended on the distance of Jupiter from the earth; and that, to account for it, we must suppose that the light is fourteen minutes in crossing the earth's orbit. The original observations have received some corrections, and it is now found that, when the earth is exactly between Jupiter and the sun, his satellites are seen eclipsed about eight minutes and a quarter sooner than they could be according to the tables; but, when the earth is nearly in the opposite point of its orbit, these eclipses happen about eight minutes and a quarter later than the tables predict them. Hence, then, it is certain that the motion of light is not instantaneous, but that it takes up about 16½ minutes of time to pass over a space equal to the diameter of the earth's orbit, which is nearly 190,000,000 of miles in length, or at the rate of 200,000 miles per second—a conclusion which, it may be added, is placed beyond doubt, by the aberration of the stars discovered by Dr. Bradley.

Upon the subject of the materiality of light, Doctor Franklin observes, in expressing his dissent from the doctrine that light consists of particles of matter continually driven off from the sun's surface, with such enormous swiftness—"Must not the smallest portion conceivable have, with such a motion, a force exceeding that of a twenty-four pounder discharged from a cannon? Must not the sun diminish exceedingly by such a waste of matter, and the planets, instead of drawing nearer to him, as some have feared, recede to greater distances, through the lessened attraction? these particles, with this amazing motion, will not drive before them or remove the least and slightest dust they meet with, and the sun appears to continue of his ancient dimensions, and his attendants move in their ancient orbits." He therefore conjectures that all the phenomena of light may be more properly solved, by supposing all space filled with a subtile elastic fluid, not visible when at rest, but which, by its vibrations, affects that fine sense in the eye, as those of the air affect the grosser organs of the ear; and even that different degrees of vibration of this medium may cause the appearances of different colours. The celebrated Euler has maintained the same hypothesis, urging some further objections to the materiality of light, besides those of Doctor Franklin above alluded to. Newton first discovered that certain bodies exercise on light a peculiar attractive force. When a ray passes obliquely from air into any transparent liquid or solid surface, it undergoes, at its entrance, an angular flexure, which is called *refraction.* The variation of this departure from the rectilineal path for any particular substance depends on the obliquity of the ray to the refracting surface; so that the sine of the angle of refraction is to that of the angle of incidence in a constant ratio. Newton, having found that unctuous or inflammable bodies occasioned a greater deviation in the luminous rays than their attractive mass, or density, gave reason to expect, conjectured that both the diamond and water contained combustible matter—a conjecture which was verified by subsequent discovery.

Doctor Wollaston invented a very ingenious apparatus, in which, by means of a rectangular prism of flint-glass, the index of refraction of each substance is read off at once by a vernier, the three sides of a movable triangle performing the operations of reduction in a very compendious manner. But transparent media occasion not merely a certain flexure of the white sunbeam, called the *mean refraction:* they likewise decompose it into its constituent colours. This effect is called *dispersion.* Now, the mean refractive and dispersive powers of bodies are not proportional to each other. In some refracting media, the mean angle of refraction is smaller, whilst the angle of dispersion is larger. From the refractive power of bodies, we may, in many cases, infer their chemical constitution. For discovering the purity of essential oils, an examination with Doctor Wollaston's instrument is of great utility, on account of the smallness of the quantity requisite for trial. This idea of Doctor Wollaston has been happily prosecuted by M. Biot with regard to gaseous compounds; and we now have accurate tables of the refractive power of all transparent, gaseous, liquid, and solid bodies. Carburet of sulphur exceeds all fluid substances in refractive power, surpassing even flint-glass, topaz,

and tourmalin; and, in dispersive power, it exceeds every fluid substance except oil of cassia. Rays of light, in traversing the greater number of crystallized bodies, are commonly split into two pencils, one of which, called the *ordinary ray*, follows the common laws of refraction, agreeably to the tables alluded to, whilst the other, called the *extraordinary ray*, obeys very different laws. This phenomenon is produced in all transparent crystals whose primitive form is neither a cube nor a regular octahedron. The division of the beam is greater or less according to the nature of the crystal, and the direction in which it is cut; but, of all known substances, that which produces this phenomenon in the most striking manner is the crystallized carbonate of lime, called *Iceland spar*.

If the white sunbeam admitted through a small hole of a window-shutter into a darkened room be made to pass through a triangular prism of glass, it will be divided into a number of splendid colours, which may be thrown upon a sheet of paper. Newton ascertained that if this coloured image, or *spectrum*, as it is called, be divided into 360 parts, the red will occupy forty-five, the orange twenty-seven, the yellow forty-eight, the green sixty, the blue sixty, the indigo forty, and the violet eighty. The red rays, being least bent by the prism from the direction of the white beam, are said to be least refracted, or the least refrangible; while the violet rays, being always at the other extremity of the spectrum, are called the most refrangible. If these differently coloured rays of light be now concentrated on one spot, by a lens, they will reproduce colourless light.

Newton ascribes the different colours of bodies to their power of absorbing all the primitive colours, except the peculiar one which they reflect, and of which colour they therefore appear to our eye. The different coloured rays possess very different powers of illumination. The lightest green, or deepest yellow, which are near the centre, throw more light on a printed page than any of the rays towards either side of the spectrum. The rays of the prismatic spectrum differ from one another also in their heating power, as was first noticed by Herschel. In viewing the sun, by means of large telescopes, through differently coloured darkening glasses, he sometimes experienced a strong heat, attended with very little light, and, at other times, he had a strong light with a little heat. This observation led to his well-known researches upon this subject, from which he concluded that the maximum heat is just without the spectrum, beyond the red ray. Others have found the greatest heat in the red ray itself; but the observations of M. Seebeck have shown that the point of greatest heat was varible, according to the kind of prism which was employed for refracting the rays. When a prism of fine flint-glass is used, the greatest heat is constantly beyond the red; when a prism of crown-glass, the greatest heat is in the red itself.

It has long been known that the solar light is capable of producing powerful chemical changes. One of the most striking instances of it is its power of darkening the white chloride of silver—an effect which takes place slowly in the diffused light of day, but in the course of two or three minutes by exposure to the sunbeam. This effect was formerly attributed to the influence of the luminous rays; but it appears, from the observations of Ritter and Wollaston, that it is owing to the presence of certain rays that excite neither heat nor light, and which, from their peculiar agency, are termed *chemical* rays. It is found that the greatest chemical action is excited just beyond the violet ray of the prismatic spectrum, that the spot next in energy is occupied by the violet ray itself, and that the property gradually diminishes as we advance to the green, beyond which it seems wholly wanting. The sunbeams, in traversing a coloured glass, produce similar effects to those caused by the differently coloured portions of the spectrum. Thus the chloride of silver acquires a black tint behind a blue or violet glass, but does not blacken behind a red or orange glass; on the other hand, it becomes red behind a red glass, and that much more quickly than even in the solar spectrum.

Light produced by coal and oil gases, or by olefiant gas, even when concentrated so as to produce a sensible degree of heat, was found, by Mr. Brande, to occasion no change in the colour of muriate of silver, nor in mixtures of chlorine and hydrogen; while the light emitted by electrized charcoal speedily affected the muriate, and caused these gases to unite, and sometimes with explosion. The concentrated light of the moon, like that of the gases, produced no change. The importance of light to plants is well known: deprived of it, they become white, and contain an excess of saccharine and aqueous particles; and flowers owe the variety and intensity of their hues to the influence of the solar beams. Even animals require the presence of the rays of the sun, and their colours seem materially to depend upon the chemical influence of these rays. A comparison between the polar and tropical animals, and between the parts of their bodies exposed and those not exposed to light, shows the correctness of this opinion. (For an account of the physical affections, and chemical effects of light, see OPTICS.)

LIGHT, in the *fine arts*.—This term is employed by the artist in contradistinction to *shadow;* and the following rules and definitions are given by Mr. Hayter, for the governance of the painter:—

1. Reflecting surfaces tincture the objects reflected on with their colour proportionately with their distance from each other, and the angle under which light operates.

2. The general prevailing colour of light tinctures every object within its influence; for instance, observe the whole hemisphere at the time of a warm setting sun, or the gray effects of a cloudy sky, or a fog.

3. The power of light, particularly sunshine, increases the warmth, and weakens the local colours of all the cold class of colours, which are *blue, green,* and *purple:* for instance, *grass*, which in shade appears a cool refreshing *green*, will appear almost *yellow* in sunshine.

4. The *warmth* of parts or breadths which lie under a partial degree of shade, where the power of lights from surrounding matter prevails, is accounted for by the quantity of such secondary light, and their local colours.

5. When a white surface *reflects* on the *shadowy* part of any colour, it looks paler than the *lighted* parts of such colour; but the power of the shadow holds its influence with regard to light.

6. Glossy surfaces receive the form and colour of all objects locally, according to their purity, and reflect them accordingly, being in such degree mirrors.

7. Every colour that is reflected by its own colour is enriched thereby, according to the strength of light on the reflector.

8. Every colour that is reflected on by its directly opposite colour will be neutralized thereby; such as *green* against *red*, *blue* against *orange*, or *purple* against *yellow*, in an equivalent degree with the power of light.

9. If any two approximate colours reflect the one on the other, the tincture will approach the appearance of that compound which the two colours would make by mixing them.

10. The direct opposite to any of the primitive colours is an equal compound of the other two.

11. The middle colour or medium in a warm effect is *red*.

12. The middle colour or medium between light and darkness, in the gradations of a cold effect, is *green*.

13. Whatever be the colour of a flat surface when viewed directly perpendicular by the visual ray, faintly lighted, must be painted of that colour when unaffected by glittering or reflection, regarding duly the influence of distance and aërial medium.

14. The *certain colours* of all visible matter must give place to their *appearances*, owing to the compounding influence of *light, shade, reflection, various distance, clearness, density*, and prevailing hue or colour of the medium under which *any colour* is seen.

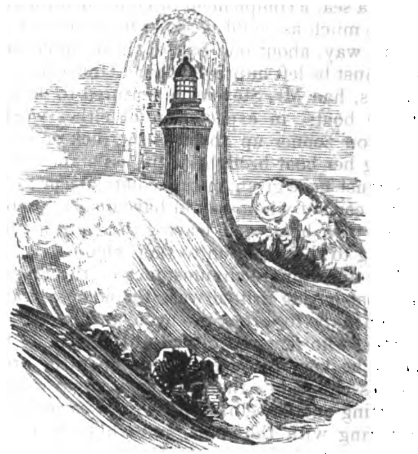
Light, Instantaneous.—There are several species of apparatus for the instantaneous production of light; but our space will permit a description of only one, which is the latest and appears the most meritorious. It forms the subject of a patent granted to Mr. Newton, of the office for patents, Chancery Lane.

The invention consists of two features: a peculiar construction of valve or stopper, which prevents the escape of acid from the bottle, and, though remaining fixed, at all times furnishing a sufficient supply to produce the ignition of the match. This valve or stopper is a leaden plug, screwed into the neck of a glass bottle, about two-thirds filled with sulphuric acid. The plug is cup-shaped on the upper surface, and convex below. One or more exceedingly small perforations are made through this plug for the passage of the acid from within, which is obtained by slightly shaking the bottle, when the drop or globule of the acid which adheres to the under side of the plug, after the bottle has been shaken, finds its way upwards through the small holes by capillary attraction, and which may be aided by the warmth of the hand expanding the air within, thereby assisting the liquid to exude into the cup above; the apertures, however, are too small to allow the damp to enter.

The other feature of novelty is in the matches, which are made of short pieces of wax taper, the size of common dressing pins, on the end of which there is a small globule of mastic, made of an inflammable material, which instantly ignites on being introduced into the cup of the bottle stopper, and burns with a steady light for a minute or more, according to the length of the match.

There are many arrangements for procuring light instantaneously through the united agencies of hydrogen gas and spongy platinum; but they speedily get out of order, and are but little fitted for general use.

LIGHT-HOUSES were in use with the ancients. The towers of Sestos and Abydos, the colossus of Rhodes, and the well-known tower on the island of Pharos, off Alexandria, are examples. Suetonius also mentions a lofty tower at Ostia, and another on the coast of Batavia, erected for the purpose of guiding the mariner by their light. In lighting a great extent of coast, it becomes necessary to provide for the distribution of the light-houses in such a manner that they may be readily distinguished from each other, and at the same time so disposed as not to leave vessels without some point by which to direct their course; and, in constructing each member of the series, care should be taken to provide for a sufficient brilliancy of light. One of the most extraordinary light-houses on our iron-bound coast stands on a reef of rocks, called the Eddystone, in the English Channel, about ten miles from the Ram Head in Cornwall. It was erected by Mr. Smeaton in 1759, and still remains a lasting monument of his scientific skill. It consists of four rooms, surmounted by a gallery and lantern. The floors are of stone, flat on the surface, but concave beneath, and are kept from pressing against the sides of the building by means of a chain which is let into the walls. The entire edifice is about eighty feet in height, and yet such is the immense power of the wind, in the neighbourhood of the rock, that the waves are seen to ascend like a cupola considerably above the lantern at top. The appearance of the light-house, when thus exposed to the violence of the stormy ocean, is well given in the accompanying engraving.



The *Bell Rock* light-house must now be noticed. It stands on the coast of Scotland, near Arbroath, in Forfarshire. To enable our readers to form some estimate of the difficulty attendant on the erection of this building, it may be enough to state that, during the lapse of twelve months, only forty-one hours offered in which the workmen could be employed on the rock. In the succeeding year (1814), fifty-three hours of labour occurred on the rock. In the third season, this was nearly doubled; but the operations of the fourth season were much retarded by several untoward accidents. In particular a heavy gale overtook the workmen while they were laying the seventh course of masonry, which obliged them to leave the rock before the necessary precautionary measures could be taken for closing and completing the work in hand, in consequence of which the stones on the eastern or weather side of this course were lifted off their bases, the oaken trenails broken, and five of the blocks of stone swept away. At another period, the Puzzolano mortar connecting the beds of two of the stones was washed out, and so much injured that the stones required to be lifted

and relaid. The works were this season intended to have been closed early in the month of October, when another unlucky gale sprung up, just as the sixteenth course had been laid, which raised seven more of the stones from their beds; but they were fortunately held by the oaken trenails, and in this state they remained for about three weeks, before a landing could possibly be effected to replace them.

There was one moment of appalling danger, during the progress of the work, which must not be passed unnoticed. On the 2nd of September, there were thirty-two persons upon the rock, and, while all the artificers were engaged in their several avocations, a gale arose, which carried the large vessel (the Smeaton) in which the workmen were usually conveyed ashore more than three miles to leeward of the rock. In this critical situation, placed upon an insulated rock, far out in the ocean, which in the progress of the flood-tide was to be laid under water to the depth of at least twelve feet in a stormy sea, the feelings of Mr. Stevenson, the engineer, may be better conceived than described. There were at this period only two boats attached to the rock, whose complement, even in good weather, did not exceed twenty-four sitters; but to row to the floating-light, with so much wind, and so heavy a sea, a complement of eight men for each boat was as much as could possibly be attempted, so that, in this way, about one-half of those employed on the rock must be left unprovided for. Under these circumstances, had Mr. Stevenson ventured to despatch one of the boats, in expectation of either working the Smeaton sooner up towards the rock or in hopes of getting her boat brought to the assistance of the rest, this must have given an immediate alarm to the artificers, each of whom would have insisted upon taking to his own boat, and leaving the eight artificers belonging to the Smeaton to their chance.

The unfortunate circumstance of the Smeaton and her boat having drifted was, for a considerable time, known only to Mr. Stevenson and to the landing-master, who removed to the further part of the rock, where he kept his eye steadily upon the progress of the vessel. While the artificers were at work, chiefly in sitting and kneeling postures, excavating the rock or boring with the tools, and while their numerous hammers and the sound of the smiths' anvil continued, the situation of things did not appear so awful. In this state of suspense, with almost certain destruction at hand, the water began to rise upon those who were at work on the lower parts of the sites of the beacon and light-house. From the ruff of sea upon the rock, the forge fire was sooner extinguished than usual, and, the volumes of smoke having ceased, objects in every direction became visible from all parts of the rock. After having had about three hours' work, the men began, pretty generally, to make towards their respective boats for their jackets and stockings, when, to their astonishment, instead of three they found only two boats, the third being adrift with the Smeaton. Not a word was uttered by any one, but all appeared to be silently calculating their numbers, and looking to each other with evident marks of perplexity depicted on their countenances. The landing-master, conceiving blame might be attached to him for allowing the boat to leave the rock, still kept at a distance. At this critical moment Mr. Stevenson was standing upon an elevated part of the rock, where he endeavoured to mark the progress of the Smeaton, not a little surprised that her crew did not cut the praam adrift, which greatly retarded her way. The workmen looked steadfastly at their leader, and turned occasionally towards the vessel, still far to leeward.

All this passed with the most perfect silence, and the melancholy solemnity of the group was such that, Mr. Stevenson states, it left an impression never to be effaced from his mind.

Mr. S. was, in the mean time, considering of various schemes which might be put in practice for the general safety of the party, in hopes that the Smeaton might be able to pick up the boats to leeward, when they were obliged to leave the rock. He was, accordingly, about to address the artificers on the perilous nature of their situation, and to propose that all hands should unstrip their upper clothing, when the higher parts of the rocks were laid under water,—that the seamen should remove every unnecessary weight and incumbrance from the boats, and a specified number of men should go into each boat,—and that the remainder should hang by the gunwales, while the boats were to be rowed gently towards the Smeaton, as the course of the Pharos or floating light lay rather to windward of the rock. But, when he attempted to speak, his mouth was so parched that his tongue refused utterance, and he says, "I now learned by experience that the saliva is as necessary as the tongue itself for speech." He then turned to one of the pools on the rock and drank a little salt water, which produced immediate relief; and his delight was in no small degree increased, when, on rising from this unpleasant beverage, some one called out "a boat! a boat!" and on looking round, at no great distance, a large boat was seen through the haze making towards the rock.

The stormy elements which surround this isolated station appear occasionally to excite the keenest fears in the minds of those who reside in the building; and although the compact erection of iron and masonry which they inhabit may for centuries bid defiance to the "northern blasts," or the "sulphureous bolts of heaven," yet it must require no small share of mental courage to resist the effect of such a combination of terrors.

Mr. Stevenson says, "I often take pleasure in looking at the seas breaking upon the light-house; and it is awfully grand at the time of high-water to observe the sprays rising to such a height on the building, and even to be on the rock at low-water, when the waves are about to break. Being in a manner only a few yards distant, they approach as if they were about to overwhelm us altogether. But, now that we are accustomed to such scenes, we think little of it. You will perhaps form a better idea of the force of the sea during these gales, when I relate to you that, on the 15th of February, the large piece of lead that was used as the back weight of the balance-crane, weighing 4 cwt. 3 qrs. 17 lbs., or nearly a quarter of a ton, was fairly lifted by the sea, and carried to the distance of six feet from the hole in which it had laid since the month of August. It was found turned round, with the ring-bolt downwards and it was with great difficulty that four of us could muster strength enough to return it to its former shelf in the rock.

"All the observations which I have made regarding the effects of the seas and weather on the light-house, while I have been here, lead me to conclude that when the wind is from the south, south-west, west,

north-west, and even north, the sea has little effect on the building; but, from south to north-easterly, the force of the waves is considerable, especially when it comes to blow hard. During the gale of the 22nd of February, I remarked that even the heaviest seas, if they broke before they came to the foot of the building, slipped past without giving the least shock to the house; and it is only a very few of the waves that reach the building in the course of a tide which cause the vibration alluded to; but we fear those seas only which come from the north-east, as they break close upon the house. I may say, in general, that the higher or stronger the wind, the less power the sea has on the light-house, the heaviest seas being accompanied with little wind, or occurring after the gale has abated.

"With regard to the comfort of this building as a dwelling, I had no other expectation but that, on account of the sea-air and newness of the walls, the house would have, in the first instance, been damp. It is however the very reverse of this; and I may confidently say that this is as dry round the inside walls, and on the floors, as any house in Edinburgh."

The domestic life of those who sojourn on the rock is worthy of notice. The following is a diary of their monotonous day, which commences by cleaning and trimming the lamps. This is usually succeeded by a walk on the waggon-ways, and an active search about the crevices of the rock for small fish, when the state of the tides and weather permit, but, when this is not the case, they find amusement in reading in a small library. On Sunday, those on the rock attend to the general rule of the service, doing no more work in the light-room than is necessary, cleaning only the reflectors, lamp-glasses, and windows, operations which are usually over in the summer season about twelve o'clock, after which they meet for prayers, and read two or three chapters in the Bible.

The best-constructed light-houses, in Great Britain, are fitted up with parabolic reflectors, consisting of a circular sheet of copper, plated with silver, in the proportion of six ounces to each pound of copper, and formed into a parabolic curve, by the assistance of a gauge, by a very nice process of hammering. The reflector, thus shaped, is then polished with the hand. An Argand lamp is placed in the focus of the paraboloidal surface, and the oil is supplied by the lamp behind. But the disadvantages of this mode are acknowledged; such as the loss of light, partly from its absorption by the reflector, and partly from the collision of the rays; the impossibility of increasing the intensity of the light in dark and hazy weather; the difficulty of forming distinguishing lights, &c. The important invention of the polyzonal lenses, in which refraction is employed instead of reflection, seems, therefore, likely to supersede the use of reflectors. Another important problem is the construction of distinguishing lights, so that the mariner may not be deceived in taking one light-house for another. Single and double stationary lights, or lights disposed in different forms, were first employed; revolving lights were next adopted, which appeared and disappeared at intervals; and these are sometimes exhibited double or triple. The lights may be so disposed as to illuminate only the safe channel. Difference of colour is sometimes made use of as a distinction. It sometimes becomes desirable, as in hazy weather, to produce a very intense light. A plan was proposed by Lieutenant Drummond to effect this object, by directing a stream of oxy-hydrogen gas upon a ball of lime, a quarter of an inch in diameter.

LIGHTNING. In our article ELECTRICITY the reader will find a series of experimental illustrations tending to prove the identity of lightning with electricity; and we now purpose furnishing a brief abstract of the labours of those men of science who succeeded the distinguished electrician by whom the public attention was first called to the subject. The earliest useful observations that were made on the electrical state of the atmosphere in Europe appear to have been those of Monnier; his experiments were performed with an apparatus which consisted of a pole, thirty-two feet in height, insulated in a piece of turf, having at its top a strong glass tube, to which a tube of tinned iron was attached, and which terminated in a point. About the middle of this tube there was fastened a fine iron wire, about fifty lines long, which, without touching any other body, was connected with a silk cord stretched horizontally. He found that, although the atmosphere was constantly electrified more or less, yet in dry weather the electricity increased from sunrise, when it was weakest, till about four o'clock in the afternoon, at which time it was strongest, gradually diminishing from that time till the dew began to fall, after which it diminished till midnight.

The Abbé Mazeas made several observations with an atmospherical apparatus consisting of an iron wire, 370 feet long, raised about ninety feet from the ground, and properly insulated. The results of his experiments with this instrument were the following:—In very dry weather the wire readily attracted light bodies, if brought within three or four lines of it; and, if the weather was not stormy, the electricity of the air was about half as great as that of a stick of sealing-wax two inches long. When he grasped the wire in his hand, the signs of electricity disappeared entirely, and did not return till after an interval of three or four minutes. He also found that the electricity of the atmosphere was not increased with storms and hurricanes unattended with rain; for during a violent storm of wind, which continued uninterruptedly for three days, in the month of July, he found it necessary to place the dust within four or five lines of the conductor, before it exhibited a sensible attraction. No change was produced by the different directions of the winds. In the driest nights of summer he never could observe any electricity in the air, but it began to appear in the morning at sunrise, and vanished in the evening at about half an hour after sunset. In the month of July, on a very dry day, when the sky was serene and the heat intense, he found the electricity stronger than he had ever observed it before: the dust was then attracted at the distance of ten or twelve lines from the conductor.

Having thus briefly noticed the effects of metallic rods for conveying the electricity of the atmosphere to the earth's surface, it may now be advisable to advert to another agent, which, although somewhat more complicated than the conducting wire, was yet found, in the hands of Dr. Franklin, a most efficient piece of apparatus. It consists in the elevation of a long conducting string by means of a windsail or kite.

An *electrical kite* should be constructed in the most simple manner, as it is an apparatus very liable to be injured or lost. In dimensions it should

not exceed four feet in height, by two feet wide. This will be found the most manageable size, and it is necessary to varnish it with drying oil to defend it from the rain. The string must be furnished with a thin copper or silver thread, interwoven through its whole length; that which is employed in the fabrication of gilt lace appears best adapted to the purpose. When the kite is raised, the string is insulated by attaching to it a silk cord, the opposite extremity of which may be fastened to a rail, or any other fixed place. The end of the metallic string may then be connected with a prime conductor, similar to that employed in the common electrical machine; and with this the experiments may be performed.

To ensure the safety of the operator, which is a very important consideration in this otherwise dangerous experiment, it will only be necessary to connect a brass rod with the earth, and bring the other end within about two inches of the prime conductor, so that, in the event of the kite coming in contact with a large electrical cloud, a ready passage may thus be found for the electric fluid to the earth. In raising or lowering the kite, shocks are frequently taken: this, however, may be effectually prevented by suffering a part of the string between the operator and the kite to bear constantly against the brass ball that is connected with the ground; and this precaution is more particularly essential when thunder-clouds are over-head.

Mr. Cavallo, from a variety of experiments made with electrical kites, furnishes the following results, which will be found correct in the generality of cases. "The air appears to be electrified at all times: its electricity is constantly positive, and much stronger in frosty than in warm weather; but it is by no means less in the night than in the daytime. When it rains, the electricity of the kite is generally negative, and very seldom positive. The aurora borealis seems not to affect the electricity of the kite. The electric spark taken from the string of the kite, or from any insulated conductor connected with it, especially when it does not rain, is very seldom longer than a quarter of an inch; but it is exceedingly pungent. When the index of the electrometer is not higher than 20°, the person who takes the spark will feel the effect of it in his legs, as it appears more like the discharge of an electric jar than the spark taken from the prime conductor of an electrical machine. The electricity of the kite is generally stronger or weaker, according as the string is longer or shorter; but it does not keep any exact proportion to it. The electricity, for instance, brought down by a string of 100 yards, may raise the index of the electrometer to twenty; when, with double that length, the index of the electrometer will not go higher than twenty-five."

The phenomena incident to a thunder-storm are always beheld with the most intense interest by the student in this science; and, although many very poetical descriptions of its effects are on record, the facts furnished by the Italian philosopher Beccaria are as illustrative as any.

"Thunder-storms," says Beccaria, "generally happen when there is little or no wind; and their first appearance is marked by one dense cloud, or more, increasing very fast in size, and rising into the higher regions of the air; the lower surface black, and nearly level, but the upper finely arched, and well defined. Many of these clouds seem frequently piled one upon another, all arched in the same manner; but they keep continually uniting, swelling, and extending their arches.

"At the time of the rising of this cloud, the atmosphere is generally full of a great number of separate clouds, motionless, and of odd and whimsical shapes. All these, upon the appearance of the thunder-cloud, begin to move towards it, and become more uniform in their shapes as they approach; till, coming very near the thunder-cloud, they mutually stretch towards one another, immediately coalesce, and together make one uniform mass. But sometimes the thunder-cloud will swell and increase very fast without the conjunction of these adventitious clouds, the vapours of the atmosphere forming themselves into clouds wherever it passes. Some of the adventitious clouds appear like white fringes at the skirts of the thunder-cloud, but these are continually growing darker and darker as they approach or unite with it.

"When the thunder-cloud is grown to a great size, its lower surface is often ragged, particular parts being detached towards the earth, but still connected with the rest. Sometimes the lower surface swells into various large protuberances, bending uniformly towards the earth. When the eye is under the thunder-cloud, after it is grown larger, and well formed, it is seen to sink lower, and to darken prodigiously, at the same time that a number of adventitious clouds (the origin of which can never be perceived) are seen in rapid motion, driving about in every direction under it. While these clouds are agitated with the most rapid motions, the rain generally falls in the greatest plenty; and, if the agitation is exceedingly great, it commonly hails."

While the thunder-cloud is swelling, and extending its branches over a large tract of country, the lightning is seen to dart from one part of it to another, and often to illuminate its whole mass. When the cloud has acquired a sufficient extent, the lightning strikes between the cloud and the earth, in two opposite places, the path of the lightning lying through the whole body of the cloud and its branches.

The electrical explosion generally takes place in the air, and at a considerable height; but in many instances it happens between the clouds and the earth. In most instances, perhaps, the lightning descends from the clouds to the earth, and the explosion is then called the descending stroke; but in some cases it is known to pass from the earth to the clouds, and is then termed the ascending stroke: of the latter kind appears to have been the explosion which took place on the Malvern Hills, in the summer of 1826, and which was attended with such melancholy consequences. A very curious instance of the ascending stroke is related by G. F. Richter, in his work on thunder. He informs us that in the cellar belonging to the Benedictine monks of Fontigno, while the servants were employed in pouring into a cask some wine which had been just boiled, a fine light flame appeared round the funnel, and they had scarcely finished their operation when a noise like thunder was heard; the cellar was instantly filled with fire; the cask was burst open, although hooped with iron; the staves were thrown with prodigious violence against the wall; and, on examination, a hole of three inches in diameter was found in the bottom of the cask.

LIMB; the outermost border or graduated edge of a quadrant, astrolabe, or such like mathematical instrument. The word is also used for the arch of the primitive circle, in any projection of the sphere *in plano*.

Limb also signifies the outermost border or edge of the sun and moon; as the upper limb or edge, the lower limb, &c.

LIME. This earth, well known in its most important properties from the remotest antiquity, exists in great abundance in nature. In treating of it in the present article, we shall confine ourselves to its chemical properties and its application to domestic purposes. Lime is obtained with most facility from the native carbonate, from which, by a strong heat, the carbonic acid may be expelled. This process is conducted on a large scale with the different varieties of limestone, which are calcined or burnt, in order to obtain the caustic earth, or *quicklime*, as it is called. The lime thus obtained, however, is rarely pure enough for chemical purposes. The chemist, therefore, when he would obtain a very perfect article, calcines transparent crystals of carbonate of lime, or prepares it from solution, in the following manner:—Marble or chalk is dissolved in diluted muriatic acid, leaving an excess of lime undissolved; ammonia is added, which precipitates any alumine or magnesia. The filtered solution is then decomposed by carbonate of potash, and the carbonate of lime, being washed with water and dried, is decomposed by a strong heat. The lime thus obtained is a soft white substance, of the specific gravity of 2.3. It requires an intense degree of heat for its fusion, which is effected only by the galvanic current, by the compound blowpipe, or by a stream of oxygen gas, directed through the flame of an alcohol lamp. The light it emits, during fusion, is the strongest the chemist can produce; and it has, accordingly, been employed for a signal light and for facilitating the observation of distant stations, in geodetical operations. Its taste is caustic, astringent, and alkaline. It is soluble in 450 parts of water, according to Sir H. Davy; and in 760 parts, according to other chemists. The solubility is not increased by heat. If a little water only is sprinkled on new-burnt lime, it is rapidly absorbed, with the evolution of much heat and vapour. This constitutes the phenomenon of slaking. The heat proceeds from the consolidation of the liquid water into the lime, forming a *hydrate*, as slaked lime is now called. It is a compound of 3.5 parts of lime with 1.25 of water, or very nearly 3 to 1. The water may be expelled by a red heat.

Lime-water is astringent and somewhat acrid to the taste. It renders vegetable blues green; the yellow, brown; and restores to reddened litmus its usual purple colour. When lime-water stands exposed to the air, it gradually attracts carbonic acid, and becomes an insoluble carbonate, while the water remains pure. If lime-water be placed in a capsule under an exhausted receiver, which also encloses a saucer of concentrated sulphuric acid, the water will be gradually withdrawn from the lime, which will concrete into small six-sided prisms. Lime, submitted to the action of galvanism, in high intensity, afforded Sir H. Davy satisfactory evidence of its compound nature. It was discovered, in common with the other earths, to consist of a metallic base (which he denominated *calcium*) and oxygen. The calcium was obtained, in these experiments, in the state of amalgamation with mercury. On exposing the amalgam to the air or to water, oxygen was absorbed, and lime reproduced. In an experiment designed to obtain the base in an insulated state, by distilling the quicksilver from it, the tube broke while warm, and, at the moment that the air entered, the metal, which had the colour and lustre of silver, took fire, and burnt with an intense white light. It used to be supposed that lime combined with sulphur and with phosphorus; but it rather appears that it is its base only that unites with these inflammables. The sulphuret of calcium is formed by heating sulphur with lime in a covered crucible. It is of a reddish-yellow colour. When thrown into water, mutual decomposition takes place, and a sulphuretted hydro-sulphuret, of a yellow colour, with a fetid odour, is produced. Phosphuret of calcium, or phosphuret of lime, as it has usually been called, is obtained in the following manner:—A few pieces of phosphorus are placed at the bottom of a glass tube, which is then filled with small pieces of lime. The part of the tube where the lime is is heated red-hot; and the phosphorus is then sublimed by heat. Its vapour, passing over the lime, decomposes it, and a reddish-coloured phosphuret of calcium is formed. This substance is remarkable for decomposing water, whenever it is dropped into it, and causing an immediate production of phosphuretted hydrogen, which takes fire at the surface of the water.

When lime is heated strongly in contact with chlorine, oxygen is expelled, and the chlorine is absorbed. For every two parts in volume of chlorine that disappear, one of the oxygen is obtained. When liquid muriate of lime is evaporated to dryness, and ignited, it forms the same substance, which is the chloride of calcium. It is a semi-transparent crystalline substance; fusible at a strong red heat; a non-conductor of electricity; has a very bitter taste; rapidly absorbs water from the atmosphere, and is hence often employed, in chemical experiments, to deprive gases of any hygrometric vapour existing in them. Chlorine also combines directly with lime, forming the very important substance used in bleaching, formerly known under the name of *oxymuriate of lime*, but at present, and more correctly, called *chloride of lime*. It is formed by passing chlorine gas over slaked lime.

A great variety of apparatus has been, at different times, contrived for favouring the combination of chlorine with slaked lime, for the purposes of commerce. In the opinion of Doctor Ure, who has given particular attention to this manufacture, the following construction for subjecting lime-powder to chlorine is the best:—It consists of a large chamber, eight or nine feet high, built of silicious sandstone, having the joints of the masonry secured with a cement composed of pitch, resin, and dry gypsum, in equal parts. A door is fitted into it at one end, which can be made air-tight by strips of cloth and clay-lute. A window in each side enables the operator to judge how the impregnation goes on, by the colour of the air, and also gives light for making the arrangements within at the commencement of the process. As water-lutes are incomparably superior to all others, where the pneumatic pressure is small, a large valve, or door, on this principle, is recommended to be made in the roof, and two tunnels, of considerable width, at the bottom of each side wall. The apartment would thus be ventilated, without the necessity of the workmen approaching the deleterious gas. A great number of wooden

shelves, or rather trays, eight or ten feet long, two feet broad, and one inch deep, are provided to receive the sifted slaked lime, containing generally about two atoms of lime to three of water. These shelves are piled one over another in the chamber, to the height of five or six feet, cross-bars below each keeping them about an inch asunder, that the gas may have free room to circulate over the surface of the powder. The alembics for generating the chlorine, which are usually nearly spherical, are in some cases made entirely of lead; in others, of two hemispheres, joined together in the middle, the upper hemisphere being lead, the under one cast-iron. The first kind of alembic is enclosed, for two-thirds from its bottom, in a leaden or iron case, the interval of two inches between the two being destined to receive steam from an adjoining boiler. Those which consist below of cast-iron have their bottom directly exposed to a very gentle fire. Round the outer edge of the iron hemisphere a groove is cast, into which the under edge of the leaden hemisphere fits, the joint being rendered air-tight by Roman or patent cement—a mixture of lime, clay, and oxide of iron, separately calcined and reduced to a fine powder. It must be kept in close vessels, and mixed with the requisite water when used. In this leaden dome there are four apertures, each secured by a water-lute. The first opening is about ten or twelve inches square, and is shut with a leaden valve, with incurvated edges, that fit in the water-channel, at the margin of the hole. It is destined for the admission of a workman to rectify any derangement in the apparatus of rotation, or to detach hard concretions of salt from the bottom. The second aperture is in the centre of the top. Here a tube of lead is fixed, which descends nearly to the bottom, and down through which the vertical axis passes, to whose lower end the cross-bars of iron or of wood, sheathed with lead, are attached, by whose revolution the materials receive the proper agitation for mixing the dense manganese with the sulphuric acid and salt. The motion is communicated either by the hand of a workman, applied from time to time to a winch at top, or it is given by connecting the axis with wheel-work, impelled by a stream of water or a steam-engine. The third opening admits the siphon-formed funnel, through which the sulphuric acid is introduced; and the fourth is the orifice of th eduction pipe.

The proportion of the materials for generating the chlorine is as follows: 10 cwt. of salt are mixed with from 10 to 14 cwt. of manganese; to which mixture, after its introduction into the alembic, from 12 to 14 cwt. of sulphuric acid are added in successive portions: that quantity of acid must, however, be previously diluted with water, till its specific gravity becomes about 1.65. The eduction pipes from all the alembics terminate in a leaden chest, or cylinder, with which they are connected by water-lutes, having a hydrostatic pressure of two or three inches. In this general *diversorium*, the chlorine is washed from adhering muriatic acid, by passing through a little water; and, from this reservoir, the gas is conducted off by one general pipe, and delivered into the top of the chamber containing the lime, where, in consequence of its gravity, it diffuses itself equally over powder spread out upon the shelves. Four days are required for making good marketable bleaching-powder.

The manufacturer generally expects from a ton of rock salt, employed as above, a ton and a half of good bleaching powder. In using the chloride of lime for bleaching, the coloured cloth is first steeped in warm water to clean it, and it is then repeatedly washed with a solution of caustic potash, so diluted that it cannot injure the texture of the cloth, and which solution is thrown upon it by a pump. The cloth is then washed and steeped in a very weak solution of the bleaching-powder; again washed, acted on by a boiling ley, as before, and again steeped in the solution; and these operations are performed alternately several times. The cloth is, lastly, immersed in very dilute sulphuric acid, which gives it a pure white colour, after which it is washed and dried. The chlorine is known to decompose water, whose hydrogen forms with it muriatic acid, which is always found in the solution (after the process) when liquid chlorine is used, and a muriate, when a chloride is employed. In a similar manner it is believed to decompose the colouring matter, one of whose elements is always hydrogen; and, its composition being thus subverted, it disappears from the fabric with which it existed.

Still more important is the use of the chloride of lime in counteracting contagion, and all noxious effluvia. MM. Orfila, Lescure, Gerdy, and Hennelle, having to examine the body of an individual who was supposed to have been poisoned, and who had been dead for nearly a month, found the smell so insupportable that they were induced to try the application of the chloride of lime, as recommended by M. Labarraque. A solution of this substance was frequently sprinkled over the body, and produced the effect of destroying, after a few aspersions, every unpleasant odour. It was afterwards used in a still more desperate case, in clearing some offensive drains in Paris, with perfect success. It was also found to be the best and most durable means of disinfecting hospitals, &c. In such cases, the powder is so exposed to the infected region as to offer the greatest amount of surface, in order that the carbonic acid of the contagious atmosphere may expel the chlorine from the chloride of lime, which it does by combining with it to form carbonate of lime. A very convenient method of applying it to ordinary apartments, which we are desirous to free from unwholesome effluvia, is to diffuse about four ounces of the powder through five gallons of water, and sprinkle it over the floor by means of a water-pot. Lime combines with the acids, neutralizing the acid properties. Its salts are, in general, decomposed by potash or soda, which precipitate the lime, but not by ammonia. Oxalic acid throws down lime from all the other acids; and, this compound being quite insoluble, oxalic acid forms the most delicate test of the presence of lime.

Carbonate of lime may be formed by adding carbonic acid to lime-water, or by decomposing any of the soluble salts of lime by any of the alkaline carbonates. It is very sparingly soluble in water. Hence lime-water is an excellent test of the presence of carbonic acid. By an excess of carbonic acid, carbonate of lime is rendered soluble. When exposed to heat, it first loses what water it contains, and, if transparent and hard, becomes white, opaque, and friable. If the heat is augmented, the carbonic acid gas is expelled, and quicklime remains. The experiments of Sir J. Hall have proved that if carbonate of lime be heated under strong pressure, so as to prevent the

escape of the carbonic acid, it may be melted at a temperature even not higher than 22° of Wedgwood's scale. By this fusion, it acquires considerable hardness and closeness of texture, approaching, in these qualities, as well as in fracture and specific gravity, to the finer kinds of marble. The acids expel the carbonic acid with effervescence; and this property of effervescing strongly, on the contact of an acid, affords a discriminating character of this salt. Carbonate of lime abounds in nature.

Nitrate of lime may be formed by dissolving lime, or its carbonate, in dilute nitric acid. The solution, on evaporation, affords deliquescent prismatic crystals, soluble in less than an equal weight of water, at the temperature of 60°, and in still less of boiling water. On being heated, it becomes phosphorescent, and retains this property when cold, forming *Baldwin's solar phosphorus*. It forms naturally in the plaster of old buildings, and in the limestone caverns of the Western States of America. *Sulphate* of lime is formed by adding lime to dilute sulphuric acid. It requires about 500 times its weight of water, at 60°, for its solution. At the temperature of 212°, it is more soluble, and this latter solution, on cooling, deposits minute crystals. Exposed to heat, it appears to effervesce, or boil, owing to the expulsion of its water; and, at the same time, becomes opaque, and falls into a white powder, which, on being diffused in water, speedily consolidates, forming a species of irregular crystallization. Sulphate of lime is one of the most abundant minerals in nature. *Phosphate* of lime may be formed by decomposing the solution of an alkaline phosphate by muriate of lime. It is a white insoluble powder, which is imperfectly vitrified by a very intense heat. It exists in the mineral kingdom, under different forms, and constitutes eighty-six per cent. of the bones of animals. *Muriate* of lime is obtained by dissolving carbonate of lime in muriatic acid. It is extremely soluble in water, the water taking up so much of it as to become of a thick consistence.

Lime, in *agriculture*. Quicklime, in its pure state, whether in powder or dissolved in water, is injurious to plants. Grass is killed by watering it with lime-water. But lime, in its state of combination with carbonic acid, is a useful ingredient in soils. When lime, whether freshly burnt or slaked, is mixed with any moist, fibrous, vegetable matter, there is a strong action between the lime and the vegetable matter, and they form a kind of compost together, of which a part is usually soluble in water. By this means matter which was before comparatively inert becomes nutritive; and, as charcoal and oxygen abound in all vegetable matters, the lime becomes converted into a carbonate. Mild lime, powdered limestone, marls, or chalks, have no action of this kind upon vegetable matter; by their action they prevent the too rapid decomposition of substances already dissolved; but they have no tendency to form soluble matter. From these circumstances, it is obvious that the operation of quicklime and marl or chalk depends upon principles altogether different. Quicklime, in the act of becoming mild, prepares soluble out of insoluble matter. It is upon this circumstance that the operation of lime, in the preparation of wheat crops, depends, and its efficacy in fertilizing peats, and in bringing into a state of cultivation all soils abounding in hard roots, or dry fibres, or inert vegetable matter. The solution of the question whether quicklime ought to be applied to a soil depends upon the quantity of inert vegetable matter it contains. The solution of the question whether marl, mild lime, or powdered limestone, ought to be applied, depends upon the quantity of calcareous matter already in the soil. All soils are improved by mild lime, and, ultimately, by quicklime, which do not effervesce with acids; and sands are more benefited by it than clays. When a soil, deficient in calcareous matter, contains much soluble vegetable manure, the application of quicklime should always be avoided, as it either tends to decompose the soluble matters by uniting with their carbon and oxygen, so as to become mild lime, or it combines with the soluble matters, and forms compounds having less attraction for water than the pure vegetable substance. The case is the same with respect to most animal manures; but the operation of the lime is different in different cases, and depends upon the nature of the animal matter. Lime forms a kind of insoluble soap with oily matters, and then gradually decomposes them by separating from them oxygen and carbon. It combines, likewise, with the animal acids, and probably assists their decomposition by abstracting carbonaceous matter from them, combined with oxygen, and consequently it must render them less nutritive. It tends to diminish, likewise, the nutritive powers of albumen, from the same causes, and always destroys, to a certain extent, the efficacy of animal manures, either by combining with certain of their elements or by giving to them new arrangements. Lime should never be applied with animal manures, unless they are too rich, or for the purpose of preventing noxious effluvia. It is injurious when mixed with any common dung, tending to render the extractive matter insoluble. In those cases in which fermentation is useful to produce nutriment from vegetable substances, lime is always efficacious, as with tanners' bark. Lime is much used by tanners, skinners, &c., in the preparation of their leather; by soap-boilers, for dissolving the oil, and facilitating its union with the alkaline salt; and by sugar-bakers, for refining their sugar. It is also of some medicinal use, being applied externally in desiccative and epulotic medicines.

Limit, in a restrained sense, is used by mathematicians for a determinate quantity, to which a variable one continually approaches; in which sense the circle may be said to be the *limit* of its circumscribed and inscribed polygons.

In *algebra*, the term *limit* is applied to two quantities, one of which is greater, and the other less, than another quantity; and in this sense it is used in speaking of the limits of equations, whereby their solution is much facilitated.

Limning, from *enluminer* (French); to adorn books with paintings. As these paintings or illuminations were always executed in water-colours, *limning* properly designates that species of art which is now known by the name of *miniature painting*, though it is sometimes used to signify the art of painting generally, and particularly portrait painting.

Line, in *mathematics*, is extension in length, without breadth or thickness; it is either straight or curved. In *navigation*, the equator is called the *line*; hence the expression "to pass the line." In decimal measures of length, it is the tenth; in duodecimal measures of length it is the twelfth part of an inch.

In *military affairs*, a series of soldiers or ships, drawn up in order of battle, are called a *line*; hence the phrase "ships of the line."

LINEN; a cloth of very extensive use, made of flax, and differing from cloths made of hemp only in fineness. In common linen, the warp and woof cross each other at right angles; if figures are woven in, it is called *damask*. The species of goods which come under the denomination of linen are table-cloths, plain and damasked, cambric, lawn, shirting, sheeting, towels, Silesias, Osnaburgs, &c. The chief countries in which linens are manufactured are Great Britain, Russia, Flanders, and Holland. Immense quantities of linen are annually exported from Ireland to England, and several other parts of Europe, as well as to North and South America, the West Indies, and Africa. The flax seed is, for the greater part, procured from America; but other nations, engaged in this lucrative branch of trade, either raise their seed at home or procure it from the north of Europe. In several parts of Germany, Switzerland, Flanders, and France, linens are frequently embellished with painting; and the produce of the Irish linen manufacture is occasionally printed in the manner of calicoes. The beauty of linen consists in the evenness of the thread, its fineness and density. The last of these qualities is sometimes produced by subjecting it to rollers; hence linen with a round thread is preferred to that with a flat thread. The warp or woof is not unfrequently made of cotton yarn, which renders the cloth less durable.

Linen threads cannot be spun by the machinery used in spinning cotton and wool, on account of the length and rigidity of the fibres of the flax. The subject of spinning flax by machinery has attracted much attention, and Napoleon once offered a reward of 1,000,000 francs to the inventor of the best machine for this purpose. (See SPINNING and WEAVING.)

In a historical view, linen is interesting, as forming the dress of the Egyptian priests, who wore it at all their religious ceremonies; hence they are styled by Ovid and Juvenal "linen-wearers." From Egypt linen passed to the Romans, but not till the time of the emperors. The Roman priests also began to wear linen garments at that time. Linen was used as a material for writing, though the expression *libri lintei, carbasini*, was also applied to cotton and silk as well as linen. The Sibylline books, and the mummy bandages, covered with hieroglyphics, are proofs of this use of linen. In the middle ages, linen and woollen cloth formed the only materials for dress, and fine linen was held in very high estimation. Germany and Brabant then carried linen manufactures to the greatest perfection. Linen is necessary for the manufacture of good paper. Cotton has, of late years, taken the place of linen for many purposes, on account of its greater cheapness.

LINT, in *surgery*, is the scrapings of fine linen, used by surgeons in dressing wounds. It is made in various forms, which have different names, according to the difference of the figures. Lint, made up in an oval or orbicular form, is called a *pledgit*; if in a cylindrical form, or in the shape of a date or olive stone, it is called a *dossil*. These different forms of lint are required for many purposes; as, 1. to stop blood in fresh wounds, by filling them up before the application of a bandage; though, if scraped lint be not at hand, a piece of fine linen may be torn into small rags, and applied in the same manner: in very dangerous hemorrhages, the lint or rags should be first dipped in some styptic liquor, as alcohol or oil of turpentine, or sprinkled with some styptic powder: 2. to agglutinate or heal wounds; to which end lint is very serviceable, if spread with some digestive ointment, balsam, or vulnerary liquor: 3. in drying up wounds and ulcers, and forwarding the formation of a cicatrix: 4. in keeping the lips of wounds at a proper distance, that they may not hastily unite before the bottom is well digested and healed: 5. they are highly necessary to preserve wounds from the injuries of the air.

Surgeons of former ages used compresses of sponge, wool, feathers, or cotton, linen being less plentiful than in later times; but lint is far preferable to all these, and is, at present, universally used. Lint is now manufactured by a machine.

LIQUEUR (from the *French*); a palatable spirituous drink, composed of water, alcohol, sugar, and some aromatic infusion, extracted from fruits, seeds, &c. The great difference in the qualities of the different *liqueurs* is owing principally to a variation in the proportions of the sugar and alcohol. The French distinguish three qualities: the first are the *ratafias*, or simple *liqueurs*, in which the sugar, the alcohol, and the aromatic substance are in small quantities: such are the anise-water, *noyau*, the apricot, cherry, &c. The second are the oils, or the fine *liqueurs*, with more saccharine and spirituous matter; as the *anisetta, curaço*, &c. The third are the *creams*, or superfine *liqueurs*, such as *rosoglio, maraschino*, Dantzic water, &c. The same aromatic infusion may, therefore, give its name to *liqueurs* of different qualities, in which the materials are the same, but the proportions different: thus one proportion of ingredients gives *eau-de-noyau*; another *crême-de-noyau*, &c.

LIQUORICE. The common liquorice grows wild in the south of Europe, and is cultivated in many places, even in this country, for the sake of the root, which is much used in pharmacy, and forms a considerable article of commerce. More than 200 tons of the extract are manufactured annually in Spain, a considerable portion of which is sent to London. It is often administered medicinally, in coughs and pulmonary affections, and the aqueous infusion is a refreshing beverage. A deep, light, and sandy soil is best adapted to its culture.

LISTEL; a small square moulding, serving to crown or accompany a larger, and to separate the flutings in columns.

L'ISTESSO TEMPO, in *music*; a phrase implying that the movement before which it is placed is to be played in the same time as the previous movement.

LITHIA; the name applied by Arfwedson to an alkali discovered by him in analyzing the petalite. Lithia has since been detected in spodumene, and several kinds of mica. The best process for procuring it is the following:—One part of petalite or spodumene, in fine powder, is mixed intimately with two parts of fluor-spar, and the mixture is heated with three or four times its weight of sulphuric acid, as long as any acid vapours are disengaged. The silica of the mineral is attacked by hydrofluoric acid, and dissipated in the form of fluosilicic acid gas, while the alumina and lithia unite with sulphuric acid. After dissolving these salts in water, the solution is boiled with pure ammonia to precipitate the alumina; is filtered, evaporated to dryness, and then heated to

redness to expel the sulphate of ammonia. The residue is pure sulphate of lithia, which is dissolved in water and decomposed by acetate of barytes; and the acetate of lithia, being heated to redness, is converted into the carbonate of lithia, and, finally, this is decomposed by lime or barytes, which affords pure lithia. Its colour is white; it is not deliquescent, but absorbs carbonic acid from the air; it is very soluble in water, is acrid, caustic, and acts on colours like the other alkalies: heated with platina, it acts on the metal. It combines with the different acids, and forms salts with them, like potash and soda, though possessed of a higher neutralizing power than these alkalies. Its phosphate and carbonate are sparingly soluble; its chloride is deliquescent and soluble in alcohol, and this solution burns with a red flame. All its salts give a red colour, when heated on a platinum wire before the blow-pipe. The muriate and nitrate are deliquescent. The metallic base of lithia was evolved by Sir H. Davy, by galvanism; the metal was found to be white like sodium, and burned with bright scintillations.

Lithic Acid, in combination with potash, is obtained from human urinary calculi, by digesting them in caustic lixivium: the lithate of potash gives up the lithic acid, on being mingled with acetic acid. It has the form of white shining plates, which are denser than water; is without taste or smell, and dissolves in 1400 parts of boiling water. It reddens the infusion of litmus. The lithates are all tasteless, and very sparingly soluble in water. Lithic acid, by repeated distillations, is resolved into ammonia, nitrogen, and prussic acid.

Lithochromics; the art of painting in oil upon stone, and of taking impressions on canvass. This process, which is designed to multiply the masterpieces of painting, was invented some years ago by Malapeau, in Paris, who received a patent for his invention, and has an establishment for lithochromic productions, which have been popular in Paris since 1823. This process is a substitute for the copying of portraits; it also serves as a cheap means of ornamenting walls. This art, however, is still in its infancy, as the lithochromic paintings hitherto produced are less valuable than the poorest copies. A similar but much superior invention has been made by Sennefelder, which he calls *mosaic impression*.

Lithography; the art of taking impressions from drawings or writings on stone, without engraving. Two substances are used for drawing upon stone—lithographic chalk and lithographic ink. The former is made of 1½ oz. of soap, 2 oz. of tallow, 1½ oz. of pure white wax, 1 oz. of shell-lac, ½ oz. of lamp-black. Another receipt gives 2 oz. of soap, 5 oz. of wax, ½ oz. of tallow, and 1 oz. of lamp-black. The soap, after it has been scraped fine, is put in an iron or earthen vessel, over the fire, and, when it is melted, little pieces of wax and tallow are added; it must be stirred the whole time, and, when the heat is extreme, the contents of the vessel are to be lighted by a burning taper, the stirring being continued. After a short time, the flame is to be extinguished; and, while the mixture is boiling, the lamp-black is to be gradually added. When this is done, the mixture is taken from the fire, and poured out on an iron or stone plate, and may be made into any form desired. For lithographic ink, a great many different receipts have been given, one of the most approved of which is a composition made of equal parts of tallow, wax, shell-lac, and common soap, with about one-twentieth part of the whole of lamp-black. These materials are mixed in an iron vessel; the wax and tallow are first put in, and heated till they take fire, after which the other ingredients are successively added; the burning is allowed to continue until the composition is reduced about one-third.

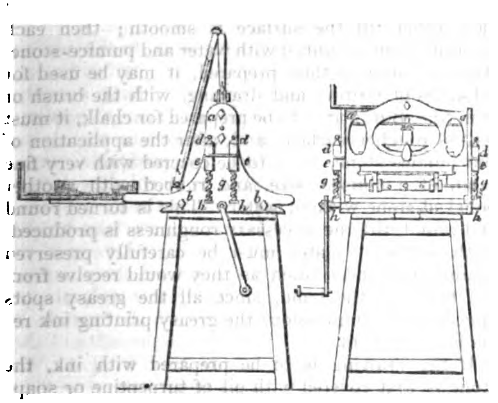
All calcareous stones, being susceptible of taking in a greasy substance, and of imbibing water with facility, are suitable for lithographic printing, provided they are compact, capable of receiving a fine polish, and of a clear and uniform colour; the more compact and uniform in colour the better. Those commonly used are a nearly pure carbonate of lime. Suitable stones are by no means scarce. The quarry from which the first lithographic stones were extracted is still that which furnishes them in the greatest abundance, and of the largest dimensions. It is situated at Solenhofen, near Pappenheim, in Bavaria. No quarries hitherto known in France afford stones equal to the German. Those found near Chateauroux are of a similar colour to those of Solenhofen, and even harder, and of a finer grain; but they are full of spots of a softer nature, so that it is difficult to procure pieces of the necessary size. In England, a stone has been used which is found at Corston, near Bath. It is one of the white lias beds, but is inferior to the German in fineness of grain and closeness of texture.

When proper stones cannot be obtained without difficulty or great expense, it is more advantageous to fabricate artificial slabs, to which a proper density and hardness may be given. An intelligent potter can easily imitate the density of natural stones. Slabs, used for this purpose, have been made of stucco, composed of lime and sand, and fastened with the caseous part of milk. Artificial slabs, however, have not been made so as to equal the real ones; and the royal institute of France have thought the subject of sufficient importance to offer a large prize for the best. The stones are polished by putting fine sand between two of them, and thus rubbing them against each other till the surface is smooth; then each separate stone is rubbed with water and pumice-stone. After the stone is thus prepared, it may be used for all kinds of writing and drawing, with the brush or pen, &c. But, if it is to be prepared for chalk, it must have a rougher surface, and, after the application of the pumice-stone, it is to be covered with very fine sand, of a uniform size, and rubbed with another polished stone without water. This is turned round and round, till the necessary roughness is produced. Both kinds of plates must be carefully preserved against greasiness, such as they would receive from the touch of the hand, since all the greasy spots appear in the impression, the greasy printing ink remaining on them.

If the drawing is to be prepared with ink, the stone is first covered with oil of turpentine or soap-water, to prevent the lines from spreading. Then the drawing may be made on the stone with a black-lead pencil or with a red crayon; but the latter is preferable, because, when the ink comes to be applied, it is easier to discover how far the lines of the drawing are really covered with ink. After having dissolved the ink in rain or river water (the former ought to have stood some time), these pencil outlines are covered with ink. If the stroke is black, or, at least, dark brown, it may be inferred that the in-

pression will succeed; but, if light brown and transparent, it will not give the impression. The ink may be laid on with the pen or brush. Goose quills, however, are not well suited for this purpose, particularly if the strokes are to be very fine; the pens are too quickly blunted; but steel pens are used with great advantage: these are made of watch springs. After the drawing, the plate is left several hours, and then put under the press. For drawing with chalk, it is necessary to apply the finest and softest tints first, and the strongest afterwards. If the proper effect cannot be given to the foreground by chalk only, a little ink is added with the brush or pen. If the drawing has very fine tints, it is necessary that the impression from the plate should be taken immediately, otherwise the oil will dry or evaporate, and the ink will not take effect on these parts. The oil varnish used must be of the best kind. Before the stone is covered with ink, it must first be dipped in nitric or sulphuric acid, diluted with water to such a degree that only a slight effervescence is produced; the proportion of acid should be but little more than one per cent.; this will make the stone in the parts not covered by the drawing more readily imbibe the water. This process is called *etching* the drawing. After this, it is merely dipped in common water. Great care must be taken that the acid is not too strong, as it will then injure the fine strokes and tints. When the stone has imbibed sufficient water, a liquid mixture must be poured over it, consisting of one-sixth linseed oil, two-sixths oil of turpentine, and three-sixths of pure water: this again must be wiped off clean, and the stone must then be covered with a solution of gum-Arabic in water; this prevents the lines from spreading. Immediately after this process it is inked. The printing-ink is applied by means of printers' balls, stuffed with hair, or by cylinders, which must be of various sizes.

The printing-press for lithographic purposes is very simple in the arrangement of its parts, which may be readily understood by reference to a diagram.



It consists of a solid table of wood, supporting two iron uprights, *b*, *b*. Between the uprights is placed a roller, *h*, and above that a blunt scraper to give the requisite pressure. The stone from which the impression is to be taken is placed on a moving platform, which passes between the roller and scraper, and, the paper being confined on the surface of the drawing, the handle is turned so that the paper is drawn under the line of pressure. The requisite amount of force is communicated by the lever *a*, and the whole regulated by the screws *d*, *e*, *g*.

The first impressions are seldom perfect. After each impression, the stone is washed with water, and, from time to time, is sponged over with gum-water, which is prepared from one ounce of finely pounded gum-Arabic and half a pound of water. The ink which has settled on a spot that should be light is either removed with a clean sponge, or by diluted acid, applied with a sponge, and the place is afterwards washed with pure water. The printing-ink is composed, like other printing-inks, of oil-varnish and fine lamp-black. To prepare the varnish, a vessel is about half filled with pure linseed oil, and heated till it takes fire from the flame of a piece of burning paper. It is allowed to burn till reduced to the proper density. Besides the mode of preparing the drawings above described, drawings are also cut into the stone, and from these impressions are taken. Engravings may also be multiplied by putting them wet on a stone, when they come from the copper-plate press, and subjecting them to pressure, by which the ink is made to leave the paper and adhere to the stone. Although lithography is of great use, and excellent impressions are produced, particularly at Munich, it is yet very imperfect. In landscapes, the soft tints and the perspective cannot be properly given; the lines are not sufficiently delicate. The number of impressions which can be taken from a lithographic chalk drawing will vary according to the fineness of the tints. A fine drawing will give 400 or 500; a strong one, 1000 or 1500. Ink drawings and writings give considerably more than copper-plates. The finest will yield 6000 or 8000, and strong lines and writings many more. Upwards of 80,000 impressions have been taken at Munich from one writing of a form for regimental returns. But the art is susceptible of further improvements.

LITHOTOMY. See STONE.

LITHOTRITIE. The stone, a disease common throughout Europe, and the most painful of all maladies, hitherto relieved only by a formidable operation, of which death was too often the result, is, by the novel process of which we are about to give an outline—a process of perfect safety and great simplicity—rendered susceptible of cure in its most advanced stages; and surgery is furnished with means of preventing its growth at an earlier period. The value of the treatment, for which we are indebted to the French, calls upon every one to assist in making known to the utmost of his power the revolution which is in progress for the relief of the greatest of human sufferings.

The Baron Heurtèloup, a French surgeon of great ingenuity and attainments, to whom the world is indebted for the perfection to which this department of his art has now arrived, has demonstrated publicly the nature and practice of this most extraordinary process, which has been named by the French faculty *lithotritie*. It consists in breaking the calculous concretions, which form within the bladder, into powder, or particles so minute that they are readily discharged by the natural passage through which the mechanism necessary for the destruction of the foreign body is introduced, without subjecting the patient to the terrors or dangers of incision. During the last seven years this process has occupied the attention of several ingenious French surgeons, amongst whose researches those of Baron Heurtèloup are the most prominent, having procured him " the grand

prize of surgery" for the year 1827 from the institute, for the perfection of the instruments he then suggested. Before his inventions, the destruction of these concretions was accomplished by repeated perforations, the result of which was their division into fragments, which fragments underwent in succession a subdivision by the same perforating instruments: but the baron saw the necessity of devising some means more rapid, and consequently less fatiguing to the organ in which they were employed; and he succeeded in obtaining them.

His instruments are introduced in a tube of small diameter, and, developing themselves in the bladder, are so adapted that the foreign body places itself within the branches which open opposite its neck, and, subsequently included within them, is retained firmly. The mechanism of this part of the apparatus, which consists of four branches, movable at will, together or separately, is peculiarly ingenious, and of very extensive application in various circumstances which may modify its use. Suffice it to say that the stone, firmly embraced by these four branches, placed in the centre of the bladder, which has been previously filled with tepid water, is submitted to the action of what the baron calls the *evideur*, by the progressive, though rapid, eccentric motion of which its interior is completely excavated; and the exterior falls into the bladder in fragments resembling portions of shell, having a convex or concave surface. For the reduction to powder of these portions, Baron Heurtèloup uses an instrument which he appropriately calls *brisecoque*, or shell-breaker. It consists of two branches, enclosed in a tube of small diameter also, which, by a very simple mechanism, extend and seize these fragments; and with extraordinary power (yet perfect protection against injury to the bladder) grind them into fine powder, which, being voided, as well as the detritus resulting from the action of the *evideur*, is passed off with the warm water previously introduced, and so terminates the operation.

We should not omit to mention an important invention auxiliary to the baron's operation—a species of bed, or great chair, on which the patient reposes, furnished with a mode of fixing the instrument (after the stone is seized), enabling the operator to dispense with the clumsy and embarrassing apparatus held by an assistant, previously in use.

Liver; a large gland which occupies a considerable portion of the cavity of the belly, and which secretes the bile. It is a single organ, of an irregular shape, brownish-red colour, and, in general, is smaller in proportion as the individual is more healthy. It occupies the right *hypochondrium*, or space included by the false ribs, and a part of the epigastric region, and lies immediately under the diaphragm (midriff), above the stomach, the transverse colon, and right kidney, in front of the vertebral column, the *aorta*, and the inferior *vena cava*, and behind the cartilaginous edge of the chest. The right false ribs are on its right, and the spleen is on its left. The superior surface is convex, and the inferior is irregularly convex and concave, which has given rise to the division into the *right* or *large* lobe, the *small* or *inferior* lobe, and the *left* lobe. The right extremity of the liver is lower than the left, and is the most bulky part of the organ. The pressure of the surrounding organs, and certain folds of *peritoneum*, called its *ligaments*, which connect it with the diaphragm, retain the liver in its place, leaving it at the same time a considerable power of changing its relative position. The organization of the liver is very complicated. Besides its peculiar tissue, or *parenchyma*, the texture of which is unknown, it receives a larger number of vessels than any other gland. A peculiar venous system—that of the *vena portarum*—is distributed in it. To this must be added the ramifications of the hepatic artery and veins, the nerves, which are small, the lymphatic vessels, the excretory tubes, and a peculiar tissue, enclosed by a double membrane, a serous or peritoneal, and a cellular one. The excretory apparatus of the bile is composed of the hepatic duct, which, rising immediately from the liver, unites with the cystic duct, which terminates in the gall-bladder. The choledochic duct is formed by the union of the two preceding, and terminates in the *duodenum*. (See Bile.)

Livre; an ancient French coin. The word is derived from the Latin *libra*, a pound. It appears as early as 810 B.C. At first the livre was divided into twenty *solidos*; afterwards into ten *sous*; in Italy into twenty *soldi*; in Spain into twenty *sueldos*, as the old German pound into twenty *schillinge*, and the English into twenty shillings. The livre was, at first, of high value. The revolution changed the name into *franc*.

Loan, Public, is the name given to money borrowed by the state. There may occur cases which require expenses for which the ordinary revenue of the state is not sufficient. If, in such cases, it is not possible to increase the usual revenue by augmenting the taxes, without great inconvenience to the nation, the state will find it advisable to borrow, and to pay interest till it can discharge the principal. If such loans are appropriated to objects by which the means of production are augmented, the state strengthened, and industry increased, they answer the same purpose as those which an industrious tradesman makes in order to enlarge and improve his business. If he be successful, he will increase his property, and the loan itself will afford the means for repaying it. This will be the case also with the state, when it employs the borrowed capital to open to the nation increased means of profitable industry, by facilitating its intercourse with other countries, giving security to its commerce, and increasing its means of production. But if the loans are expended in useless or unfortunate wars, or in other unprofitable ways, they diminish the means of labour or enjoyment, and burden the nation with taxes to pay the interest and discharge the capital. The capitalists who aid in producing, when they lend their capital to men of business, and receive their interest from the proceeds of their capitals, become unproductive subjects as soon as they lend it to the state which expends it uselessly,—for now they live on the products of the capitals of others, when before they lived on the products of their own. As loans, however, may become necessary to the state, the only question is, What is the most advantageous method of making them? A chief distinction among loans is this—that the government promises either the repayment of the capital at a particular time, until which it pays interest, or reserves the liberty to retain the capital, according to its own pleasure, only paying interest regularly. The first kind is liable to occasion trouble to the state, because the payment may often

fall at an inconvenient time. The payment of large sums, too, at a particular period, has this disadvantage, that the nation, when the payment is to be made, becomes destitute of ready money. Therefore large loans are usually contracted in such a way that the payment is made, successively, at many periods, or remains entirely indefinite. The last kind of loans requires that the credit of the state should be undoubted, and also that large capitals should have been accumulated in the hands of many rich people, who find their greatest advantage in disposing of them in loans.

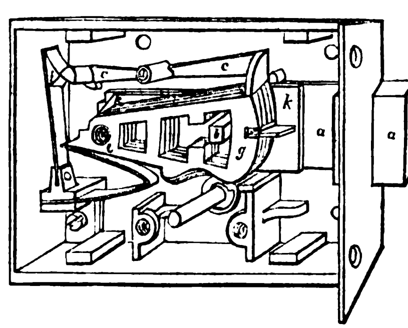
Where there is a well-founded system of credit, statesmen think it most advantageous to secure only the regular payment of the stipulated interest, but to leave the payment of the capital at the pleasure of the state. This is called the *funding system*, as far as fixed funds are assigned for the perpetual payment of the interest. These *perpetual annuities*, as they are called, had their origin in this country, but have since been imitated in Holland, France, Russia, Austria, and many other states. In order to provide for the redeeming of the capital, a sinking-fund is established, together with the fund appropriated to the payment of the annuities. This is procured by means of a tax large enough to pay the annuity as long as it lasts, and to redeem, annually, a part of the capital debt. This sinking-fund is increased every year, if the annuities annually redeemed are added to it. (See SINKING-FUND.) According to this method, the state cannot be said, properly, to borrow capital; it sells annuities, and fixes, at the sale, the rate at which they may be redeemed. They are commonly estimated at so much per cent. The government says—I offer you an annuity of three, four, five, &c., per cent., redeemable at my pleasure, How much will you give me for it? According to the market rate of interest, and the degree of credit which the state enjoys, the capitalists offer 50, 60, 70, 80, 90, &c., per cent.

The sinking-fund aims to discharge the debt gradually, by redeeming, annually, part of the annuities at the market price. If the latter exceed the price for which it had sold its annuities, it will be obliged to redeem them with loss; but, if it be less, it can redeem them with gain. Another kind of loan is when the capitalists pay 100 per cent. at a fixed rate of interest, the government reserving the right to pay the capital at any convenient time. Suppose that the state, when it wishes to borrow, is obliged to pay eight per cent., and that these stocks in the course of three years should rise in the market 100 per cent. above par; the state would easily find capitalists who would lend at the rate of four per cent. annually, and with this it could redeem the eight per cent. stocks. If, therefore, the state has reason to expect that the price of the stocks will rise, its best plan is to receive a fixed capital sum at such a rate of interest as it is obliged to give. But, if it fears that the interest or the prices of the stocks will fall, it is for its advantage to procure the necessary money by the sale of stocks at the market price, because it may hope to redeem them at a reduced rate. Sometimes premiums, or the chances of a lottery, are employed to stimulate reluctant capitalists, and sometimes even force. If a government must have recourse to other means than those arising from the annuity or interest offered, it is a certain sign that it enjoys but a feeble credit, or that there is a want of capital. How fertile modern history is in loans of every kind, and into what an unhappy situation many states have fallen by reason of them, are well known. In Austria, the proprietors of the stocks have been forced several times to advance further sums, to avoid losing what they had already lent. (See NATIONAL DEBT.)

LOCK; a well known instrument, used for fastening doors, chests, &c., generally opened by a key. The lock is reckoned the master-piece in smithery, a great deal of art and delicacy being required in contriving and varying the wards, springs, bolts, &c., and adjusting them to the places where they are to be used, and to the several occasions of using them. The principle on which all locks depend is the application of a lever to an interior bolt, by means of a communication from without, so that, by means of the latter, the lever acts upon the bolt, and moves it in such a manner as to secure the lid or door from being opened by any pull or push from without.

The security of locks, in general, therefore depends on the number of impediments we can interpose betwixt the lever (the key) and the bolt which secures the door: and these impediments are well known by the name of *wards*, the number and intricacy of which are supposed to distinguish a good lock from a bad one. If these wards, however, do not, in an effectual manner, preclude the access of all other instruments besides the proper key, it is still possible for a mechanic, of equal skill with the lock-maker, to open it without the key, and thus to elude the labour of the other. Various complicated and difficult locks have been constructed by Messrs. Bramah, Taylor, Spears, and others. In a very ingenious lock, invented by Mr. Perkins, twenty-four small blocks of metal, of different sizes, are introduced, corresponding to the letters of the alphabet. Out of these, an indefinite number of combinations may be made. The person locking the door selects and places the blocks necessary to spell a particular word, known only to himself, and no other person, even if in possession of the key, can open the door, without a knowledge of the same word.

The *detector lock*, invented by Mr. Chubb, has many advantages over those already adverted to. It is represented in the accompanying engraving.



The principal bolt is shown at *a a*, in which is placed a square pin fitting in the grooves above. The "detector," shown at *c c*, is made to move on the centre *d*, and its motions are regulated by the spring at *f*. The tumblers *g* are lifted by the key to such a position as will enable the square pin *b* of the bolt to pass in unlocking. Should one or more of the n-

blers be lifted by a "pick," or false key, in the least degree beyond their present position, the detector *c c*, being thus over-shot, will, by the angle of the spring *f* pressing on the opposite side of the angle of the detector, force its hook into a notch in the bolt, and be firmly held so until disengaged by the regulating slide *k*.

One peculiar feature in this lock arises from the great durability of its parts, which are peculiarly formed to resist any attempt at external violence; and so little is it acted on by friction that a lock of this description was actually opened and shut 460,000 times without the least apparent wear of its parts. Mr. Chubb has another arrangement of bolts for massive chests, which may be opened and shut with a handle, and yet securely fastened by a small lock on this principle.

Lock, Detonating. The employment of fulminating powder for firing the common fowling-piece has many advantages over the common flint and steel. The success of this arrangement has given it a place in his Majesty's service for firing cannon. In the latter case, the detonating powder is contained in a small paper tube, and is certain in its operation.

Locks, in *canal navigation*. When a canal changes from one level to another of different elevation, the place where the change of level takes place is commanded by a lock. Locks are tight oblong enclosures, in the bed of the canal, furnished with gates at each end, which separate the higher from the lower parts of the canal. When a boat passes up the canal, the lower gates are opened, and the boat glides into the lock, after which the lower gates are shut. A sluice, communicating with the upper part of the canal, is then opened, and the lock rapidly fills with water, elevating the boat on its surface. When the lock is filled to the highest water level, the upper gates are opened, and the boat, being now on the level of the upper part of the canal, passes on its way. A process the reverse of this is performed when the boat is descending the canal. Locks are made of stone or brick, sometimes of wood. The gates are commonly double, resembling folding doors. They meet each other, in most instances, at an obtuse angle, and the pressure of the water serves to keep them firmly in contact. Cast-iron gates are sometimes used in this country, curved in the form of a horizontal arch, with their convex side opposed to the water. In China, inclined planes are said to be used instead of locks, along which the boats are drawn up or let down.

Locomotion. The chief obstacles which oppose locomotion, or change of place, are gravity and friction, the latter of which is, in most cases, a consequence of the former. Gravity confines all terrestrial bodies against the surface of the earth, with a force proportionate to the quantity of matter which composes them. Most kinds of mechanism, both natural and artificial, which assist locomotion, are arrangements for obviating the effects of gravity and friction. Animals that walk obviate friction by substituting points of their bodies instead of large surfaces, and upon these points they turn, as upon centres, for the length of each step, raising themselves wholly or partly from the ground in successive arcs, instead of drawing themselves along the surface. As the feet move in separate lines, the body has also a lateral vibratory motion. A man in walking puts down one foot before the other is raised, but not in running. Quadrupeds, in walking, have three feet upon the ground for most of the time; in trotting, only two. Animals which walk against gravity, as the common fly, the tree-toad, &c., support themselves by suction, using cavities on the under side of their feet, which they enlarge at pleasure, till the pressure of the atmosphere causes them to adhere. In other respects their locomotion is effected like that of other walking animals. Birds perform the motion of flying by striking the air with the broad surface of their wings in a downward and backward direction, thus propelling the body upward and forward. After each stroke the wings are contracted, or slightly turned, to lessen their resistance to the atmosphere, then raised, and spread anew. The downward stroke also being more sudden than the upward is more resisted by the atmosphere. The tail of birds serves as a rudder to direct the course upward or downward. When a bird sails in the air without moving the wings, it is done in some cases by the velocity previously acquired, and an oblique direction of the wings upward; in others, by a gradual descent, with the wings slightly turned in an oblique direction downward. Fishes, in swimming forward, are propelled chiefly by strokes of the tail, the extremity of which, being bent into an oblique position, propels the body forward and laterally at the same time. The lateral motion is corrected by the next stroke, in the opposite direction, while the forward course continues. The fins serve partly to assist in swimming, but chiefly to balance the body, or keep it upright; for, the centre of gravity being nearest the back, a fish turns over when it is dead or disabled. Some other aquatic animals, as leeches, swim with a sinuous or undulating motion of the body, in which several parts at once are made to act obliquely against the water. Serpents, in like manner, advance by means of the winding or serpentine direction which they give to their bodies, and by which a succession of oblique forces are brought to act against the ground. Sir Everard Home is of opinion that serpents use their ribs in the manner of legs, and propel the body forwards by bringing the plates on the under surface of the body to act, successively, like feet against the ground. This he deduces from the anatomy of the animal, and from the movements which he perceived in suffering a large coluber to crawl over his hand. Some worms and larvæ of slow motion extend a part of their body forwards, and draw up the rest to overtake it, some performing this motion in a direct line, others in curves.

When land animals swim in water, they are supported, because their whole weight, with the lungs expanded with air, is less than that of an equal bulk of water. The head, however, or a part of it, must be kept above water, to enable the animal to breathe; and to effect this, and also to make progress in the water, the limbs are exerted, in successive impulses, against the fluid. Quadrupeds and birds swim with less effort than man, because the weight of the head, which is carried above water, is, in them, a smaller proportional part of the whole than it is in man. All animals are provided by nature with organs of locomotion best adapted to their structure and situation; and it is probable that no animal, man not excepted, can exert his strength more advantageously by any other than the natural mode, in moving himself over the common surface of the ground. Thus walking cars, velocipedes, &c., although they may enable a man to increase his velocity, in favourable situations, for a short time, yet

they actually require an increased expenditure of power, for the purpose of transporting the machine made use of, in addition to the weight of the body. When, however, a great additional load is to be transported with the body, a man or animal may derive much assistance from mechanical arrangements.

For moving weights over the common ground, with its ordinary asperities and inequalities of substance and structure, no piece of inert mechanism is so favourably adapted as the wheel-carriage. It was introduced into use in very early ages. Wheels diminish friction, and also surmount obstacles or inequalities of the road, with more advantage than bodies of any other form in their place could do. The friction is diminished by transferring it from the surface of the ground to the centre of the wheel, or, rather, to the place of contact between the axletree and the box of the wheel; so that it is lessened by the mechanical advantage of the lever, in the proportion which the diameter of the axletree bears to the diameter of the wheel. The rubbing surfaces, also, being kept polished, and coated with some unctuous substance, are in the best possible condition to resist friction. In like manner the highest ridges that present themselves in the public roads are surmounted by a wheel with peculiar facility. As soon as the wheel strikes against a stone, or similar hard body, it is converted into a lever for lifting the load over the resisting object. If an obstacle eight or ten inches in height were presented to the body of a carriage unprovided with wheels, it would stop its progress, or subject it to such violence as would endanger its safety. But, by the action of a wheel, the load is lifted, and its centre of gravity passes over in the direction of an easy arc, the obstacle furnishing the fulcrum on which the lever acts. Rollers placed under a heavy body diminish the friction in a greater degree than wheels, provided they are true spheres or cylinders, without any axis on which they are constrained to move; but a cylindrical roller occasions friction whenever its path deviates in the least from a straight line. The mechanical advantages of a wheel are proportionate to its size, and the larger it is the more effectually does it diminish the ordinary resistances. A large wheel will surmount stones and similar obstacles better than a small one, since the arm of the lever on which the force acts is longer, and the curve described by the centre of the load is the arc of a larger circle, and of course the ascent is more gradual and easy. In passing over holes, ruts, or excavations, also, a large wheel sinks less than a small one, and consequently occasions less jolting and expenditure of power. The wear also of large wheels is less than that of small ones; for, if we suppose a wheel to be three feet in diameter, it will turn round twice while one of six feet in diameter turns round once; so that its tire will come twice as often in contact with the ground, and its spokes will twice as often have to support the weight of the load. In practice, however, it is found necessary to confine the size of wheels within certain limits, partly because the materials used would make wheels of great size heavy and cumbersome, since the separate parts would necessarily be of large proportions to have the requisite strength, and partly because they would be disproportioned to the size of the animals employed in draught, and compel them to pull obliquely downwards, and therefore to expend a part of their force in acting against the ground.

Locomotive Engine is that which is calculated to produce locomotion, or motion from place to place. (See Steam-Engine.)

Log; a machine used to measure the rate of a ship's velocity through the water. For this purpose, there are several inventions, but the one most generally used is the following, called the *common log*. It is a piece of thin board, forming a quadrant of a circle of about six inches radius, and balanced by a small plate of lead, nailed on the circular part, so as to swim perpendicularly in the water, with the greater part immersed. The log-line is fastened to the log by means of two legs, one of which is knotted, through a hole at one corner, while the other is attached to a pin, fixed in a hole at the other corner, so as to draw out occasionally. The log-line, being divided into certain spaces, which are in proportion to an equal number of geographical miles as a half or quarter minute is to an hour of time, is wound about a reel. The whole is employed to measure the ship's head-way in the following manner:—The reel being held by one man, and the half-minute glass by another, the mate of the watch fixes the pin, and throws the log over the stern, which, swimming perpendicularly, feels an immediate resistance, and is considered as fixed, the line being slackened over the stern, to prevent the pin coming out. The knots are measured from a mark on the line, at the distance of twelve or fifteen fathoms from the log. The glass is therefore turned at the instant that the mark passes over the stern; and, as soon as the sand in the glass has run out, the line is stopped. The water, then being on the log, dislodges the pin, so that the board, now presenting only its edge to the water, is easily drawn aboard. The number of knots and fathoms which had run off at the expiration of the glass determines the ship's velocity. The half-minute glass, and divisions on the line, should be frequently measured, to determine any variation in either of them, and to make allowances accordingly. If the glass run thirty seconds, the distance between the knots should be fifty feet. When it runs more or less, it should therefore be corrected by the following analogy:—As thirty is to fifty so is the number of seconds of the glass to the distance between the knots upon the line. As the heat or moisture of the weather has often a considerable effect on the glass, so as to make it run slower or faster, it should be frequently tried by the vibration of a pendulum. As many accidents attend a ship during a day's sailing, such as the variableness of winds, the different quantity of sail carried, &c., it will be necessary to heave the log at every alteration, and, even if no alteration be perceptible, yet it ought to be occasionally heaved. The inventor of this simple but valuable device is not known, and no mention of it occurs till the year 1607, in an East India voyage, published by Purchas.

Log-Board; two boards shutting together like a book, and divided into several columns, containing the hours of the day and night, the direction of the winds, and the course of the ship, with all the material occurrences that happen during the twenty-four hours, or from noon to noon, together with the latitude by observation. From this table, the officers work the ship's way, and compile their journals. The whole, being written with chalk, is rubbed out every day at noon.

LOG-BOOK; a book into which the contents of the log-board are daily transcribed at noon, together with every circumstance deserving of notice that may happen to the ship, or within her cognizance, either at sea, or in a harbour, &c. The intermediate divisions or watches of a log-book, containing four hours each, are usually signed by the commanding officer thereof, in ships of war or East Indiamen.

LOGARITHM. "The logarithms of numbers are the exponents of the different powers to which a constant number must be raised in order to be equal to those numbers; the principles, therefore, which apply to exponents in general apply to logarithms." To constitute a logarithm, it is necessary that the exponent should refer to a system or series. These exponents, therefore, constitute a series of numbers in arithmetical proportion, corresponding to as many others in geometrical proportion. Take, for instance, the series $10^1 = 10$; $10^2 = 100$; $10^3 = 1000$; $10^4 = 10{,}000$: then we have the logarithm of $10 = 1$; logarithm $100 = 2$; logarithm $1000 = 3$; logarithm $10{,}000 = 4$, &c.

Perhaps the definition of a logarithm may be more scientifically expressed thus: *logarithm* is a mathematical term for a number by which the magnitude of a certain numerical ratio is expressed in reference to a fundamental ratio. The value of a ratio becomes known to us by the comparison of two numbers, and is expressed by a number called the *quotient* of the ratio; for instance, 12:4 is expressed by 3, or 18:9 by 2; 3 and 2 being called the *quotients* of the two proportions 12:4 and 18:9. If we now imagine a series of proportions which have all the same value or quotient, as, for instance, 1 to 3, 3 to 9, 9 to 27, 27 to 81, &c. (in which 9 and 3, 27 and 9, 81 and 27, are in the same ratio as 3 and 1), and if we at the same time adopt the ratio 3 to 1 as the fundamental ratio (or the unit of these ratios), then 9 to 1 is the double of this ratio, 27 to 1 the triple, 81 to 1 the quadruple, and so on. The numbers 1, 2, 3, 4, which indicate the value of such ratios in respect to the fundamental ratio, are called *logarithms*. If, therefore, in this case, 1 is the logarithm of 3, 2 must be the logarithm of 9, 3 of 27, 4 of 81, &c. If we adopt, however, the ratio of 4:1 as the fundamental one, and hence 1 as the logarithm of 4, then 2 would be the logarithm of 16, 3 of 64, &c. The logarithms of the numbers which lie between must be fractions, and are to be calculated and put in a table.

A table of logarithms, made according to an assumed basis or fundamental ratio, of all numbers to a certain limit, is called a *logarithmic system*. The most common, at present, is that of Briggs, in which the fundamental basis is 10 to 1; hence 1 is the logarithm of 10, 2 of 100, 3 of 1000, 4 of 10,000, &c. It is evident that all logarithms of numbers between 1 and 10 must be more than 0, yet less than 1, i. e. a fraction; thus the logarithm of 6 is 0.7781513. In the same way, the logarithms of the numbers between 10 and 100 must be more than 1, but less than 2, &c.; thus the logarithm of 95 is $= 1.9777236$. All logarithms of the numbers between 0, 10, 100, 1000, &c., are arranged in tables, the use of which, particularly in calculations with large numbers, is very great. The process is simple and easy. If there are numbers to be multiplied, we have only to add the logarithms; if the numbers are to be divided, the logarithms are merely to be subtracted; if numbers are to be raised to powers, their logarithms are multiplied; if roots are to be extracted, the logarithms are merely to be divided by the exponent of the root. In a table of logarithms, the integer figure is called the *index* or *characteristic*. The decimals are called, by the Germans and Italians, the *mantissa*. In general, the logarithms of the system in which 1 indicates 10 are called *common logarithms*.

The properties of logarithms, and some of their uses, were taken notice of by Stiefel or Stifelius, a German clergyman, who wrote as early as 1530; but the use of them in trigonometry was discovered by John Napier, a Scotch baron, and made known by him in a work published at Edinburgh, in 1614. Logarithmic tables are of great value, not only to mathematicians, but to all who have to make calculations with large numbers. Logarithms are of incalculable importance in trigonometry and in astronomy. Vega's edition of Vlacq's tables contains a trigonometrical table of the common logarithms of the radius or *log. sin. tot.* $= 10.0000000$, which gives the logarithms of sines, arcs, co-sines, tangents, and co-tangents for each second of the two first and two last degrees, and for each ten seconds of the rest of the quadrant. Under Napier's direction, B. Ursinius first gave the logarithm of the sines of the angles from 10 to 10″, the logarithm of the tangents, which are the differences of the logarithms of each sine and co-sine, together with the natural sine for a radius of 100,000,000 parts. Kepler turned his attention particularly to the invention of Napier, and gave a new theory and new tables. Briggs was also conspicuous in the construction of tables. Mercator showed a new way for calculating the logarithms easily and accurately. Newton, Leibnitz, Halley, Euler, L'Huillier, and others, perfected the system much, by applying to it the binomial theorem and differential calculus. The names of Vlacq, Sherwin, Gardiner, Hutton, Taylor, Callet, and others, deserve to be honourably mentioned. The edition of Vlacq, within a few years, by Vega, is particularly valuable. During the French revolution, when all measures were founded on the decimal division, new tables of the trigonometrical lines and their logarithms became necessary. The director of the *bureau du catastre*, M. Prony, was ordered, by government, to have tables calculated, which were to be not only extremely accurate, but to exceed all other tables in magnitude. This colossal work, for which the first mathematicians supplied the formulas and the methods for using the differences in the calculations, was executed, but the depreciation of the paper money prevented its publication. The tables would have occupied 1200 folio pages.

LOGGE DI RAFFAELLO. This wonderful logge has formed a school and *studio* to every artist who has visited Rome since its completion. There is scarcely a scroll ornament of any value in the works of the modern artists that may not be traced to those designed by Raphael, and executed by his pupils in this place. Leo X. had these *logge* or arcades built under the direction of Raphael. There are three stories, which enclose a court called *il Cortile di S. Damaso*. The middle story is the most celebrated. It is formed by thirteen arches, and the vault of each contains four paintings in fresco, representing scenes from the Old Testament, and executed by Giulio Romano, Pierin dal vaga, Pellegrino da Modena, Polidoro, and Maturino da Caravaggio, and others, after cartoons prepared by the great Raphael himself,

The number of these exquisite pictures is fifty-two; the arches and pilasters are adorned with grotesque paintings, executed by Giovanni da Udine, so famous in this branch, also under the direction of Raphael.

LOGWOOD. This important article of commerce is the wood of the *hæmatoxylon Campechianum*, a small straggling tree, belonging to the family *leguminosæ*, which grows wild in moist places, along the western shores of the gulf of Mexico. The wood is red, tinged with orange and black, so heavy as to sink in water, and susceptible of receiving a good polish; but it is chiefly employed in dyeing. The black and purple colours are very much used, but they are not so permanent as some obtained from other substances. Though cultivated to some extent in Jamaica, the logwood of commerce is chiefly obtained from Honduras, where the cutting of it forms an extensive, but unhealthy, branch of business.

LOMBARD HOUSES. See PAWNBROKERS.

LONGEVITY. The extreme limit of human life, and the means of attaining it, have been a subject of general interest, both in ancient and modern times, and the physiologist and political economist are alike attracted by the enquiry. It is for the student of biblical antiquities to decide in what sense we are to understand the word *year* in the scriptural accounts of the antediluvians; whether it signifies a revolution of the sun or of the moon, and, if the former, whether their extreme longevity is to be traced to supernatural causes. According to the sense which we now give to the word *year*, the constitution of men at the period referred to must have been very different from what it is at present, or has been at any period from which observations on the duration of human life have been transmitted to us. The results of all these observations, in regard to the length of life in given circumstances, do not essentially differ. Pliny affords some valuable statistical information, if accurate, regarding the period at which he lived, obtained from an official, and, apparently, authentic source,—the census directed by the emperor Vespasian, in the year 76 of the Christian era. From this we learn that, at the time of the computation, there were, in the part of Italy comprised between the Appennines and the Po, 124 individuals aged 100 years and upwards, viz. 54 of 100 years, 57 of 110, 2 of 125, 4 of 130, 4 of 135 to 137, and 3 of 140. At Parma, a man was living aged 120, and 2 aged 130; at Faenza, a female aged 132; and at a small town near Placentia, called Velleiacium, lived 6 persons aged 110 years each, and 4 of 120. These estimates, however, do not accord with those of Ulpian, who seems to have taken especial care to become acquainted with the facts of the case. His researches prove that the expectation of life in Rome, at that time, was much less than it now is in London, or in any of our cities. Hufeland, indeed, in his *Macrobiotics*, asserts that the tables of Ulpian agree perfectly with those afforded by the great cities of Europe, and that they exhibit the probabilities of life in ancient Rome to have been the same as those of modern London. But Doctor Hawkins, in his Elements of Medical Statistics (London, 1829), says that the tables kept by the censors for 1000 years, and constituting registers of population, sex, age, disease, &c., according to Ulpian (who was a lawyer, and a minister of Alexander Severus), refer only to free citizens, and that, to draw a just comparison between Rome and London, it would be necessary to take, among the inhabitants of the latter city, only those who were similarly circumstanced, viz. those whose condition is easy; in which case, the balance would be greatly in favour of modern times. Mr. Finlayson has ascertained, from very extensive observation on the decrement of life prevailing among the nominees of the Tontines, and other life annuities, granted by the authority of parliament, during the last forty years, that the expectation of life is above fifty years for persons thus situated, which affords the easy classes of England a superiority of twenty years above even the easy classes among the Romans.

The mean term of life among the easy classes of Paris is, at present, forty-two years, which gives them an advantage of twelve years above the Romans. In the third century of the Christian era, the expectation of life in Rome was as follows:—From birth to twenty, there was a probability of thirty years; from twenty to twenty-five, of twenty-eight years; from twenty-five to thirty, twenty-five years; from thirty to thirty-five, twenty-two years; from thirty-five to forty, twenty years; from forty to forty-five, eighteen years; from forty-five to fifty, thirteen years; from fifty to fifty-five, nine years; from fifty-five to sixty, seven years; from sixty to sixty-five, five years. Further than this the computation did not extend. The census taken from time to time in this country affords us information of an unquestionable character. The first actual enumeration of the inhabitants was made in 1801, and gave an annual mortality of one in 44.8. The third census was made in 1821, and showed a mortality of one to fifty-eight. The mortality then had decreased considerably within twenty years; which may also be said with regard to the last census in 1831. In France, the annual deaths were, in 1791, one in twenty-nine; in 1802, one in thirty; in 1823, one in forty. In the Pays de Vaud, the mortality is one to forty-nine; in Sweden and Holland, one to forty-eight; in Russia, one to forty-one; in Austria, one to thirty-eight. Wherever records have been kept, we find that mortality has decreased with civilization. Perhaps a few more persons reach extreme old age among nations in a state of little cultivation; but it is certain that more children die, and the chance of life, in general, is much less. In Geneva, records of mortality have been kept since 1590, which show that a child born there has, at present, five times greater expectation of life than one born three centuries ago. A like improvement has taken place in the salubrity of large towns. The annual mortality of London, in 1700, was one in twenty-five; in 1751, one in twenty-one; in 1801, and the four years preceding, one in thirty-five; in 1811, one in thirty-eight; and in 1821, one in forty; the value of life having thus doubled, in London, within eighty years. In Paris, about the middle of the last century, the mortality was one in twenty-five; at present, it is about one in thirty-two; and it has been calculated that, in the fourteenth century, it was one in sixteen or seventeen. The annual mortality in Berlin has decreased during the last fifty or sixty years from one in twenty-eight to one in thirty-four. The mortality in Manchester was, about the middle of the last century, one in twenty-five; in 1770, one in twenty-eight; forty years afterwards, in 1811, the annual deaths were diminished to one in forty-four; and in 1821 they seem to have been still fewer. In the middle of the last century, the mortality in Vienna was one in twenty; it has not, however, improved in the same

proportion as some of the other European cities. According to recent calculation, it is, even now, one in twenty-two and a half, or about twice the proportion of Philadelphia, Manchester, or Glasgow. Many years ago, Mr. Finlayson drew up the following table, to exhibit the difference in the value of life, at two periods of the seventeenth and eighteenth centuries.

Ages.	Mean Duration of Life, reckoning from 1693.	1789.	So that the Increase of Vitality is in the inverse ratio of 100 to
Years.	Years.	Years.	
5	41.05	51.20	125
10	38 93	48.28	124
20	31.91	41.33	130
30	27.57	36.09	131
40	22.67	29.70	131
50	17.31	22.57	130
60	12.29	15.52	126
70	7.44	10.39	140

The following is the annual mortality of some of the chief cities of Europe and America:—

Philadelphia	1 in 45.68
Glasgow	1 in 44
Manchester	1 in 44
Geneva	1 in 43
Boston	1 in 41.26
London	1 in 40
New York	1 in 37.83
St. Petersburg	1 in 37
Charleston	1 in 36.50
Baltimore	1 in 35.44
Leghorn	1 in 35
Berlin	1 in 34
Paris, Lyons, Barcelona, and Strasburg	1 in 32
Nice and Palermo	1 in 31
Madrid	1 in 29
Naples	1 in 28
Brussels	1 in 26
Rome	1 in 25

The following is a general bill of all the christenings and burials within the City of London and Bills of Mortality, from December 15, 1830, to December 13, 1831:—

Christened—Males, 14,217; females, 14,046; total, 28,263; showing an increase of 1520 births over those of the previous year.

Buried—Males, 12,769; females, 12,568; total, 25,337.

Whereof have died,

Under two years of age	7812
Between two and five	2647
Five and ten	1031
Ten and twenty	934
Twenty and thirty	1649
Thirty and forty	1968
Forty and fifty	2175
Fifty and sixty	2169
Sixty and seventy	2237
Seventy and eighty	1786
Eighty and ninety	825
Ninety and one hundred	101
One hundred	1
One hundred and one	1
One hundred and five	1

On the average of eight years, from 1807 to 1814 inclusive, there died annually within the city of Philadelphia and the Liberties, the following proportion of persons, of different ages, compared with the total number of deaths:—

	Per Cent.
Under one year	25.07
From one to two years	10.71
Two to five	5.67
Five to ten	3.00
Ten to twenty	3.60
Twenty to thirty	8.63
Thirty to forty	10.99
Forty to fifty	7.98
Fifty to sixty	5.95
Sixty to seventy	4.29
Seventy to eighty	3.27
Eighty to ninety	1.89
Ninety to one hundred	0,50
One hundred to one hundred ten	0.0009

Another question of interest is the enquiry in what degree the various trades and professions are favourable to human life, or the contrary. Several statements have lately been published respecting this subject, but further and more copious observations are required, to afford satisfactory results. The *Literary Gazette* gives, in a tabular form, the results of a work on this subject, from the pen of Mr. Thackrah, an eminent surgeon of Leeds.

Out-of-door occupations.—Butchers are subject to few ailments, and these the result of plethora. Though more free from diseases than other trades, they, however, do not enjoy greater longevity: on the contrary, Mr. Thackrah thinks their lives shorter than those of other men who spend much time in the open air. Cattle and horse-dealers are generally healthy, except when their habits are intemperate. Fishmongers, though much exposed to the weather, are hardy, temperate, healthy, and long-lived; cart-drivers, if sufficiently fed and temperate, the same. Labourers in husbandry, &c., suffer from a deficiency of nourishment. Brickmakers, with full muscular exercise in the open air, though exposed to vicissitudes of cold and wet, avoid rheumatism and inflammatory diseases, and attain good old age. Paviers are subject to complaints in the loins, increasing with age, but they live long. Chaise-drivers, postilions, coachmen, guards, &c., from the position of the two former on the saddle, irregular living, &c., and from the want of muscular exercise in the two latter, are subject to gastric disorders, and finally to apoplexy and palsy, which shorten their lives. Carpenters, coopers, wheelwrights, &c., are healthy and long-lived. Smiths are often intemperate, and die comparatively young. Rope-makers and gardeners suffer from their stooping postures.

In-door occupations. — Tailors, notwithstanding their confined atmosphere and bad posture, are not liable to acute diseases, but give way to stomach complaints and consumption. The prejudicial influence of their employment is rather insidious than urgent: it undermines rather than destroys life. Stay-makers have their health impaired, but live to a good age. Milliners, dress-makers, and straw-bonnet-makers are unhealthy and short-lived. Spinners, cloth-dressers, weavers, &c., are more or less healthy, according as they have more or less exercise and air. Those exposed to inhale imperceptible particles of dressings, &c., such as frizers, suffer from disease, and are soonest cut off. Shoemakers are placed in a bad posture. Digestion and circula-

tion are so much impaired that the countenance marks a shoemaker almost as well as a tailor. The secretion of bile is generally unhealthy, and bowel complaints are frequent. In the few shoemakers who live to old age, there is often a remarkable hollow at the base of the breast-bone, occasioned by the pressure of the last. Curriers and leather-dressers are very healthy, and live to old age. Saddlers lean much forward, and suffer, accordingly, from headache and indigestion. Printers (our worthy co-operators) are kept in a confined atmosphere, and generally want exercise. The constant application of the eyes to minute objects gradually enfeebles these organs. The standing posture, long maintained here, as well as in other occupations, tends to injure the digestive organs. Pressmen, however, have good and varied labour. Bookbinders,—a healthy employment. Carvers and gilders look pale and weakly, but their lives are not abbreviated in a marked degree. Clock-makers are generally healthy and long-lived; watch-makers the reverse. House servants, in large smoky towns, are unhealthy. Colliers and well-sinkers—a class by themselves—seldom reach the age of fifty.

Employments producing dust, odour, or gaseous exhalations.—These are not injurious, if they arise from animal substances, or from the vapour of wine or spirits. Tobacco manufacturers do not appear to suffer from the floating poison in their atmosphere. Snuff making is more pernicious. Men in oil-mills are generally healthy. Brush-makers live to a great age. Grooms and ostlers inspire ammoniacal gas, and are robust, healthy, and long-lived. Glue and size boilers, exposed to the most noxious stench, are fresh-looking and robust. Tallow-chandlers, also exposed to offensive animal odour, attain considerable age. Tanners are remarkably strong, and exempt from consumption. Corn-millers, breathing an atmosphere loaded with flour, are pale and sickly, and very rarely attain old age. Malsters do not live long, and must leave the trade in middle life. Tea-men suffer from the dust, especially of green teas; but this injury is not permanent. Coffee-roasters become asthmatic, and subject to headache and indigestion. Paper-makers, when aged, cannot endure the effect of the dust from cutting the rags. The author suggests the use of machinery in this process. In the wet and wear and tear of the mills, they are not seriously affected, but live long.

Masons are short-lived, dying generally before forty. They inhale particles of sand and dust, lift heavy weights, and are too often intemperate. Miners die prematurely. Machine-makers seem to suffer only from the dust they inhale, and the consequent bronchial irritation. The (iron) filers are almost all unhealthy men, and remarkably short-lived. Founders (in brass) suffer from the inhalation of the volatilized metal. In the founding of yellow brass, in particular, the evolution of oxide of zinc is very great. They seldom reach forty years. Copper-smiths are considerably affected by the fine scales which rise from the imperfectly volatilized metal, and by the fumes of the spelter, or solder of brass. The men are generally unhealthy, suffering from disorders similar to those of the brass-founders. Tin-plate workers are subjected to fumes from muriate of ammonia, and sulphureous exhalations from the coke which they burn. These exhalations, however, appear to be annoying rather than injurious, as the men are tolerably healthy, and live to a considerable age. Tinners, also, are subject only to temporary inconvenience from the fumes of the soldering. Plumbers are exposed to the volatilized oxide of lead, which rises during the process of casting. They are sickly in appearance, and short-lived. House-painters are unhealthy, and do not generally attain full age.

Chemists and druggists, in laboratories, are sickly and consumptive. Potters, affected through the pores of the skin, become paralytic, and are remarkably subject to constipation. Hatters, grocers, bakers, and chimney-sweepers (a mixed association) also suffer through the skin; but, although the irritation occasions diseases, they are not, except in the last class, fatal. Dyers are healthy and long-lived. Brewers are, as a body, far from healthy. Under a robust and often florid appearance, they conceal chronic diseases of the abdomen, particularly a congested state of the venous system. When these men are accidentally hurt or wounded, they are more liable than other individuals to severe and dangerous effects. Cooks and confectioners are subjected to considerable heat. Our common cooks are more unhealthy than house-maids. Their digestive organs are frequently disordered: they are subject to headache, and their tempers rendered irritable. Glass-workers are healthy. Glass-blowers often die suddenly.

Literary occupations do not appear to be more injurious to long life than many others. Many of the first literati, most distinguished for application throughout life, have attained old age, both in modern and ancient times.

We will add a few instances of extraordinary longevity. Our own countryman, Parr, who was born in 1483, married when at the age of 120, retained his vigour till 140, and died at the age of 152. from plethora. Harvey, the distinguished discoverer of the circulation of the blood, who dissected him, found no decay of any organ. (*Philosophical Transactions*, vol. iii. 1698.) Henry Jenkins, who died in Yorkshire, in 1670, is, perhaps, the greatest authentic instance of longevity. He lived 169 years. Margaret Forster, a native of Cumberland, died in 1771, aged 136; and James Lawrence, a Scotchman, lived 140 years. A Dane, named Drakenberg, died in 1772, in his 147th year; and John Effingham, or Essingham, died in Cornwall, in 1757, aged 144. In 1792, a soldier, named Mittelstedt, died in Prussia, at the age of 112. Joseph Surrington, a Norwegian, died at Bergen, in 1797, aged 160 years. The St. Petersburg papers announced, in 1830, the death of a man 150 years old, at Moscow; and, in 1831, the death of a man in Russia, 165 years old, was reported. On May 7, 1830, died a man named John Ripkey, at the age of 108, in London. His sight remained good till the last. In 1830, a poor man, near lake Thrasimene, died 123 years old. He preserved his faculties to the last. In 1825, pope Leo XII. gave him a pension.

Belsham's Chronology informs us that twenty-one persons, who had attained the age of 130 and upwards, died between the years 1760 and 1829; of these, one was aged 166. In the same period, thirty-nine had attained the age of 120, and not 130. The number who attained the age of 110, and not 120, was thirty-six in the same space. And those who died after the age of 100, and before 110, were fifty-four within the period. Of the whole number recorded, ninety-four were natives of England, twenty-

three of Ireland, and twelve of Russia. Doubtless many more have died after the age of 100, without having had their names recorded. The northern climates afford more instances of longevity than the southern; and, although far the greater part of those who have attained extreme old age have been distinguished for sobriety, yet some of them do not appear to have been in the habit of restraining their appetites. In China, where old age is much respected, people receive presents from government when they have attained a great age.

LONGIMETRY; the measuring of lengths or distances, both accessible and inaccessible. Accessible distances are measured by the application of some measure a certain number of times, as a foot, chain, &c.; and inaccessible distances are measured by taking angles, &c., by means of proper instruments, as the *circumferentor, quadrant, theodolite,* &c. This embraces a great number of cases, according to the situation of the object and observer.

LONGITUDE, GEOGRAPHICAL; the distance measured, according to degrees, minutes, seconds, &c., on the equator, or a parallel circle, from one meridian to another, which is called the first or prime meridian. Longitude is divided into eastern and western. It is altogether indifferent through what point we draw the first meridian, but it must be settled what point we adopt. In this country Greenwich is always adopted; in Germany, the Island of Ferro; in France, the observatory at Paris; in Prussia, that of Berlin; in the United States of America, the meridian of Washington is sometimes taken as a first meridian; but Greenwich is usually adopted. Some geographers reckon from the first meridian 180 degrees west, and the same number east; others, on the contrary, reckon the longitude from the west to the east, the whole length of the equator, to 360 degrees. The longitude of any place, together with the latitude, is requisite for the determination of the true situation of the place upon the earth. From the form of our earth, it follows that the degrees of longitude must always decrease towards the poles. The degrees of latitude, on the contrary, are all taken as equal to each other, and each amounts to sixty geographical miles. The measure of a degree of longitude upon any parallel of latitude is found by multiplying the length of a degree on the equator by the co-sine (taking radius equal to 1) of the latitude of the parallel. The longitude shows the difference of time between any place and the first meridian. The sun performing its apparent revolution in twenty-four hours, a place which lies fifteen degrees further to the west than another will have noon one hour later. Places whose difference of longitude amounts to 180° have opposite seasons of the day, since in the one place it is mid-day, and in the other, at the distance of 180°, it is midnight at the same moment. The difference in longitude of any two places may also be determined by observations of the time of certain celestial phenomena, taken at both places, such as eclipses of the moon, occultations of fixed stars, and, in particular, the eclipses of Jupiter's satellites; and, *vice versâ,* we can, from the difference of longitude of two places, accurately ascertain the difference of their time. 15° upon the parallel circle correspond to one hour, 1° gives 4′ of time, 15′ give 1′ of time, 15″ give 1″ of time, &c. The difference of longitude between Boston in America and London may serve as an example. This difference is 70°, 4′, 9″; consequently, noon at London is four hours, forty-four minutes, and six seconds earlier than at Boston.

The determination of longitude at sea, or of the situation of a ship at any moment, is highly difficult and important. Parliament, in 1714, offered a reward of 20,000*l.* for an accurate method of finding the longitude at sea, within one half of a degree; but this act was repealed July 15, 1828. A watch which would preserve a uniform motion was the most suitable means that could be afforded to the navigator, who might, from the difference of the time of noon on board the ship and the time by the watch immediately determine the difference between the longitude of the place for which the watch was regulated and that wherein the ship then was. Harrison was the first who invented a chronometer of the requisite accuracy. Upon the first voyage, it deviated only two minutes in four months. Other artists followed, namely, Kendall, Mudge, Berthoud, Le Roy, &c.; and Arnold, Vulliamy, and Dent have prepared such accurate chronometers that they have been used for the determination of longitude upon land, as well as at sea, with great success. Nevertheless, astronomical observations furnish the most exact methods of determining longitude. As eclipses and occultations are comparatively rare, and are somewhat difficult of observation, the distances of the moon from the sun or some of the fixed stars have been adopted for the calculation of longitude, because these can be measured almost every night, and an accurate knowledge of the moon's orbit is the only thing requisite thereto.

Longitude in the heavens, as that of a star, &c., is an arc of the ecliptic comprehended between the first of Aries and a circle perpendicular to the ecliptic, passing through the place of the star. The computation is made according to the signs of the ecliptic. The longitude of a star is found by means of its right ascension and declination. It changes on account of the precession of the equinoxes. (See PRECESSION.)

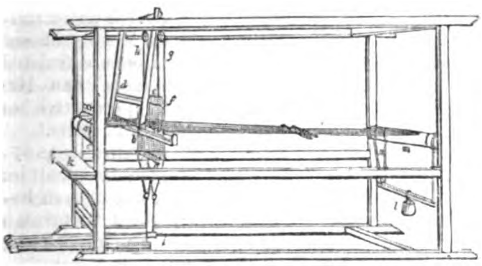
LOOM. This simple machine appears to have been originally invented in the East, and traces of it in its primitive simple form may still be found in the interior of India. The anonymous author of a treatise on the manufacture of silk, when speaking of the common forms of the loom, says, that, simple as they are, they can yet be favourably contrasted with the rude contrivances still pursued in India, where the wretched weaver performs his labours in the open air, choosing his station under trees whose shade may protect him from the scorching rays of the sun. Here, extending the threads which compose the warp of his intended cloth lengthwise, between two bamboo rollers, which are fastened to the turf by wooden pins, he digs a hole in the earth large enough to contain his legs when in a sitting posture; then, suspending to a branch of a tree the cords which are intended to cause the reciprocal raising and depressing of the alternate threads of his warp, he fixes underneath and connected with the cords two loops, into which inserting the great toe of either foot, he is ready to commence his operations. The shuttle with which he causes the cross threads or *woof* to interlace the *warp* is in form like the netting needle; and, being somewhat longer than the breadth of the warp, is made to perform the office of a batton, by striking the threads of the woof close up to each other.

With this rude apparatus the patient Indian suc-

ceeds in weaving fabrics which for delicacy of texture cannot be surpassed, and can hardly be rivalled, by the European weaver, even when his labours are aided by the most elaborate machinery. But it is only in climates where the absolute natural wants of men are few, and under systems of government where the oppressions of the dominant caste deprive the unhappy bulk of the people of all means for attaining more than suffices for the barest supply of those wants, that such labours can be so performed.

The art of weaving varies but little, whatever may be the material which is the subject of the manufacture. The principal difference discernible in the construction of looms intended for the weaving of silken or of woollen fabrics consists in the greater strength and stability required for the latter machine, in consequence of the less delicate nature of the substance employed.

The simple loom ordinarily used in weaving plain silks is represented in the accompanying engraving,



and may be thus described: *m* is the beam, or yard-roll, on which the threads which form the warp are wound. Having procured a sufficient quantity of single threads to form the warp, it is then passed through a sort of comb, *b*, and attached to the loom. *a* is the cloth-beam, or breast-roll, to which the ends of the warp are also attached, and on which the woven silk is wound when finished; *l* is a weight attached to the frame of the loom, and suspended over the yard-roll, to produce, by the friction of its cord, the requisite tension of the threads of the warp; *i* are the treadles, on which the weaver presses his feet alternately; and as the one treadle is attached to one portion of the heddle or harness, *h*, whilst the other treadle is attached to the heddle *e f g*, it will be evident that the depression of each treadle will correspondingly influence the position of its heddle. The two heddles are each formed of two horizontal sticks, connected through the whole extent by numerous small cords of an equal length; and the two heddles are so united by a rope and pulley, as shown in the engraving, that the depression of the one must cause the raising of the other. These heddles, which are commonly called the harness of the loom, are furnished with loops at the points where they will be intersected by the warp, each individual thread of which is passed, in regular succession, through the cords of one or other of the heddles, so that each alternate thread of the warp is passed through the loops of the one heddle, while the intermediate threads are passed through the cords of that one, and through the loops of the other heddle. It is now evident that the depression of one heddle by means of the treadle will cause the depression of all the threads of the warp which pass through its loops, and at the same time will raise the other heddle, together with all the intermediate threads of the warp which pass through its loops, leaving between the two divisions of threads a space of about two inches, for the passage of the shuttle. A modern improvement substitutes for the loops small metallic eyes, through which the warp threads are passed, and by this means the wearing of the threads is in some measure avoided. *d* is the reed, which is composed sometimes of small portions of split reeds, or canes, but most frequently of flattened wires. These are fixed, like the teeth of a comb, in a frame, which rests upon the shuttle-race, and the threads of the warp are passed through the interstícial spaces of the reed. These are covered by a top-piece, having a longitudinal groove along its lower side, and which is called the lay-cap. *k* is the weaver's seat, and being hung by rounded ends, resting in corresponding brackets fixed to the framing, the position of this seat accommodates itself to the convenience of the weaver in the different movements of his labour. It must be lifted up when the weaver either takes or quits his seat at the loom, and can be readily replaced.

Having thus given our readers an account of the loom for plain weaving, we must briefly notice the fanciful and ornamental part of the business. Figures, or patterns, are produced in the loom by employing threads of different colours either in the warp or weft. By the proper use of these, some colours may be concealed, or kept back, whilst others are thrown into the front of the fabric. These are made to change places at the will of the weaver, or, as in the case of the *Jaccard* loom, by the agency of machinery. In other cases, the same end is accomplished by employing two or three shuttles, with different coloured threads, either of which may be introduced at pleasure. (See POWER LOOM.)

LOTH; a German weight, the half of an ounce, or the thirty-second part of a pound avoirdupois. The lead used by navigators and mechanics is also called *Loth* in German.

LOTION, in *medicine* and *pharmacy*, is a wash for beautifying the skin, by clearing it of the deformities occasioned by a preternatural secretion. Almost all the lotions advertised for sale contain much deleterious matter, and therefore ought never to be had recourse to.

LOTTERY; a scheme for the distribution of prizes by chance. Lotteries, like every other species of gambling, no doubt have a pernicious influence upon the character of those concerned in them. Though this influence is not so direct, and the immediate consequences are not so disastrous, as those of some other species of gambling, which call into exercise the violent passions, and stake the gambler's whole fortune upon a single chance or exertion of skill,—still, as this kind can be carried on secretly, and the temptations are thrown in the way of both sexes, all ages, and all descriptions of persons, it spreads more widely in a community, and may thus silently affect the sober, economical, and industrious habits of a people more extensively and deeply than those species of gambling which are attended with greater turbulence, and a train of other vices. Lotteries are of different kinds: I. *Numerical lottery;* invented by the Genoese. At the elections of the counsellors, the names of the candidates were cast into a vase, and then into a "wheel of fortune," when wagers were laid upon the event of the elections: the state finally

undertook the superintendence of the bank. It is said that Benedetto Gentile, a counsellor, first introduced this lotto in 1620; and because the name *Gentile*, by chance, had never been drawn, the popular belief prevailed that the devil had carried him off, together with his name, to punish him for this unlucky invention. Numbers were afterwards substituted instead of the names of eligible noblemen, and hence the lotto assumed its present form. The numbers from one to ninety are used; from these, on the day of drawing, five numbers are always drawn. Out of the ninety numbers, each adventurer chooses for himself such and as many numbers as he likes, and specifies with what sum and upon what kind of chance he will back each selected number; whereupon he receives a printed ticket. In this lottery there are four kinds of chances: 1. An *estrado*, so called, which requires only one number among the five that are drawn, and in which the successful adventurers receive fourteen times the stake. By this the lotto gains sixteen per cent., because there are seventeen blanks to one prize. 2. The *wager*, in which a man lays a wager, as it were, with the lotto, that one of the selected numbers will have the first, second, third, fourth, or fifth place in the order of drawing. Should this event happen in the drawing, the bettor obtains sixty-seven times the sum deposited. By this the lotto gains about twenty-five per cent. 3. The third is an *ambo*, in which, if, of the numbers drawn, there are two which the adventurer has pitched upon, he receives from the lotto 240 times the stake. In this case the lotto gains thirty-seven per cent., there being 399 blanks to one prize. 4. The last is a *terno*, by which the lotto gains fifty-four per cent., there being 11,347 blanks to one prize. It requires the adventurer to pitch upon three of the five numbers drawn, in which case he wins 4800 times the amount of the stake. The *quaternes* and *quinternes* are a later invention, and seldom applied to practice, because the lotto thereby gains eighty-eight per cent. and more. The lotto was every where patronized by the multitude, with an interest increasing almost to madness. Wise governments soon saw into the destructive tendency of the lotto, and put an end to it, or prohibited adventuring in it under a severe penalty.

Though the profit of the lotto banks was evident, yet fortune, by means of *ternes* and *quinternes*, brought many of them to ruin, or at least to its very verge, and hence, if numbers were backed too frequently, the conductors took the precaution to secure themselves, by declaring before the drawing that such numbers were full, and they could receive no further stake upon them. Frauds also were practised by means of violent riding and carrier-pigeons, on those lottos the under offices of which, being placed at a distance, were accustomed to sell tickets after the drawing in the principal offices had commenced. II. *The proper lottery*, called also *class lottery*, when divided into classes. Its origin is more ancient than that of the lotto. It has been referred to the Roman *Congiaria*. It is more probable that it originated from the transfer of merchandise by lot, of which method the Italian merchants made use even in the middle ages, and of which we also find traces in Germany; for, as early as 1521, the council at Osnaburg is said to have established lotteries for merchandise. So also in France, under Francis I., similar lotteries for merchandise were permitted to the merchants, under the inspection of government, in consideration of certain duties.

A money lottery was established at Florence in 1530. In 1571 there appears to have been a public officer in Venice for the inspection of the lottery. From Italy, lotteries passed into France, under the name of *blanque* (from the Italian *bianca*, because most of the tickets were blanks, mere white paper, *carta bianca*). In 1582 and 1588 Louis de Gonzaga established such a *blanque* in Paris, for providing poor girls of his estates with dowries; and, in 1656, Lawrence Tonti (from whom the Tontines derive their name) sought to establish a large *blanque royale*, which was first accomplished in 1660. Since this time, there have been in France only *lotteries royales*, the income of which is commonly applied to public buildings. This iniquitous traffic has been revived in France, on a much larger and more destructive scale than it has attained in any other country. In 1810 lotteries were drawn twice a week at Paris, and so often at Bordeaux, Brussels, Lyons, and Strasburg, as to afford one every other day. Twelve millions of francs were yearly produced to government by this public gambling; and it has been estimated that, at Paris, the result has been more than 100 suicides annually. It is, however, productive of much less harm than the private tables in Paris.

In this country, the first lottery occurs in 1567-1568. In 1612 a lottery was granted in behalf of the Virginia Company, and, in 1680, one also in behalf of the undertaker of an aqueduct to furnish London with water. In 1709 the rage for private, and, in many instances, most fraudulent lotteries, was at its height in England, and shop-keepers of all descriptions disposed of their goods in this way, the price of tickets being as low as half-a-crown, a shilling, or even sixpence. Towards the close of the year, an existing act of parliament was put in force for their suppression, and another to the same purpose was passed in the 10th of queen Anne. The first parliamentary lottery was instituted in 1709, and, from that time till 1824, no session passed without a lottery bill. In 1826 lotteries were formally abolished in this country, but in the present parliament (1833) this species of legalized gambling was revived, under the pretext that it furnished the only practicable mode of effecting some important improvements in the city of Glasgow. As early as 1549 a lottery was drawn in Amsterdam, to procure money for the erection of the tower of a church, and, in 1595, one at Delft. In 1653 one was established at Hamburg, according to the Dutch method; in 1699 the first class lottery appeared at Nuremberg; and, in 1740, the first one was drawn in Berlin. Most of the late German lotteries are drawn in classes in order to facilitate the sale of tickets. The great lottery of Hamburg goes upon the plan of one drawing. Latterly, lotteries for merchandise of all kinds, under the inspection of government, have been frequent in Germany. The managers of the principal lotteries sell only whole tickets. Brokers, however, divide them into halves, quarters, eighths, and even sixteenths, in order to facilitate their sale. In some places they even let out tickets, and parts of tickets, upon a particular number of drawings; in which case they are not obliged to pay the prize which may fall to the ticket, unless it be drawn within the stipulated number of drawings. If the principal prizes remain for a long time in the lottery, so that the

probability of being able to obtain them increases at each successive drawing, then a great profit is made in buying and selling tickets, and there are cases in which, in the last drawings, ten and even twenty times the original price of the ticket have been demanded. Lately, in the Austrian monarchy, in the kingdom of Bavaria, and in the duchy of Mecklenburg, estate lotteries have been got up, and manufactories, the estates of noblemen, and even whole lordships, have been disposed of by lottery, under public sanction, and ordinarily under the security of important mercantile houses, which undertook the disposal of the property, in order to settle the debts of the owners. A money lottery has ordinarily been combined with them.

When the credit of the state is low, or when the rate of interest is high, efforts have been made to induce capitalists to put their money into the hands of the state, by means of a lottery, which gives them the expectation of a premium above the customary interest of the country. For example: If a government is uncertain of obtaining, or cannot obtain, money at seven per cent., it may, perhaps, effect its object by offering four per cent. for a loan, and dividing the remaining three per cent. among the lenders by means of a lottery; for the hope of winning the great prizes in the lottery, in addition to the certainty of disposing of their capital at four per cent., has a stronger influence on many men than the offer of seven per cent interest. In this way loans have been raised in Austria, Denmark Baden, Prussia, and other states. By this means, in Prussia, stocks to the amount of 30,000,000*l.* were sold at their full nominal value, while, in the market, they were current only at about seventy per cent. In most if not all of the United States of America, lotteries not specially authorised by the legislatures of the states are prohibited, and the persons concerned in establishing them are subjected to a heavy penalty. In some of the states, lotteries have been very numerous. This is the case with several of the southern states, Virginia, Maryland, and particularly Tennessee. They have also been numerous in New York. The object for which they have been granted has been generally the assistance of literary or benevolent institutions, colleges, academies, hospitals, asylums, or of public works, as roads, bridges, the improvement of the navigation of rivers, &c. Their pernicious effects have induced the legislatures of some of the United States to decline granting them in any case.

LUNAR YEAR. This division of time consists of twelve moons, or 354 days. But it is so ill adapted for the computation of time in a civilized nation that none but Mahometans continue to use it. Amongst those nations which still employ it, many persons can scarcely remember their fasts and festivals as they alternately wander from summer to winter, and again from winter to summer; and their seed-time and harvest change in the same way from the beginning of the year to the end.

The *luni-solar* year is that in which the months are regulated according to the course of the moon, but to which from time to time a month is added whenever the year would range too widely from its original situation. This year is inconvenient, from its varying duration; but as, in a long course of years, the months remain nearly in the same situation, it is less objectionable than the pure lunar year. It was the mode of computation originally adopted by the Greeks and Romans, and is even now that of the Tartars and Japanese.

LUNACY, in *medicine*. See MENTAL DERANGEMENT.

LUNETTE, in *fortification*; a very vague expression, which, in its original signification, probably comprised every detached work built in the form of an angle, and consisting of but two faces. It was afterwards used in a more limited sense, to denote, 1. Small, generally irregular, works, with or without flanks, that are placed in the principal ditch, before the ravelins or other out-works, for the purpose of covering such places of the chief rampart as may be seen from the open field, or of defending from the side such points as, through a mistake in the original plan of the fortifications, were left unprotected, the guns from the bastions not being able to reach them. 2. Advanced works on or before the glacis are sometimes constructed in the form of an angle, sometimes in the form of a bastion. Lunettes, skilfully disposed on the weak fronts of a place, and arranged in one or two lines, so as to flank one another, may check the approach of the enemy for a considerable time, by obliging him to make his trenches at a greater distance than he would otherwise have done, and subjecting him to losses in the capture of each lunette. Particular attention must be paid to dispose them in such a manner as to render it impossible for the enemy to attack two lunettes at the same time. (See FORTIFICATION.)

LUNGS; the organs of respiration in the mammalia (man, quadrupeds, and the cetaceous animals), birds, and reptiles. The lungs are situated in the chest, and are divided into two parts, called *lobes*. They are enveloped in a delicate and transparent membrane, derived from the pleura, through which they have the appearance of net-work, and are connected with the spine by the pleura, with the neck by the windpipe, and with the heart by the roots of the pulmonary artery and veins. In their specific gravity, they are the lightest of all the animal organs, even when exhausted of air; hence their name of *lights*. To the touch, they are soft, spongy, and elastic. In their internal structure, they are composed of an infinite number of membranous cellular blood-vessels, nerves, and lymphatics, all connected by other cellular substances. The cells communicate with each other, but have no communication with the cellular substance: small tubes arise from them, which are finally united into one large tube from each lobe: and these two at length join to form the windpipe. The blood-vessels called the *pulmonary* vessels are destined to distribute the blood through the cells, for the purpose of subjecting it to the action of the air, while the bronchial vessels are intended to supply the blood which nourishes the lungs. The cetacea (whales, seals, &c.) breathe by lungs, and are therefore obliged to ascend, at intervals, to the surface of the water, to obtain a supply of atmospheric air. The respiratory orifice, in these animals, is not situated at the extremity of the snout, but on the top of the head. In birds, the lungs are smaller than in quadrupeds, but they have air distributed throughout their muscular system and in the cavities of the bones.

The lungs afford a means of ascertaining whether a new-born child, which is found dead, was or was not living when born,—a question often of great importance in forensic medicine. The lungs of the

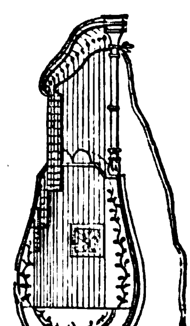
infant are placed in water to see whether they will swim or sink. Before birth, the lungs are dark red, contracted into a small place within the cavity of the breast, firm, and specifically heavier than water. They therefore sink in water, whether they are entire or cut into pieces; and, when cut, no air-bubbles come forth, either in or out of the water, nor does much blood appear. But if the infant has lived after birth, and therefore breathed, air has entered the lungs, has thus enlarged the cavity of the chest, and the lungs themselves are expanded, appear ot a loose, spongy texture, of a pale red colour, cover the heart, and fill the chest. They then swim in water, as well in connection with the heart as without it, as well entire as in pieces. If cut, a peculiar sound is audible; air proceeds from them, and rises, if they are pressed under water, in small bubbles. From the incisions in the lungs, red blood issues.

Against this test it has been objected—1. That air may be found in the lungs, though the infant never breathed. This could happen, however, only (1) from air having been blown into them; but, in this case, the chest of the infant is not arched, very little blood is to be found in the lungs, and it is not bright red: (2) from putrefaction; but, in this case, the other parts of the body would also be affected by putrefaction: the lungs are not expanded, pale-red air-bubbles show themselves only on the surface, and not in the interior substance, unless the highest degree of putrefaction has taken place. 2. It is said that the child may have breathed, and therefore lived, without air being found in the lungs. This is not proved, and is at variance with the received ideas of the manifestation of life. 3. One part of the lungs may swim, another may sink. This can happen only with lungs in a diseased state, and would only prove an attempt of the infant to breathe, without the possibility of living. 4. That a child may have lived without breathing; but this state of apparent death cannot be called life: life cannot be supposed without breath. If all precautions are taken, all attending circumstances considered, the external appearance of the infant well observed, and the state of the other intestines examined, the foregoing test may be considered as sufficient for the decision of the question whether a child has lived after birth or not. Another kind of test by means of the lungs has been proposed, which is founded on the proportion of the weight of the whole body to a lung which has breathed and one which has not; and still another, which rests on the circumference of the chest before and after breathing has commenced; but both are more complicated, troublesome, and less certain than the former one.

LUPULIN. M. Planche first ascertained that the three active ingredients of the hop, viz. the oil, resin, and bitter principle, reside in the brilliant yellow grains scattered over the calicinal scales of the cones which serve as their envelope. MM. Payen and Chevalier have since confirmed this position. This matter, when insulated, is of a golden yellow colour, in little grains, without consistence, which attach themselves to the fingers, and render them rough. It has a penetrating aromatic odour: 200 parts of it afforded, 1. water; 2. essential oil; 3. carbonic acid; 4. subacetate of ammonia; 5. traces of osmazome; 6. traces of fatty matter; 7. gum; 8. malic acid; 9. malate of lime; 10. bitter matter, 25 parts; 11. a well characterized resin, 105 parts; 12. silica, 8 parts; 13. traces of carbonate, muriate, and sulphate of potash; 14. carbonate and phosphate of lime; 15. oxide of iron and traces of sulphur. The bitter matter, introduced into the stomach, destroys appetite.

LUTE is an instrument which originated from the ancient lyre. Some, however, think that it was introduced into Spain by the Moors, and from thence into Italy, where it received the name of *liuto*. The *chelys*, or *testudo*, of the Romans, was probably a similar instrument. It was formerly much in use, and contained only five rows of strings, to which one, or more, were afterwards added. The lute consists of four parts, viz. the table; the body, which has nine or ten sides; the neck, which has as many stops or divisions; and the head, or cross, in which the screws for turning it are inserted. In playing this instrument, the performer strikes the strings with the fingers of the right hand, and regulates the sounds with those of the left. The notes for the lute are generally written on six lines, and not on five. There were formerly various kinds in use. The lute, simply constructed, is called the *French lute;* if it has two necks, one of which sustains the base notes, it is called a *theorbo;* if the strings of the *theorbo* are doubled, it is called an *arch-lute*. The difficulty of playing upon this instrument, as well as that of tuning it, is probably the reason that it has gone out of use.

The difficulties inseparable to the common lute has induced a distinguished foreigner to turn his attention towards the general arrangement of its parts. Indeed, the instrument we are about to describe under this title possesses all the characteristics of the harp. Signor Ventura, the inventor of this instrument, has so combined the principles of the harp, lute, and guitar, as to enable the performer to stop the treble strings on a finger board, by which he materially increases its compass, and yet retains the fulness and sweetness of its tones. The engraving will give a perfect notion of the general arrangement of the instrument, and it may only be necessary to add that the strain on its neck is considerably less than in a harp of the same size, and, as such, that it must continue much longer in tune.



LUXATION, in *surgery*, is the removal of a bone out of its place or articulation, so as to impede or destroy its proper motion or office; hence luxations are peculiar to such bones as have movable joints.

LYCANTHROPY; defined by Cottgrave as "a frenzie or melancholie, which causeth the patient (who thinks he is turned woolf) to flee all company and hide himself in dens and corners." Herodotus, with great *naïveté* tells us, that, when he was in Scythia, he heard of a people that once a year changed themselves into wolves, and then resumed their original shape; "but," adds he, "they cannot make me believe such tales, although they not only tell them, but swear to them." But the lycanthropes of the middle ages, or *loups-garoux*, as they were called by the French, were sorcerers, who, during their wolfhood, had a most cannibal appetite for human flesh. The Germans call them *Währwölfe*. Many marvellous stories are told by the writers of the middle

ages of these wolf-men, or *loups-garoux*, and numerous narratives remain of victims committed to the flames for this imaginary crime, often on their own confessions.

Lymph; an aqueous liquid, colourless, insipid, and diaphanous, diffused through the whole animal economy, in vessels called *lymphatics*. If allowed to stand, it separates into two parts, like the blood—a serous fluid, and a solid, or clot. The lymph serves to repair losses of the blood, by bringing to it various materials from different parts of the system, and chyle, which is mixed with the lymph in the thoracic duct. It seems also to remove those elements of nutrition whose place is to be supplied by others, and to transmit them to the surface. The uses and history of lymph, however, are yet but imperfectly known. The lymphatic vessels were not known till towards the middle of the seventeenth century. They are small, thin, transparent, furnished with valves, like the veins, and spread through different parts and organs. The cause of the circulation of the lymph is unknown, as there does not appear to be any impelling organ analogous to the heart. It has been supposed that the absorbent power exercised at their mouths impels the liquid forward, that already absorbed being thus displaced by the new absorptions. These vessels arise in every part of the body, and terminate in the thoracic duct.

Lyre; the most ancient stringed instrument among the Egyptians and Greeks. The mythological tradition of the origin of the Egyptian lyre, the more ancient of the two, is curious. After an inundation of the Nile, a tortoise was left ashore among other animals; after its death, its flesh decayed, and some of the tendons were dried by the sun, so as to produce a sound when touched by Hermes, as he was walking on shore. He immediately made an instrument in imitation of it, and thus invented the lyre. This lyre, originally, had but three strings. The Greeks ascribed the invention of the lyre to their Hermes (Mercury), the son of Jupiter and Maïa. They also say that Hermes first used the shell of a tortoise. According to others, Mercury merely improved the invention of the Egyptians. The muses, after this, invented a tone, and Orpheus, Linus, and Thamyras, one each. These, being added to the three-stringed Egyptian lyre, gave rise to the heptachord, or seven-stringed lyre of the Greeks. The invention of the instrument has also been ascribed to each of its chief improvers. The Egyptian and Grecian lyres were, at first, strung with the sinews of animals. The number of the strings was at last increased to eleven. It was played with the *plectrum*, or lyre-stick, of ivory or polished wood; also with the fingers. The lyre was called by different names—*lyra, phorminx, chelys, barbitos, barbiton, cithara.* The body of the lyre was hollow, to increase the sound.

Few objects are so graceful in form, and susceptible of such varied applications in the fine arts, as the lyre, which is even yet used as a musical instrument. It is the symbol of Apollo; yet other deities also bear the lyre; and mythology mentions many gods who distinguished themselves on this instrument. It was played by educated Greeks in general; and, Themistocles having once declined playing when requested, he was considered a person without cultivation. In a work of Doni, entitled *Lyra Barberina*, the various forms of the lyre are collected in two large volumes.

MACCARONI, a preparation of fine flour, which forms a favourite article of food among the Italians. It is eaten in various ways, generally simply boiled, and served up with grated cheese. Maccaroni, is generally made in pieces resembling a long pipe handle, of small diameter; sometimes, however, in other shapes, as flat, square, &c. It is a national dish of the Italians, particularly of the Neapolitans, and is a wholesome food. It is made best in the neighbourhood of Naples, whole villages living almost solely by the manufacture; and, in Naples, it is continually sold in the streets, cooked for the lower classes, particularly for the *lazzaroni*. The pieces being very long, and being held in the fingers during the process of eating, some skill is required to manage them. This fashion of eating yard-long maccaroni forms a subject of ridicule against the Neapolitans in more than one Italian comedy. The modes of cooking maccaroni are various; the simplest is the best. Maccaroni is well made at Aix in France, and pretty well in Germany.

Mace. Clubs of various descriptions are found among almost all savages, formed of a hard and heavy wood, some broad and flat, others round, angular, long, or short, some plain and rude, others neatly carved. From this simple implement, the mallet, hammer of arms, and mace originated, which were generally used, of old, both in Great Britain and on the continent of Europe. The gradual progress of improvement having rendered armour impenetrable by edged weapons, some instrument of effectual demolition became necessary. An author on military affairs, of the sixteenth century, recommends a leaden mallet, five feet long. The mallet was wielded with both hands, and horsemen had it hung by a thong or chain from the pommel of the saddle. The hammer of arms greatly resembled a common hammer. It differed from the mallet in being square, or a little rounded or convex, while one side of the mallet was square and the other pointed or edged.

The mace in its simplest form is only an iron club, short, and strong. Its shape varied among different nations and at different times. One, still preserved, is of iron, two feet one inch long, with a hollow handle, and a head seven inches long, consisting of seven iron leaves perpendicularly fixed round a cylinder, and equidistant. The whole weighs three pounds nine ounces. Two maces, said to have belonged to Roland and Oliver de Roncevaux, famous champions under Charlemagne, were preserved in France towards the beginning of the last century, and perhaps later, consisting of a handle two feet long, to which an iron ball was attached by a triple chain. It appears that the ball was frequently covered with iron spikes, and was attached to the handle by a single chain. Mr. Grose states that similar implements were long used by the trained bands of London, under the names of *morning stars*.

Mace; the outer, fleshy, and coriaceous cover of the nutmeg. When the fruit is gathered, the mace is carefully separated from the nut, dried in the sun, and afterwards packed in chests of different sizes, in which state it is obtained in commerce. (See Nutmeg.)

Machinery. The utility of machinery, in its application to manufactures, consists in the addition

which it makes to human power, in the economy of human time, and in the conversion of substances apparently worthless into valuable products. The forces derived from wind, from water, and from steam, are so many additions to human power, and the total inanimate force thus obtained in Great Britain (including the commercial and manufacturing) has been calculated, by Dupin, to be equivalent to that of 20,000,000 of labourers. Experiments have shown that the force necessary to move a stone on the smoothed floor of its quarry is nearly two-thirds of its weight; on a wooden floor, three-fifths; if soaped, one-sixth; upon rollers on the quarry floor, one-thirty second; on wood, one-fortieth. At each increase of knowledge, and on the contrivance of every new tool, human labour is abridged: the man who contrived rollers quintupled his power over brute matter. The next use of machinery is the economy of time, which is too apparent to require illustration, and may result either from the increase of force or from the improvement effected in the form of tools, or from both united. Instances of the production of valuable substances from worthless materials are constantly occurring in all the arts; and, though this may appear to be merely the consequence of scientific knowledge, yet it is evident that science cannot exist, nor could its lessons be made productive by application, without machinery.

In the history of every science we find the improvements of its machinery, the invention of instruments, to constitute an important part. The chemist, the astronomer, the physician, the husbandman, the painter, the sculptor, is such only by the application of machinery. Applied science in all its forms, and the fine and useful arts, are the triumphs of mind, indeed, but gained through the instrumentality of machinery. In the infancy of any branch of manufactures we always commence with *tools*, which are ultimately converted into *machines;* but the distinction between the two is so accurately given by Mr. Babbage, in his work on the economy of machinery, that we cannot do better than quote it verbatim.

"The difference between a *tool* and a *machine* is not capable of very precise distinction; nor is it necessary, in a popular explanation of those terms, to limit very strictly their acceptation. A *tool* is usually more *simple* than a machine; it is generally used with the hand, whilst a machine is frequently moved by animal or steam power. The simpler *machines* are often merely one or more *tools* placed in a frame, and acted on by any moving power. In pointing out the advantages of *tools* we shall commence with some of the simplest.

"To arrange twenty thousand needles thrown promiscuously into a box, mixed and entangled with each other in every possible direction, in such a form that they shall be all parallel to each other, would, at first sight, appear a most tedious occupation; in fact, if each needle were to be separated individually, many hours must be consumed in the process. Yet this is an operation which must be performed many times in the manufacture of needles; and it is accomplished in a few minutes by a very simple *tool,* nothing more being requisite than a small flat tray of sheet iron, slightly concave at the bottom. The needles are placed in it and shaken in a peculiar manner, by throwing them up a very little, and giving at the same time a slight longitudinal motion to the tray. The shape of the needles assists their arrangement; for if two needles cross each other (unless, which is exceedingly improbable, they happen to be precisely balanced) they will, when they fall on the bottom of the tray, tend to place themselves side by side, and the hollow form of the tray assists this disposition. As they have no projection in any part to impede this tendency, or to entangle each other, they are, by continually shaking, arranged lengthwise, in three or four minutes. The direction of the shake is now changed, the needles are but little thrown up, but the tray is shaken endways; the result of which is that in a minute or two the needles which were previously arranged endways become heaped up in a wall, with their ends against the extremity of the tray. They are now removed by hundreds at a time, by raising them with a broad iron spatula, on which they are retained by the fore-finger of the left hand. During the progress of the needles towards their finished state, this parallel arrangement must be repeated many times; and, unless a cheap and expeditious method had been devised, the expense of manufacturing needles would have been considerably enhanced.

"Another process in the art of making needles furnishes an example of one of the simplest contrivances which can come under the denomination of a *tool.* After the needles have been arranged in the manner just described, it is necessary to separate them into two parcels, in order that their points may be all in one direction. This is usually done by women and children. The needles are placed sideways in a heap, on a table, in front of each operator, just as they are arranged by the process above described. From five to ten are rolled towards this person by the forefinger of the left hand; this separates them a very small space from each other, and each in its turn is pushed lengthwise to the right or to the left, according as its eye is on the right or the left hand. This is the usual process, and in it every needle passes individually under the finger of the operator. A small alteration expedites the process considerably; the child puts on the forefinger of its right hand a small cloth cap or finger-stall, and, rolling out of the heap from six to twelve needles, he keeps them down by the forefinger of the left hand, whilst he presses the forefinger of the right hand gently against their ends: those which have the points towards the right hand stick into the finger-stall; and the child, removing the finger of the left hand, slightly raises the needles sticking into the cloth, and then pushes them towards the left side. Those needles which had their eyes on the right hand do not stick into the finger-cover, and are pushed to the heap on the right side previously to the repetition of this process. By means of this simple contrivance each movement of the finger, from one side to the other, carries five or six needles to their proper heap; whereas, in the former method, frequently only one was moved, and rarely more than two or three were transported at one movement to their place.

"Various operations occur in the arts in which the assistance of an additional hand would be a great convenience to the workman, and in these cases tools or machines of the simplest structure come to our aid: vices of different forms, in which the material to be wrought is firmly grasped by screws, are of this kind, and are used in almost every workshop;

but a more striking example may be found in the trade of the nail-maker.

"Some kinds of nails, such as those used for defending the soles of coarse shoes, called hobnails, require a particular form of the head, which is made by the stroke of a die. The workman holds the red-hot rod of iron out of which he forms them in his left hand; with his right hand he hammers the end of it into a point, and, cutting the proper length almost off, bends it nearly at right angles. He puts this into a hole in a small stake-iron immediately under a hammer connected with a treadle, which has a die sunk in its surface corresponding to the intended form of the head; and, having given one part of the form to the head by the small hammer in his hand, he moves the treadle with his foot, which disengages the other hammer, and completes the figure of the head, the returning stroke produced by the movement of the treadle striking the finished nail out of the hole in which it was retained. Without this substitution of his foot for another hand, the workman would probably be obliged to heat the nails twice over.

"Another, although fortunately a less general substitution of tools for human hands, is used to assist the labour of those who are deprived by nature or by accident of some of their limbs. Those who have had an opportunity of examining the beautiful contrivances for the manufacture of shoes by machinery which we owe to the fertile invention of Mr. Brunel must have noticed many instances in which the workmen were enabled to execute their task with precision, although labouring under the disadvantage of the loss of an arm or a leg. A similar instance occurs at Liverpool, in the Institution for the Blind, where a machine is used by those afflicted with blindness for weaving sash-lines; it is said to have been the invention of a person suffering under that calamity. Other instances might be mentioned of contrivances for the use, the amusement, or the instruction of the wealthier classes, who labour under the same natural disadvantages. These triumphs of skill and ingenuity deserve a double portion of our admiration when applied to mitigate the severity of natural or accidental misfortune—when they supply the rich with occupation and knowledge — when they relieve the poor from the additional evils of poverty and want."

All machines are intended either to produce power, or merely to transmit power and execute work. Of the class of mechanical agents by which motion is transmitted—the lever, the pulley, the wedge—it has been demonstrated that no power is gained by their use, however combined. Whatever force is applied at one part can only be exerted at some other, diminished by friction and other incidental causes; and whatever is gained in the rapidity of execution is compensated by the necessity of exerting additional force. These two principles should be constantly borne in mind, and should teach us to limit our attempts to things which are possible. (See HYDRAULICS, HYDROSTATICS, MECHANICS, and STEAM-ENGINE.)

1. *Accumulating Power*. When the work to be done requires more force for its execution than can be generated in the time necessary for its completion, recourse must be had to some mechanical method of preserving and condensing a part of the power exerted previously to the commencement of the process. This is most frequently accomplished by a fly-wheel, which is a wheel having a heavy rim, so that the greater part of the weight is near the circumference. It requires great power, applied for some time, to set this in rapid motion, and, when moving with considerable velocity, if its force is concentrated on a point, its effects are exceedingly powerful. Another method of accumulating power consists in raising a weight and then allowing it to fall. A man, with a heavy hammer, may strike repeated blows on the head of a pile without any effect; but a heavy weight, raised by machinery to a greater height, though the blow is less frequently repeated, produces the desired effect.

2. *Regulating Power*. Uniformity and steadiness in the motion of the machinery are essential both to its success and its duration. The governor, in the steam-engine, is a contrivance for this purpose. A vane or fly of little weight, but large surface, is also used. It revolves rapidly, and soon acquires a uniform rate, which it cannot much exceed, because any addition to its velocity produces a greater addition to the resistance of the air. This kind of fly is generally used in small pieces of mechanism, and, like the heavy fly, it serves to equalize the moving power.

3. *Increase of Velocity*. Operations requiring a trifling exertion of force may become fatiguing by the rapidity of motion necessary, or a degree of rapidity may be desirable beyond the power of muscular action. Whenever the work itself is light, it becomes necessary to increase the velocity in order to economise time. Thus, twisting the fibres of wool by the fingers would be a most tedious operation. In the common spinning-wheel the velocity of the foot is moderate, but, by a simple contrivance, that of the thread is most rapid. A band, passing round a large wheel, and then round a small spindle, effects this change. This contrivance is a common one in machinery.

4. *Diminution of Velocity*. This is commonly required for the purpose of overcoming great resistances with small power. Systems of pulleys afford an example of this.

5. *Spreading the action of a force exerted for a few minutes over a large extent of time*. This is one of the most common and useful employments of machinery. The half minute which we spend daily in winding up our watches is an exertion of force which, by the aid of a few wheels, is spread over twenty-four hours. A great number of automata, moved by springs, may be classed under this division.

6. *Saving time in natural operations*. The process of tanning consists in combining the tanning principle with every particle of the skin, which, by the ordinary process of soaking it in a solution of the tanning matter, requires from six months to two years. By enclosing the solution, with the hide, in a close vessel, and exhausting the air, the pores of the hide being deprived of air exert a capillary attraction on the tan, which may be aided by pressure, so that the thickest hides may be tanned in six weeks. The operation of bleaching affords another example.

7. *Exerting forces too great for human power*. When the force of large bodies of men or animals is applied, it becomes difficult to concentrate it simultaneously at a given point. The power of steam, air, or water is employed to overcome resistances which it would require a great expense to surmount by animal labour. The twisting of the largest cables, the rolling, hammering, and cutting of large masses of iron,

the draining of mines, require enormous exertions of physical force, continued for considerable periods. Other means are used when the force required is great and the space through which it is to act is small. The hydraulic press can, by the exertion of one man, produce a pressure of 1500 atmospheres, or rather more than 20,000 lbs.

8. *Executing operations too delicate for human touch.* The same power which twists the stoutest cable, and weaves the coarsest canvass, may be employed to more advantage than human hands in spinning the gossamer thread of the cotton, and entwining, with fairy fingers, the meshes of the most delicate fabric.

9. *Registering Operations.* Machinery affords a sure means of remedying the inattention of human agents, by instruments, for instance, for counting the strokes of an engine, or the number of coins struck in a press. The tell-tale, a piece of mechanism connected with a clock, in an apartment to which a watchman has not access, reveals whether he has neglected, at any hour of his watch, to pull a string in token of his vigilance.

10. *Economy of Materials.* The precision with which all operations are executed by machinery, and the exact similarity of the articles made, produce a degree of economy in the consumption of the raw material which is sometimes of great importance. In reducing the trunk of a tree to planks, the axe was formerly used, with the loss of at least half the material. The saw produces thin boards, with a loss of not more than an eighth of the material.

11. *The Identity of the Result.* Nothing is more remarkable than the perfect similarity of things manufactured by the same tool. If the top of a box is to be made to fit over the lower part, it may be done by gradually advancing the tool of the sliding rest; after this adjustment, no additional care is requisite in making a thousand boxes. The same result appears in all the arts of printing: the impressions from the same block, or the same copper-plate, have a similarity which no labour of the hand could produce.

12. *Accuracy of the Work.* The accuracy with which machinery executes its work is, perhaps, one of its most important advantages. It would hardly be possible for a very skilful workman, with files and polishing substances, to form a perfect cylinder out of a piece of steel. This process, by the aid of the lathe and the sliding rest, is the every-day employment of hundreds of workmen. On these last two advantages of machinery depends the system of copying, by which pictures of the original may be multiplied, and thus almost unlimited pains may be bestowed in producing the model, which shall cost 10,000 times the price of each individual specimen of its own perfection. Operations of copying take place by printing, by casting, by moulding, by stamping, by punching, with elongation, with altered dimensions. A remarkable example of the arts of copying lies before the eye of the reader in these pages. 1. They are copies obtained by printing from stereotype plates. 2. Those plates are copies obtained (by casting) from moulds formed of plaster of Paris. 3. The moulds are copies obtained by pouring the plaster in a liquid state upon the moveable types. 4. The types are copies (by casting) from moulds of copper, called *matrices*. 5. The lower part of the matrices, bearing the impressions of the letters or characters, are copies (by punching) from steel punches, on which the same characters exist in relief. And, lastly, the cavities in these steel punches, as in the middle of the letters *a*, *b*, &c., are produced from other steel punches in which those parts are in relief.

MACRABIOTICS; the science of prolonging life. Hufeland called his well-known work *Makrabiotik*, or the Art of Prolonging Human Life. (See LONGEVITY.)

MADDER. This plant is much used, on account of the fine scarlet colour afforded by the roots; and, indeed, this substance is essential to dyers and calico-printers, and their manufactures could not be carried on without it. In consequence, it has become an important article of commerce, and is imported into Britain from Holland to a very great extent. Though cultivated in France for a century and a half, the supply is yet inadequate to the consumption in that country, and it is largely imported from the Levant as well as from Holland. Since the extension of manufactures in the United States of America, it has become an object of importance to introduce the culture of madder, and the subject has engaged the attention of several intelligent and public-spirited individuals. The most approved method of culture is from seed; and, where this practice is pursued, certain precautions are requisite. As the madder of hot climates affords more colouring matter, as well as a deeper tint, it is best for those who live in a northern region to import the seed from the south. Again, when the seed is too much dried, it may remain in the ground two or three years before it will germinate. On this account, it should be kept in a bed of moistened earth or sand, whenever there is any delay in sowing it. A light, rich, and deep soil is the most suitable, and it should be ploughed to the depth of two feet. The time of sowing is in February, or the beginning of March, for the more northern, and in September or October for the more southern regions. This kind of crop requires but little care and attention: for the first year it is only necessary to keep it free from the weeds, and to hoe it slightly once during the summer: for the second, it requires hoeing in the spring, in the summer, and again, a little more deeply, in the latter part of the season; the same is requisite for the third year, except that the earth is heaped up about the base of the stems, in order to make them shoot with more vigour, and enlarge the roots. It is usual, before the second time of hoeing, to cut the stems for cattle, who are very fond of it; but this practice should not be repeated during the season, as recommended by some writers, or the roots will suffer. It is only at the end of the third year that the crop is ready for harvesting; but, if it is suffered to remain in the ground beyond this period, more is lost than gained. The roots at this time contain the greatest quantity of colouring matter, and have attained their full size.

The best method of obtaining the roots is the following:—A trench is dug along the rows, to the depth of two feet, when, by loosening the earth about the roots, they may be taken up entire. In a good soil, a single plant may yield forty pounds of the fresh roots, which diminish, in drying, six-sevenths or seven-eighths of their weight. The roots should be immediately washed, freed from all decayed parts, and dried as quickly as possible, either by the sun or in a kiln. It is well observed that madder is a hazardous crop, as, from its yielding a return only after a lapse of three years, it is often impossible to foresee what will be the state of the

market at that time. Another mode of cultivation is from the roots, which are divided and set out: 20,000 plants may be allotted to an acre. In England, the madder from Holland is most esteemed, and it is cultivated in that country to a great extent.

The process of pulverizing the roots, which is done by pounding or grinding, was, for a long time, kept a secret by the Dutch. In the state of a powder, it is of an orange-brown colour, and is liable to become damp, and to be spoiled, if kept in a moist place. Madder is used for dyeing woollen, silk, and also cotton goods: the colour is very lasting, and resists the action of the air and sun. Within a few years, a method has been discovered of rendering the red exceedingly brilliant, and approaching to purple. It also forms a first tint for several other shades of colour, and, besides, has of late been successfully used by painters, and is found to yield a fine rose colour. Madder possesses the singular property of imparting its red colour to the bones of those animals which have used it for food, and also to the milk of cows, if they have eaten of it freely.

Composition of Madder, and its employment in Dyeing. All the parts of the plant contain a yellow colouring matter, which, by absorption of oxygen, becomes red; the root is, however, most productive in this colouring matter, and is the only part employed in dyeing. It is distinguished into three parts—the bark, the middle portion, and the interior woody fibre. The bark contains the same colouring matter as the wood, but mixed with much brown extractive matter, which injures the hue. The bark may be separated in the milling; for it is more readily ground, and may thus be removed by the sieve. In the middle part of the root, which contains the finest colouring matter, and that in largest quantity, there may be distinguished by the microscope a great many shining red particles, dispersed among the fibres. These constitute the rich dyeing material. The fibres contain a brown substance, similar to what is found in bark. The roots occur in commerce dried and in powder. They are also sold fresh, in which state they yield finer colours, dye more, and give up their colouring matter with one-third less water. According to experiments made in this country, four pounds of fresh roots go as far as five of the dry ones; and it is estimated that eight pounds of fresh roots are reduced to one in drying; hence the great advantage of using the green roots becomes apparent.

The madders of Germany and Holland are orange-yellow, passing into brown red, having an acid and saccharine taste, and a strong smell. A distinguished chemist found, in 100 parts of madder,

Fatty matter, of a red-brown colour, resembling wax	1.0
Red resinous matter	3.0
Red extractive matter	20.0
Oxidized extractive	5.0
Brownish gum	8.0
Ligneous fibre	43.5
Acetate of potash and lime	8.0
Phosphate, muriate, and sulphate of potash, about	2.0
Silica	1.5
Oxide of iron	0.5
Waste	7.5
	100.0

According to other analyses, madder contains free tartaric acid. Kuhlmann finds, in the madder of Alsace, red colouring matter, dun colouring matter, ligneous fibre, vegetable acids, mucilage, vegeto-animal matters (azotized), gum (four per cent.), sugar (sixteen per cent.), bitter matter, resin, salts: the last consist of carbonate, sulphate, and muriate of potash, carbonate and phosphate of lime, with silica.

The researches of MM. Robiquet, Colin, and Kuhlmann, seem to prove that the differences in the madder dyes proceed from the relative proportions of two distinct colouring principles in madder, which they have called *alizarine* and *xanthine.* By digesting the powder of madder in water, and acting upon the jelly-like solution thus obtained by boiling alcohol, an extract is afforded, which, at a subliming heat, yields the proper red colouring matter of madder, or alizarine. Or the ground madder may be treated directly with boiling alcohol, and dilute sulphuric acid added to the alcoholic solution, which will throw down the alizarine in a copious orange precipitate. Alizarine has a golden-yellow hue, is insoluble in water, but soluble in alcohol and ether: it is precipitated by acids, but not by alkalies, showing distinctly an analogy to resins. The xanthine was obtained from a fawn-yellow matter, soluble in alcohol and water, by precipitation with oxide of lead, washing the precipitate with alcohol, and extricating the colour by sulphuric acid. It has an orange-green tint, and a saccharine taste; alkalies cause it to pass into red, and acids to lemon-yellow. It is inferred by these chemists that in those fabrics which exhibit rose-tints the xanthine predominates, while in the violet it is nearly wanting. From a knowledge of these facts, it becomes easy for a skilful dyer to promote the absorption, by the cloth, of one or other of these colouring principles, or to remove one of them, should both together have been attached to it.

Kurrer has published, in the *Polytechnic Journal* of Dingler for 1827, a process, by a spirituous or vinous fermentation, and an immediate subsequent washing, which gives a perfect result with all the madders of commerce. The madder, penetrated with water, and covered over merely one inch, ferments in from thirty-six to forty-eight hours, when the whole is transferred into a tub containing a considerable quantity of cold water. Here the madder precipitates, and must be washed with several cold waters. The ordinary madder-red dye is given in the following way:—The yarn or cloth is put into a very weak alkaline bath, at the boiling temperature, then washed, dried, and galled; or, when the calico is to be printed, for this bath may be substituted one of cow-dung, subsequent exposure to the air for a day or two, and immersion in very dilute sulphuric acid. In this way the stuff becomes opened, and takes and retains the colour better. After the galling, the goods are dried, and alumed twice; then dried, rinsed, and passed through the madder-bath. This is composed of three-quarters of a pound of good madder for every pound weight of the goods. The bath is slowly raised to the boiling point in the course of fifty or sixty minutes, more or less, according to the shade of colour wished for. When the boiling has continued for a few minutes, the stuff is taken out, washed slightly, and dried a second time in the same manner, and with as much madder. It is then washed and dried, or passed through a hot soap-bath, which carries off the fawn-coloured par-

ticles. Other dyes likewise are added to the madder-bath, to obtain other shades of colour; for instance, a decoction of fustic, weld, logwood, or quercitron, the mordants being modified accordingly. Hoelterhoff prescribes for *ordinary madder-red* the following proportions:—twenty pounds of cotton yarn, fourteen pounds of Dutch madder, three pounds of gall-nuts, five pounds of alum; to which are added, first, a pound and a half of acetate of lead, and, subsequently, a quarter of a pound of chalk. When bran is added to the madder-bath, the colour becomes much lighter, and of a more agreeable tint.

Adrianople madder-red is given by many distinct operations. The first consists in cleansing or scouring the goods by alkaline baths, after which they are steeped in oily liquors, and brought to a creamy state by a little carbonate of soda solution. Infusion of sheep's dung is often used as an intermediate or secondary steep. The operation of oiling, with much manual labour, and then removing the superfluous or loosely-adhering oil with an alkaline bath, is repeated two or three times, taking care to dry hard, after each process. Then follows the galling, aluming, maddering, and brightening, for removing the dun-coloured principle, by boiling at an elevated temperature, with alkaline liquids and soap.

MAGELLANIC CLOUDS; whitish appearances, like clouds, seen in the heavens towards the south pole, and having the same apparent motion as the stars. They are three in number, two of them near each other. The largest lies far from the south pole; but the other two are about 11° distant. They may be multitudes of stars, like the milky way.

MAGIC. Men, as soon as they began to observe the phenomena around them, could not help seeing the close connexion which exists between man and external nature. When the sun sets, he wants rest, and sleep approaches with night; atmospheric changes affect his health; certain wounds become painful with the change of weather, or at certain phases of the moon; some men are painfully affected in the presence of particular animals; certain liquids exhilarate, others destroy life. Such and similar observations, combined with many of an erroneous and exaggerated character, springing from credulity and ignorance, soon led men to treat this mysterious connection of man and nature, and the influence of things or causes without him upon his mind and body, as a peculiar science, which, when occupations were not yet divided, of course belonged to the priests, whose exclusive possession of knowledge made them the guides of men in science and the arts as well as in religion. This is considered, by some, the natural origin of supernatural magic; others, on the contrary, believe that there once actually existed a deeper knowledge of the powers and influences of nature, transmitted from earlier and purer ages, but lost with increasing folly and guilt; and others believe that men once possessed the means of producing supernatural effects with the assistance of evil spirits, as those particularly gifted by Providence were able to produce supernatural effects with the assistance of God.

Media, Persia, and the neighbouring countries, famous for their knowledge of astronomy and astrology, are described as the chief seats of the ancient magi, whose doctrine seems to be, in part, of great antiquity. This doctrine represented opposition or strife as the parent and original cause of all things. After the opposition between light and darkness (Ormuzd and Ahriman) was established, the whole series of finite beings, the whole sensual world, proceeded from this constant struggle of light and darkness, good and evil. The change of day and night, light and darkness, the whole series of ages, time itself, is only a consequence of this struggle, in which sometimes light, sometimes darkness, appears victorious, until finally light shall conquer for ever. If all finite things stand under the influence of preserving and destroying powers in nature, it is clear that he who could master these powers could dispose, at his pleasure, of the things subject to them; and the doctrine of the Magians was, that by prayer and a true knowledge of those laws of opposition, love and hatred, light and darkness, such power could be obtained; and that thus, also, it was possible to search into futurity. But it was believed that as the world became sinful the light of the ancient doctrine of the magi was obscured, and those who bore the name became, at last, only evil-disposed sorcerers. One important branch of their art was the excitement of love by potions and enchantments. Their love-potions consisted partly of ingredients which are still known to physicians as stimulants, and partly of parts of animals which had died longing for food or air. Magic, at this period, also occupied itself with fortune-telling, calling up the dead, bewitching by the look, or evil eye (a superstition which we find existing in the processes against witches in modern times), with the preparation of amulets, the inflicting of pain on a person by correspondent applications to his image in wax, &c. He who wishes to become acquainted with the poetical side of magic ought to read the Arabian Nights. It can hardly be doubted that the art of the ancient magicians was founded, to a considerable degree, upon a superior knowledge of the powers of nature. The name of the magnet, *magnes*, or *enchanting stone* (according to one derivation), seems to indicate that it was not unknown to the magi; and some of their phenomena seem referrible to galvanism.

MAGNESIA; one of the earths, having a metallic basis called *magnesium*. It exists in nature, under various states of combination, with acids, water, and other earths, and is found in various mineral springs, and the water of the ocean, united with sulphuric and muriatic acids. It may be obtained by pouring into a solution of its sulphate a solution of subcarbonate of soda, washing the precipitate, drying it, and exposing it to a red heat. It is usually procured in commerce by acting on magnesian limestone with the impure muriate of magnesia, or bittern of the sea-salt manufactories. The muriatic acid goes to the lime, forming a soluble salt, and leaves behind the magnesia of both the bittern and the limestone; or the bittern is decomposed by a crude subcarbonate of ammonia, obtained from the distillation of bones in iron cylinders. Muriate of ammonia and subcarbonate of magnesia result. The former is evaporated to dryness, mixed with chalk, and sublimed. Subcarbonate of ammonia is thus recovered, with which a new quantity of bittern may be decomposed. 100 parts of crystallized Epsom salt require, for complete decomposition, fifty-six of subcarbonate of potash, or forty-four of dry subcarbonate of soda, and yield sixteen of pure magnesia after calcination. Magnesia dissolves very sparingly in water, requiring 5142 times its weight of water at 60°, and 36,000

of boiling water, for solution. The resulting liquid does not change the colour of violets; but when pure magnesia is put upon moistened turmeric paper it causes a brown stain. It possesses the still more essential character of alkalinity in forming neutral salts with acid in an eminent degree. It absorbs both water and carbonic acid when exposed to the atmosphere. It is infusible, except in the intense heat of the compound blow-pipe. The salts of magnesia are in general very soluble, and crystallizable, and possessed of a bitter taste. The *carbonate* is prepared for medicinal use, by dissolving equal weights of sulphate of magnesia and carbonate of potash, separately, in twice their weight of water; mixing them together, and diluting with eight parts of warm water; the magnesia attracts the carbonic acid, and the compound, being insoluble, is precipitated, while the sulphate of potash that remains continues in solution. The mixture is made to boil for a few minutes; after cooling a little it is poured upon a filter; the clear fluid runs through, and the precipitate or carbonate of magnesia is washed with water till it is tasteless. When the process is conducted on a large scale, the bittern, or liquor remaining after the crystallization of sea-salt, which is principally a solution of muriate and sulphate of magnesia, is substituted for the pure sulphate, and this is precipitated by a solution of pearlash or of carbonate of ammonia. Carbonate of magnesia is perfectly white, friable, and nearly tasteless. It is very sparingly soluble in water, requiring at least 2000 times its weight at 60°. When acted on by water impregnated with carbonic acid, it is dissolved; and from this solution, allowed to evaporate spontaneously, the carbonate of magnesia is deposited in small prismatic crystals, which are transparent and efflorescent.

Nitrate of magnesia has a bitter and acrid taste. Its crystallization exhibits a mass of needle-like crystals, deliquescent, soluble in half their weight of water at 60°.

Sulphate of magnesia, generally known by the name of *Epsom salt*, is made directly by neutralizing dilute sulphuric acid with carbonate of magnesia; but in the large way by the action of dilute sulphuric acid on magnesian limestone, and the native carbonate of magnesia. It is possessed of a saline, bitter, and nauseous taste. It crystallizes readily in small quadrangular prisms, which effloresce in a dry air. It is obtained also in larger six-sided prisms, terminated by six-sided pyramids. Its primary form is a right rhombic prism, the angles of which are 90° 30′ and 89° 30′. It is soluble in an equal weight of water at 60°, and in three-fourths of its weight of boiling water. It undergoes the watery fusion when heated. On mixing solutions of sulphate of magnesia and sulphate of potash in atomic proportion, and evaporating, a double salt is formed, which consists of one equivalent of each of the salts and six equivalents of water. A similar double salt is formed by spontaneous evaporation from the mixed solutions of sulphate of ammonia and sulphate of magnesia.

Phosphate of magnesia, formed from the combination of the acid and the earth, crystallizes in prisms, which are efflorescent, soluble in about fifteen parts of cold water, and which, by heat, melt into a glass.

A *triple phosphate of magnesia and ammonia* exists, which is formed by adding phosphoric acid with ammonia, in excess, to a magnesian salt. It is insoluble, and is precipitated in a soft white powder of shining lustre. It forms one variety of urinary calculi, and its formation affords one of the best tests for the discovery of magnesia.

Muriate of magnesia has such an affinity to water that it can be obtained in acicular crystals only by exposing its concentrated solution to sudden cold. No chloride of magnesium can be obtained by heating this salt; for the acid is expelled from it undecomposed, by the application of heat.

Chloride of magnesia may be formed in the same manner as chloride of lime. It has the same bleaching power, and it has been proposed to apply it to the same purpose. When the chloride of lime is used, a small quantity of lime is left on the cloth: this, in the last operation of washing the cloth with water acidulated with sulphuric acid, is converted into sulphate of lime, which, being insoluble, remains, and affects the colours, when the cloth is dyed. The advantage of employing the chloride of magnesia is, that, if sulphate of magnesia be formed, it is so soluble as to be easily removed by washing. Magnesia is a very useful article of the *materia medica*. It is used as an antacid and cathartic. It is however nearly inoperative, unless there is acid in the stomach, or unless acid is taken after it. The carbonate and sulphate are the most frequently used of the preparations of magnesia; but the pure earth, sold under the name of *calcined magnesia*, is sometimes preferred; it is liable, however, to form large and dangerous accumulations in the bowels, of several pounds weight, when its use has long been persevered in.

MAGNETISM. This science may justly be considered as yet but in its infancy, although the facts elicited since the commencement of the nineteenth century, by Barlow, Morichini, Faraday, and Davy, bid fair to throw considerable light on some of its more recondite principles.

The theory of magnetism bears a very strong resemblance to that of electricity. We have seen the electric fluid not only exerting attractions and repulsions, and causing a peculiar distribution of the neighbouring portions of a fluid similar to itself, but also excited in one body and transferred to another in such a manner as to be perceptible to the senses, or at least to cause sensible effects, in its passage. The attraction and repulsion, and the peculiar distribution of the neighbouring fluid, are found in the phenomena of magnetism; and we now perceive an actual excitation or perceptible transfer of the magnetic fluid from one body to another: it has also this striking peculiarity, that metallic iron is very nearly the only substance capable of exhibiting any strong indications of its presence.

The most simple experimental illustration of the effects of magnetic attraction may be thus shown. If the north pole of a magnetized bar be presented to a similar pole of another bar, it will be repelled or driven away from it; but if, on the contrary, two opposite poles be presented towards each other, they will be attracted.

From this it will be seen that a north pole always repels a north pole, and attracts a south pole. And, if a neutral piece of soft iron be brought near to the north pole of a magnet, the fluid will become so distributed by induction as to form a temporary south pole next to the magnet, and the whole piece will of course be attracted, from the greater proximity of the attracting pole. If the bar is sufficiently soft, and not

too long, the remoter end becomes a north pole, and the whole bar a perfect temporary magnet. But, when the bar is of hard steel, the state of induction is imperfect, from the resistance opposed to the motion of the fluid; hence the attraction is less powerful, and an opposite pole is formed at a certain distance within the bar, and beyond this another pole, similar to the first, the alternation being sometimes repeated. The distribution of the fluid within the magnet is also affected by the neighbourhood of a piece of soft iron, the north pole becoming more powerful by the vicinity of the new south pole, and the south pole being consequently strengthened in a certain degree; so that the attractive power of the whole magnet is increased by the proximity of the iron. A weak magnet is capable of receiving a temporary induction of a contrary magnetism from the action of a more powerful one, its north pole becoming a south pole on the approach of a stronger north pole; but the original south pole still retains its situation at the opposite end, and restores the magnet nearly to its original condition, after the removal of the disturbing cause.

To explain the phenomena of magnetism, Æpinus suggested the following hypothesis. He imagined that there must exist a fluid capable of producing all the phenomena of attraction and repulsion, and with a subtilty so great as to penetrate the pores of all bodies; and also of an elastic nature, its particles being repulsive of each other. At the same time he imagined a mutual attraction between the magnetic fluid and iron, or other ferruginous bodies. According to this hypothesis, iron and all ferruginous substances contain a quantity of magnetic fluid which is equally dispersed through their substance, when those bodies are not magnetic; in which state they show no attraction or repulsion towards each other, because the repulsion between the particles of the magnetic fluid is balanced by the attraction between the matter of those bodies and the said fluid, in which case those bodies are said to be in a natural state; but, when in a ferruginous body the quantity of magnetic fluid belonging to it is driven to one end, then the body becomes magnetic, one extremity of it being now overcharged with magnetism and the other extremity undercharged. Bodies thus modified, or rendered magnetic, exert a repulsion between their overcharged extremities, in virtue of the repulsion between the particles of that excess of magnetic fluid, which is more than overbalanced by the attraction of their matter. There is an attraction exerted between the overcharged extremity of one magnetic body and the undercharged extremity of the other, on account of the attraction between that fluid and the matter of the body; but, to explain the repulsion which takes place between their undercharged extremities, we must either imagine that the matter of ferruginous bodies, deprived of its magnetic fluid, must be repulsive of its own particles, or that the undercharged extremities appear to repel each other, only because either of them attracts the opposite overcharged extremities, both which suppositions are embarrassed with difficulties. A ferruginous body, therefore, is rendered magnetic by having the equable diffusion of the magnetic fluid throughout its substance disturbed, so as to have an overplus of it in one or more parts, and a deficiency of it in the remainder, and it remains magnetic as long as its impermeability prevents the restoration of the balance between the overcharged and undercharged parts.

The distinction between conductors and non-conductors is, with respect to the electric fluid, irregular and intricate: but in magnetism the softness or hardness of a ferruginous body constitutes the main distinction. And it is well known that magnetic effects are produced by quantities of iron incapable of being detected either by their weight or the most delicate chemical tests. M. Cavallo found that a few particles of steel, adhering to a hone on which the point of a needle had been slightly rubbed, imparted to it magnetic properties; and M. Coulomb has observed that there are scarcely any bodies in nature which do not exhibit some marks of being subjected to the influence of magnetism, although its force is generally proportional to the quantity of iron which they contain, as far as that quantity can be ascertained. Dr. Young considers a single grain sufficient to make twenty pounds of another metal sensibly magnetic.

The *loadstone*, or natural magnet, is a heavy iron ore, and is found in large masses in every quarter of the globe.

Three very large loadstones have been brought from Moscow to this country, and an account of them read before the Wernerian Society, by Mr. Deuchar. The largest of these natural magnets weighs more than 125 lbs., and measures in length ten inches and three quarters, in breadth eight and a half, and in height nine inches and a half. When first examined it supported 163 lbs.; but, by gradually increasing the weight, it was afterwards brought to support 165 lbs., exclusive of a connecting iron and supports of 40 lbs. The weight of the second loadstone had not been taken previous to fitting on the armature, but it was supposed to be nearly half that of the large one, and it supported above 80 lbs. These natural magnets were brought to this country in the same vessel, and it appeared probable that the corresponding poles had been placed together, as those of the weakest had been reversed.

There are some important circumstances which require attention, in order to enable us to ascertain the best method of constructing artificial magnets.

The nature of the body must be adapted to the power which is to render it magnetic; remembering that soft ferruginous bodies both acquire and lose magnetism more easily than those which are harder.

Several magnets are much preferable to a single one, for the purpose of communicating magnetism, in the application of which it must be remembered that the south pole of the magnet produces a north pole in the part of the ferruginous body to which it is first applied, while the north pole of the magnet produces a south pole.

If it be required to construct a strong magnet, when the operator has either no magnet at all or a very weak one, he must proceed gradually. It being impossible for a hard and large steel bar to receive any sensible degree of magnetism from the action of the earth, or of any other weak magnet, the operator must begin with giving magnetism to several small and soft steel bars, impregnating one at a time by means of the weak magnet, or, if he have no magnet, by means of one or more iron rods properly situated, which in that case are real though weak magnets. Then, by joining in a proper manner the small steel

bars already made magnetic, he may communicate a stronger power to larger and harder steel bars.

Should the experimentalist possess several magnets, he may materially facilitate the process by adopting the arrangements represented at *figs.* 1 and 2, *Plate* I., MAGNETISM. In the first figure four bars may be magnetized by two possessing the magnetic influence. These are to be drawn, with their opposite poles in succession, over the former series, commencing in the centre. In the second arrangement double sets of bars are used, forming a species of horse-shoe magnet; and the weight and mass of iron serve the double purpose of steadying the bars and increasing the facility with which they acquire magnetism.

Mr. Michell's method of making magnets may be thus described:—Prepare a dozen bars of steel, of about an ounce and three quarters weight each, six inches long, and half an inch broad: let these be hardened by immersion into water at a red heat. The size and shape of the bars may be varied at pleasure, provided that the length be proportioned to the thickness. The best sort of steel is that which has no veins of iron in it, and Mr. Michell found the common blistered steel at least equal to any other. In order to preserve the bars, they must be placed in a box furnished with two pieces of iron, about an inch long each. These pieces of iron may be about a quarter of an inch square, and should be filed perfectly smooth on the sides. Against these are to be placed, with their edges towards them, the twelve magnetical bars, six on one side, with their south or north poles one way, and six on the other side, with the same poles the contrary way. It is necessary to observe that these bars should be introduced in pairs, or single magnets on either side; for if two only be left with their poles of the same denomination the same way, without one or more on the other side to counterbalance their effects, they will injure each other. In order to make the marked ends of these bars south poles, and the other ends north poles, place six of them in a line north and south, bringing the unmarked end of one to touch the marked end of the next throughout, the marked ends lying towards the north, which will be some advantage to them. Then take an armed magnet, and placing it with both poles upon one of the bars, the north pole towards the marked end, which is to be a south pole, and the south pole towards the unmarked end, which is to be a north pole, slide it backwards and forwards from end to end of the whole line of bars three or four times, taking care that they all touch. Then, taking it off, remove the two endmost bars into the middle, and pass over them again three or four times. Having thus touched the bars, it will not be improper to turn them with the other side uppermost, and to magnetize again on that side as before, omitting the endmost bars, till they are removed into the middle, when they must undergo the same process.

Professor Steinhauser has ascertained that if by the process of Canton we unite, in the form of a square, two steel bars, and two contacts of iron, it is better to operate by the double touch in a circle than by a motion backwards and forwards. Again, when we combine these bars in a square, the force of that which we wish to magnetize ought to increase in proportion as the other magnet has become more energetic. In magnetizing horse-shoe magnets, it is much more advantageous to place two of these bent bars with their friendly poles so situated as that the magnetic circle be completed; and that we should then touch circularly, with the magnet destined to communicate the power. When the two horse-shoe bars are separated, they lose usually a considerable part of their force, if we do not previously decompose the great circuit into two smaller ones, by applying each contact to its curved magnet before the separation. In this way, the two separated magnets lose little or nothing of their power; and two may be touched in the same time that one is on the usual plan. By conforming to these rules, Professor Steinhauser has succeeded in making magnets of extraordinary power, in the least possible time.

Among artificial magnets, those which are bent into such a form that the two ends nearly meet, and therefore called horse-shoe magnets, are reckoned the most powerful. To render such a shaped piece magnetic, place a pair of magnetized bars against the ends of the horse-shoe, with the south end of the bar against that of the horse-shoe which is intended to be north, and the north end of the bar to that which is to be the south, the lifter, of soft iron, to be placed at the other end of the bars: also rub the surfaces of the horse-shoe with the pair of bars disposed like the legs of compasses when a little open, or with another horse-shoe magnet, turning the poles properly to those of the proposed magnet, and being careful that these bars never touch the ends of the straight bars. To prevent a sudden separation of the bars from the horse-shoe, which would considerably diminish the force of the latter, slide on the lifter, or support, to the end of the horse-shoe magnet, but in such a manner that it may not touch the bars; they may then be taken away, and the support slid to its place.

The following mode of making strong magnets, by percussion, was invented by Captain Scoresby, and published in the Philosophical Transactions for 1822. He observes—"The strong magnetizing effects of percussion on soft steel induced me to apply this property to the formation of magnets. For this purpose, I procured two bars of soft steel, thirty inches long and an inch broad; also six other bars of soft steel, eight inches long and half an inch broad, and a large bar of soft iron. The large steel and iron bars were not, however, absolutely necessary, as common pokers answer the purpose very well; but I was desirous to accelerate the process by the use of substances capable of aiding the developement of the magnetical properties in steel. The large iron bar was first hammered in a vertical position; it was then laid on the ground, with its acquired south pole towards the south; and, upon this end of it, the large steel bars were rested while they were hammered; they were also hammered upon each other. On the summit of one of the large steel bars, each of the small steel bars, held also vertically, was hammered in succession; and, in a few minutes, they had all acquired considerable lifting powers. Two of the smaller bars, connected by two short pieces of soft iron, in the form of a parallelogram, were now rubbed with the other four bars in the manner of Canton. [This process is, to take two of the four bars, and place them together so as to make a double bar in thickness, the north pole of one even with the south pole of the other, the remaining two being put to these, one on each side, so as to have two north and two south poles together. Separate the north pole from

the south pole at one end by a large pin, and place the bars perpendicularly, with that end downwards, on the middle of one of the parallel bars, the two north poles towards the south, and the two south poles towards its north end; slide them backward and forward three or four times the whole length of the bar, and, removing them from the middle of this, place them on the middle of the other bar, as before directed, and go over that in the same manner; then turn both the bars the other side upwards, and repeat the former operation. This being done, the two bars that have been thus treated are to change places with two of the touching bars, which are to be subjected to the same process, and so with the two other touching bars.] These were then changed for two others, and these again for the last two. After treating each pair of bars in this way a number of times, and changing them whenever the manipulations had been continued for about a minute, the whole of the bars were at length found to be magnetized to saturation, each pair readily lifting above eight ounces. In accomplishing this object, I took particular care that no magnetic substance was used in the process. All the bars were freed of magnetism before the experiment, so that none of them, not even the largest, produced a deviation of five degrees on the compass at three inches distance. Any bars which had been strongly magnetized, and had had their magnetism destroyed or neutralized (either by hammering, heating, or by the simultaneous contact of the two poles of another magnet placed transversely), I always found had a much greater facility for receiving polarity in the same direction as before than the contrary. Hence it generally happened that one blow with the original north end downwards produced as much effect as two or three blows did with the original south end downward." The correspondence between magnetism and electricity, in many of their phenomena, has, as we have already stated, led philosophers to refer both to a common principle.

The power of a magnet, and of iron or steel impregnated with the magnetic virtue, may be impaired by long lying in a wrong position, with regard to the earth or with respect to each other. Thus, if two magnets be placed so that their contrary poles may be contiguous, they will preserve one another's power; but if the north pole of one be placed near the north pole of the other, and the south near the south, then they will entirely destroy, or diminish each other's magnetism; and, if their original powers were very unequal, the polarity of the weaker magnet will be changed by the action of the stronger one.

In general, the same means which facilitate the communication of magnetism, when pieces of iron, &c., are properly situated with respect to the poles of the earth, or of other magnets, will likewise facilitate the loss of magnetism when the magnets are improperly situated; thus a red heat destroys in a great measure, or entirely, the power of a magnet. A steel bar, strongly magnetic, will have its power much diminished by being repeatedly struck between two stones, especially if it be struck standing in a direction perpendicular to the magnetic meridian. A bar of hard iron, which has acquired some degree of permanent magnetism, by being made red-hot and then cooled in the direction of the magnetical line, will have that power destroyed, or much diminished, by a few blows on its middle.

The directive power of a magnet is extended to a greater distance than its attractive power; for instance, if a magnet be freely suspended, another magnet properly situated within a certain distance of the former will turn it out of its ordinary direction; yet the degree of attraction exerted by these magnets against each other is not sensible at that distance, which may be easily tried by fixing one of the magnets to the scale of a balance. The reason of this property is, that the directive power depends both upon the attraction of the poles of different names and on the repulsion of those of the same name; whereas the attraction takes place only between poles of different names. In order to render this view of the matter more intelligible, we may imagine a magnetic needle freely suspended, and placed within the influence or sphere of action of a magnet. In this disposition, suppose that the north pole of a magnet attracts the south pole of a magnetic needle with a force equal to ten grains, and, as the attraction between poles of different names is nearly equal to the repulsion between poles of the same name, it follows that the same north pole of the magnet repels the north pole of the magnetic needle with a force equal to ten grains: but these two forces both concur in altering the direction of the needle; therefore, the endeavour of the magnet to turn the needle's direction is equal to twenty grains; whereas the attraction, or the force by which the needle is drawn towards the magnet, is only equal to the difference between the two above-mentioned opposite forces, which difference arises from the pole of the magnet being nearer to one than to the other of the poles of the needle. The same reasoning may be applied to the action between the south pole of the magnet and the suspended needle.*

The most remarkable phenomenon of the magnet, in relation to the earth, is the variation of the magnetic meridian in most parts of the globe, upon which depends the declination of the needle. Accurate observation of this phenomenon has ascertained the following facts:—There are certain points on the earth where no declination exists. The lines formed by their series, however, do not coincide with the geographical meridians; but, on the contrary, deviate from them very irregularly. According to the most recent observations, there exists a line without declination in the Atlantic Ocean, between the old and the new world. It intersects the meridian of Paris at a southern latitude of about 65°; thence it mounts to the north-west, to about 35° west longitude from this meridian, or 32° 39′ 37″ from Greenwich, as high as the latitude of the coast of Paraguay; after which, becoming again almost north and south, it skirts the coast of Brazil, and proceeds to the latitude of Cayenne. Then, turning suddenly to the north-west, it takes the direction of the United States of America, and thence proceeds to the northern parts of that continent, which it traverses in the same direction. The position of this line on the globe is not immutable; at least for a century and a half it has been tending considerably from the east to the west. It passed London in 1657, and Paris in 1664. Thus, in its present direction, it has traversed in the latitude of these places nearly 80° of longitude in 150 years. But there is no doubt that this change is not uniform. It is even very unequal in different parallels. In the

* See "*Manual of Natural Philosophy*," by the Editor of this work.

West Indies, for example, the declination of the needle has hardly varied for 140 years. In general, the slowness of this movement leaves it uncertain whether it is constantly progressive or whether it must continue in any particular direction. The very accurate observations habitually made in several observatories of England and France have appeared to indicate, for some years, a commencing retrogradation towards the east; but, even in the years 1790 and 1791, a similar retrogradation had been observed, which did not, however, continue.

The very exact measures of the inclinations or dip of the needle made at different periods, by Gilpin and Cavendish, in London, have proved that this element is also variable, though much less so than the declination. The inclination was, at London, in 1775, 72° 30′; in 1805, 70° 21′. This result has been confirmed in France, by the observations of Humboldt. It has been also proved, in a still more striking manner, by the successive measures of the inclination made by different navigators, between 1751 and 1792, at the Cape of Good Hope, which indicate, during this time, a progressive increase of inclination amounting to 5°. There is another line without declination, almost opposite to the preceding, which beginning in the great Southern Ocean, and running constantly in a north-western direction, cuts the western point of New Holland, traverses the Indian Ocean, enters the continent of Asia at Cape Comorin, and thence, passing through Persia and Western Siberia, ascends to Lapland. This line, however, divides near the great archipelago of Asia, and gives rise to another branch, which, running almost directly north and south, passes this archipelago, crosses China, and runs into the eastern part of Siberia. The two branches which intersect this line either experience no change of place or move with much slowness. The declination of the needle does not appear to have varied sensibly for 140 years at New Holland. Indications of a fourth line without declination were observed by Cook in the South Sea, towards the point of greatest inflexion of the magnetic equator. On the other hand, the points where the greatest declination of the needle has been observed are in high latitudes north and south. The greatest observed by Cook in the southern hemisphere was at 60° 40′ of latitude, and 91° 24′ 37″ west from Greenwich. In the northern hemisphere, where the magnetic pole has been much more nearly approached, much greater declinations have been observed, amounting, in fact, to nearly 90° west. If the magnetic pole had been crossed, the north pole of the needle would have been turned to the south, and, directly over the pole, its direction would have been vertical, and of course it would have had no horizontal direction. It appears, therefore, that the horizontal direction will be very weak when the dip or inclination is great; so that a very slight extraneous influence, such as the iron on ship-board, may render the compass useless.

Besides these variations, others occur daily, and others according to the seasons. From eight o'clock A.M., the declination increases until about three o'clock; then it decreases until eight o'clock P.M., and remains unaltered until eight A. M. The amount of these daily deviations is the greatest from April to July, when it is from 13′ to 16′; in the other months, it is from 8′ to 10′. The direction of the needle is said to be affected by approaching earthquakes, or eruptions of volcanoes. If a needle stands in the magnetic meridian, and is displaced by foreign power, it returns, when the power ceases to act, to its former situation by a series of oscillations. The time of an oscillation, in the case of the same needle, has a certain relation to the magnetic power of the earth, and serves as a measure of it, in a similar way as the oscillations of the pendulum serve for the measurement of the degrees of gravity. Humboldt found that a needle which, in Paris, made 245 oscillations in ten minutes, made, in Peru, but 211 in the same time, which would give the proportion of the magnetic power of the earth at Paris to that in Peru nearly as 135 : 100. On the other hand, according to Gay-Lussac, an elevation of 3532 toises (about 22,600 feet) over the level of the sea (in a balloon) showed no influence upon the magnetic power. The number of the oscillations, and of course the intensity of the magnetic power of the earth, always diminish in approaching the magnetic equator and increase in approaching the magnetic pole.

Another remarkable and evident manifestation of the influence of the magnetism of the earth upon the needle is the inclination or dip of the latter; i. e. a deviation from the horizontal plane, in northern regions of the north pole of the magnet, in the southern regions of the south pole of the magnet, and which, in the region of the magnetic equator, is 0, but increases towards the poles. This phenomenon, also, is subject to differences, because the magnetic equator of the earth cuts the terrestrial equator, and winds through it in a serpentine line, in which it reaches twice on each side its maximum of distance from the earth's equator, which is nowhere more than 40° 10′. The inclination, in the northern hemisphere of the earth, is the strongest between 70° and 80° latitude. Under 74° 47′, where Parry remained during the winter, the inclination amounted to 88° 43′ 45″. The cause of all these phenomena is as yet unexplained. That there are great magnets in the earth, which move periodically, or (according to Professor Steinhauser) that an interior planet (Minerva) revolves round the centre of the earth once in 440 years, and thus produces the magnetic phenomena on the surface, or that (as Sander supposes) these are to be ascribed to a magnetic planet on the other side of Herschel, completing a revolution only once in 1720 years, may be matter of interesting speculation, but can hardly be looked on as any thing more.

It had long been doubted whether any real analogy could be traced between light and magnetism; that problem is now, however, solved by Dr. Faraday's experiments. The only apparatus which serves to show on a large scale the identity which exists between light and magnetism is now placed in the National Gallery of Practical Science. It is delineated in *figs.* 3 and 4, *Plate* II., MAGNETISM, and the same letters refer to both figures. This instrument is of the horse-shoe form, and is composed of twelve sheer-steel plates, *aa*, each twenty-eight inches in length from the poles to the centre edge. At the greatest width of the curve the horse-shoe is seven inches across, and the extremities of the poles, *b*, *c*, are an inch and a half asunder. The keeper, or lifter, *d*, which is made of the purest soft iron, is five inches in length, two inches and a half wide, and one inch thick. Around the middle of the keeper, and occupying with its lower section the space between the poles, is a wooden winder, having about 100 yards of common threaded bonnet-wire, from which the

two ends, *e, f*, composed of four lengths of the wire twisted together, are carried out. One of the twisted ends passes beyond each end of the keeper, and rests upon the respective poles of the magnet *b, c*. A short lever, *g*, placed in a frame, is so attached to the winder and keeper as to admit of their being forced up by the hand applied to the longer end of the lever. Every time this is effected a brilliant coruscation of light is produced at the end of the wire. The sparks thus elicited will ignite inflammable bodies, and the whole experiment proves to a demonstration the intimate analogy which exists between light, magnetism, and heat.

Under the article ELECTRO-MAGNETISM our readers will find a series of experiments intended to illustrate the phenomena which result from combining voltaic electricity with the magnetic powers. We now revert to the subject to point out a mode of preparing a horse-shoe magnet of prodigious powers from a piece of common soft iron. The apparatus we are about to describe is the only one yet constructed on so large a scale, combining a perfect scientific arrangement with enormous magnetic power. It is represented at *figs*. 1 and 2, *Plate* II., MAGNETISM, and consists of a bar of soft iron bent into the form of a horse-shoe, and weighing about thirty-four pounds: it is surrounded with systematic reduplications of copper wire. There are ten series of the wire, each containing ninety feet. The commencing extremities are all soldered to a thick wire, *b*, while those terminating are likewise affixed to another wire, *c*. This arrangement affords the means of transmitting an electric current through the whole series of wires at the same time with great facility. The voltaic battery, *d*, employed to make the magnet, is very small, and composed of a double concentric cylinder of copper, and a movable cylinder of zinc, *e*. By the aid of this apparatus the horse-shoe of soft iron may in an instant be converted into a magnet capable of supporting a weight of 500 lbs. attached to the scale *f*, beneath. The whole is supported by a strong triangular stand, *g*.

The compass furnishes a most important application of magnetism to practical science. A common compass, in its early form, is delineated at *fig*. 4, *Plate* I., MAGNETISM. It consisted of a cylindrical box, *b*, supported by two centres or pivots resting in the uprights *h, h*. In the middle of the box was placed the compass card, turning freely on a centre: motion was communicated to the card, shown also at *fig*. 3, by the bar magnet, *k l m*. Now this arrangement admitted of motion but in one direction; but in the form delineated at *fig*. 2 a double motion is produced, and, whatever be the direction of the supporting box, the compass needle must of necessity hang flat.

In the *azimuth* compass sights are added, shown at F, G, by which a star or any other distant body may be observed. The whole apparatus turns on the foot E, to which are attached the uprights C, D. B represents the ring which, by means of two screws, supports the central box. The compass card is shown at H. The azimuth compass will also answer for a steering compass.

MAGNETISM, ANIMAL. This fanciful science appears to have originated with Mesmer and other German illuminés, who believed that the power of a common magnet might be made to act on the human frame. They also believed that this power once imparted to a professor might afterwards be communicated to others without the agency of ferruginous bodies. So much of interest has lately been excited by the attempts to revive the long-exploded doctrines of animal magnetism that it may be advisable to present our readers with a brief outline of its history, and the phenomena said to be elicited. The principal means used to produce the effects of animal magnetism are such as touching and stroking with the hands, breathing on a person, fixing the eyes upon him, &c.; the magnetized person must always be of a weaker constitution, and, if possible, of a different sex, from the magnetizer; and it is indispensable that he should be of a disposition to believe without doubting. The phenomena themselves consist partly in bodily sensations (for instance, chilliness, heaviness, flying pains, oppressions, &c.), partly in a diminished activity of the external senses, partly in fainting, convulsions, sleep, with lively dreams, in which the magnetized person is transported to higher spheres, observes the internal organization of his own body, prophesies, gives medical prescriptions, receives inspired views of heaven, hell, purgatory, &c., reads sealed letters laid on his stomach, and, when awakened, is totally unconscious of what he has experienced. At the same time, the soul becomes so elevated and refined that the magnetized individual has an instinctive perception of the presence of the impure, and falls into fits at the approach of disbelievers in animal magnetism, and of all who investigate it by the rules of ordinary reason. Hence it is necessary to keep sceptics at a distance, when it is desired to witness the highest phenomena.

The magnetized person shows a remarkable connection with, and dependence on, the magnetizer, tasting what he eats, smelling what he holds before his nose, and no one else can bring him back from the magnetic state. In the sequel we shall give a brief exposition of the phenomena, as stated by Kluge, who appears, in his *Attempt at an Exhibition of Animal Magnetism*, to have given the fullest account of them. A scientific investigation of the influence which we are considering is hardly consistent with the views entertained of it by its adherents; for they maintain that mere reason cannot approach nor conceive this great mystery; it can be rightly apprehended only by a believer. The whole of the effects of animal magnetism seem to be ascribable to a heated imagination, to an excitement, half spiritual, half sensual, and to a morbid sensitiveness. The history of animal magnetism may be thus briefly detailed:—Anthony Mesmer, in 1772, attempted cures with the mineral magnet, and excited some sensation in Vienna, but at length declared that not the magnet, but a mysterious power in his own person caused the effects ascribed to the magnet, and that this power was related not only to the magnetic power, but to the attraction dispersed throughout the universe. But, a fraud which he attempted (the pretended restoration of sight to a girl) having been discovered, he proceeded, in 1778, to Paris. The great supporters of animal magnetism have recently been Kieser in Jena, and Wolfart in Berlin; the former explains the phenomena by the striking difference between life by day and life by night, both in the case of animals and vegetables; the latter adopts the mystical jargon of Mesmer. In 1820, the Prussian government caused a prize to be offered for the best treatise on this subject, but it was subsequently withdrawn.

We now proceed to an outline of the phenomena of animal magnetism, as described in Mr. Kluge's work. The phenomena, in the case of the magnetizer and the magnetized, are as follows:—

1. *The magnetizer.*—He is generally capable of producing a positive effect only so far as he possesses a higher degree of energy and vital power than the person magnetized. The man generally effects more than the woman. If the magnetizer is the weaker person, there either takes place no apparent effect, or the effects are inverted, viz. the positive effects are apparent in him, and the negative in the person magnetized. If the magnetizer undertakes the manipulation of a susceptible subject, he always feels a glow, and the sensation of a gentle flow from his palm, and particularly from the points of his fingers. If he covers his hands with silk gloves, or other electric bodies, he has not this latter feeling, and his operation is fruitless; but linen or leather gloves do not prevent the effect. After a successful operation, the magnetizer feels a general unpleasantness, a weakness in the digestive system, and, in general, a loss of power, in proportion to the susceptibility of the magnetized subject, and the duration or frequency of the operation. If the magnetizer, during the operation, is isolated with the magnetized subject by electrical bodies, his loss of power is less, but the effects which he produces are stronger.

2. *Phenomena in the person magnetized.*—The phenomena produced in the subject by a positive operation are of a double kind; either they have reference to the general state of the body, are then not periodical, but last during the whole cure, and therefore may be considered as the general effects of magnetism; or they have reference only to particular activities of the organization. Of the former sort are, 1. a general awakening and strengthening of the vital powers in all parts of the body, without considerable excitement, as well in the systems of the nerves and muscles, the vascular and digestive system, as the organs of secretion; 2. a mild excitement over the whole surface of the body, by which every irregularity and local reaction is neutralized and the equilibrium restored; 3. a withdrawing of the heightened vital power from the suffering organs to others; 4. a diminution or total suppression of the excitement producing the morbid activity of the nerves. The magnetizer not only should have a stronger body than the person magnetized, but also a perfectly healthy one. He must have attained the maturity of his bodily powers, but must still be within the age of active life; the mind, too, must be sound and strong, in order to master the affections and passions, to have a living faith and a firm will, and thus to attain perfect control over this means of cure, as also over the patient.

The phenomena of animal magnetism have been divided into six degrees. Those of the first degree are generally the following: first, the feeling of a strong current from the head to the extremities, after which a higher degree of heat follows, easily observable by the thermometer, greater redness of the skin, with increased perspiration, and a feeling of ease and comfort throughout the whole body. In the second degree, the warmth increases, and appears to the patient to diffuse itself from the stomach, as if from a central point, over the whole body. The pulse becomes generally fuller and stronger, and the breathing easier and deeper. The patient feels a heaviness in the eyelids and an irresistible desire to close them. If he does close them, they seem to him cemented by the strongest power, and, during the remainder of the magnetic effects, it is impossible for him to open them. All the other senses, however, remain active, and their activity is often heightened. The patient knows therefore every thing which is done about him, though he is not always capable of speaking. At the close of the magnetic operation, he opens his eyes by himself, or with the assistance of the magnetizer, and feels generally strengthened and well. After this, the patient observes, sometimes, a shining appearance before his eyes, similar to repeated lightning, a pricking in the points of the fingers and toes alternately, a heaviness and coldness in the extremities, unpleasant feelings about the region of the stomach, sickness, violent shuddering, wish to cough, &c.

The particular signs often accompanying the third degree are, especially, swoons, convulsive tremblings, real convulsions, cataleptic and even apoplectic fits. This state generally begins with all the signs of an approaching drowsiness. Repeated yawning, stretching, heaviness of the eyelids, announce it. A deep sigh generally follows, after which the eyes close entirely, and a state begins similar to sleep, in which the patient seems to be deprived of all sensation and consciousness. In the fourth degree, the patient awakens, not from his sleep, but within himself, and regains his consciousness; he knows himself again, yet in a changed relation to surrounding circumstances. The external senses are either closed entirely, or their character is changed, and only the internal sense remains the same. The *somnambulist* (as he is called in this state), entirely awakened within himself, distinguishes with his eyes nothing but light and darkness, and not always even these, although, as is sometimes the case, the eyelids are open. The ball of the eye is either drawn up convulsively or stiff, the pupil widened and without sensation. Next, the sense of feeling is metamorphosed into that of seeing, so that the somnambulist can distinguish by it, not only the outlines of things, but also colours, with perfect precision. The region of the stomach becomes the central point of all sensation, and it is chiefly through this region that the sense of sight is supplied. The somnambulist, therefore, can ascertain the time perfectly well by a watch, closely held to the pit of the stomach. By repeated exercise, the patient obtains this faculty in a higher degree, and what originally appeared to him indistinct becomes very clear. Persons appear to him more distinct than inanimate subjects.

Hearing is likewise performed in this state by the pit of the stomach, and the sense of smell becomes sometimes so acute as to distinguish the different ingredients of compound scents. Objects which the person does not regard in a healthy and natural state have often very sensible and even dangerous effects on him when in a state of somnambulism. The vicinity of a living being, whom the patient perceives at a distance of from ten to fifteen paces, is generally very disagreeable to him. If persons whom he dislikes touch him, paleness and coldness occur in the parts touched, and convulsions are generally the consequence. Among inanimate subjects, metals have the most unpleasant effect. To the magnet the somnambulist is still more sensitive than towards other metals. Of every thing which has occurred to the patient during this period, what he has perceived

thought, said, or done, he has, when awaking, either no recollection or a very faint one; but, if he is brought again into this state, he recollects every thing very well.

In the fifth degree, the patient attains, by his heightened consciousness and the increased strength of his general feelings, to that internal self-contemplation by which he is able to investigate even the minutest parts of his bodily structure. By virtue of this accurate knowledge of his internal frame, the *clairvoyant*, as he is called in this state, not only determines very distinctly the seat and quality of his disease, but at the same time an instinct developes itself in him which makes him understand the means necessary for his cure. Besides mentioning the remedies, the *clairvoyant* also indicates the kind of magnetizing necessary, and thus directs his own cure. This deep insight is not limited to the *clairvoyant* alone, but extends to persons brought into magnetic relations with him, whose sensations are always communicated to him. Between the magnetizer and the *clairvoyant* this sympathy is the strongest and most remarkable. Very often the feeling of disease in the magnetizer is not only communicated to the patient, but the disease itself, which in some cases has continued after the patient was awakened. Affections of the soul also pass from the magnetizer to the *clairvoyant*. Sometimes this sympathy reaches such a height that it remains even when the parties are distant from each other. This magnetic sympathy may be still more heightened, and then the *clairvoyant* has a clear insight into the internal physical state of persons in a magnetic connection with him, just as he has of his own; can determine their disease, its course and future phenomena, and prescribe the means of cure accordingly. He insists that he perceives the diseased state of others precisely as his own, by the stomach. His language becomes more elevated than ordinary, and is marked by fire, spirit, precision. His perception is livelier and stronger, his thinking freer and deeper, his judgment quicker and more penetrating. He not only perceives the present, and the influence of external relations, much more distinctly than before, but penetrates also into the most distant period of past time.

There is an obvious inclination of patients for each other, if they are treated by the same magnetizer, and particularly if they are in a state of somnambulism at the same time. The patient who has attained internal clearness by the fifth degree penetrates, in the sixth degree, the darkness of external things, and attains a higher view of the whole of nature. With uncommon clearness he often distinguishes the secrets of the past, what is distant and unknown in the present, and the events of coming time. If the patient is asked how he knows all this, he generally answers that it is as if he were told of it by some other person, or that he feels it through the pit of the stomach. He is always fully convinced of the truth of what he thus acquires. In respect to the choice of proper remedies, the *clairvoyant* is less limited than before. In the former degree, it was necessary to put him into connection with another person, by intermediate bodies; but, in this degree, he can be in this relation with any distant person, if he knows him, or feels a lively interest for him, or even if the magnetizer, or any other person brought into connection with the *clairvoyant* by actual touch, knows the distant person, and thinks intently of him. The view of the *clairvoyant* extends even into the future condition of others. He attains to a higher, fuller life than he had before. The body seems to be intimately amalgamated with the mind, to be blended into the most harmonious union with it. The individual is removed from every thing coarse and sensual, and placed in a state of serene and elevated self-contemplation. The feeling of the greatest bodily comfort and purity of soul produces a serene peace within him, which indicates itself by the noblest feelings. In this state, which, according to the *clairvoyants*, borders on heavenly felicity, they are incapable of impurity, and even the guilty fancy themselves virtuous.

Such are the wonders of animal magnetism, of which our readers may believe much or little. The attention which the subject has attracted in Europe is our excuse for the length of this article. The footing which it has gained, and the effects which it has produced, strikingly exemplify the power of imagination. It would require too much space to describe all the various manipulations and other operations by which the patient is placed in the magnetic state.

MAGNITUDE, APPARENT. If straight lines be drawn from the extremities of a visible object to the centre of the pupil of the eye, the angle formed by them is called the *visual angle*, or the *apparent magnitude* of the object. This angle varies with the different distances of objects, being larger when they are near and smaller when they are remote. Hence our idea of the magnitude of any object depends not only upon its true dimensions, but also upon the angle under which we view it; and objects of very different dimensions will appear of equal magnitudes if the visual angles under which they are seen are equal. Thus, for instance, the sun and moon, though their diameters are vastly different, each subtend an angle of about a degree. Besides, numerous prejudices and optical illusions, which we can never overcome, modify our ideas of the magnitude of objects. One of the most remarkable examples of such involuntary deception is that which every one has experienced in looking at the moon: when it has just risen, it appears larger than when it has reached the zenith. In the horizon, we are apt to imagine it at a greater distance from us than in the zenith, because in the former case there are intervening objects with which we can compare it, but in the latter no such objects occur. If the moon be viewed through a telescope, or an open tube, so as to exlude the intervening objects, it will appear of equal magnitude in both cases, and the whole illusion will immediately vanish.

MAHOGANY; the wood of the *swietenia mahogoni*, a lofty and beautiful South American tree. The wood is hard, compact, reddish-brown, and susceptible of a brilliant polish. It is one of the best and most ornamental woods known, forming very elegant articles of furniture. It is brought principally from Honduras and the West Indies, from which places it is exported, in vast quantities, to Great Britain, the continent of Europe, and especially to the United States of America, where it is so abundant and cheap as to have brought into disuse many of the native kinds of wood, which otherwise would be highly esteemed in cabinet-making. The tree is of rapid growth, and its trunk often has a diameter of four feet. Mahogany-cutting constitutes a principal occupation of the British settlers in Honduras. Gangs of Negroes, consisting of from ten to fifty each, are employed in this work: one of their number is styled

the *huntsman*, and his duty is to traverse the woods in search of the trees. When these have been discovered, a stage is erected against each, so high that the tree may be cut down at about twelve feet from the ground. After the branches are lopped, the task commences of conveying the logs to the water's side, which is often a work of considerable difficulty. They now float down the current singly, till they are stopped by cables which are purposely stretched across the river at some distance below. Here the different gangs select their own logs, and form them into separate rafts, preparatory to their final destination. Mahogany now begins to be rare in St. Domingo, Jamaica, and the other West India Islands. It is said to have been introduced into this country about the year 1724.

MAIDEN is the name of an instrument of capital punishment, formerly used at Halifax, in Yorkshire, and in Scotland, which is the prototype of the French guillotine. The maiden is a broad piece of iron a foot square, sharp on the lower part, and loaded above with lead. At the time of execution it was pulled up to the top of a frame ten feet high, with a groove on each side, for the maiden to slide in. The prisoner's neck being fastened to a bar underneath, on a sign given the maiden was let loose, and the head instantly severed from the body.

MAIL, COAT OF; also called *habergeon*. There are two sorts—*chain* and *plate mail.—Chain-mail* is formed by a number of iron rings, each ring having four others inserted into it, the whole exhibiting a kind of net-work, with circular meshes, every ring separately riveted. This kind of mail answers to that worn on the ancient breast-plates, whence they were denominated *loricæ hammatæ*, from the rings being hooked together. The habergeon, or hauberk, resembled a shirt in make, and was thrown over the upper part of the body above the clothing; a collar was applied round the neck; and there was a hood, or net helmet, to cover the head. Sometimes the crown consisted of plates of iron instead of rings, and iron plates in like manner were sometimes clasped around the breast and back. In addition to these parts, there were trowsers of similar construction, and it is probable that the feet were defended by a guard of the same description. A knight armed with a combination of chain and scale mail is shown in the engraving beneath.

Plate mail consisted of small *laminæ* or plates, usually of tempered iron, laid over each other like the scales of a fish, and sewed to a strong linen or leather jacket. The plates were in general very numerous, small, and united so as to move freely without impeding the motion of the wearer. The plate-mail was much more cumbrous than the chain-mail, a complete suit of ring-mail, still in existence, weighing thirty-nine pounds, while one of plate weighs between seventy and eighty, and in many cases much more. The hands were defended by gauntlets, sometimes of chain mail, but more frequently of small plates of iron riveted together, so as to yield to every motion of the hand. Some gauntlets enclosed the whole hand as in a box or case: others were divided into fingers, each finger consisting of eight or ten separate pieces, the inside being gloved with buff-leather: some of these reached no higher than the wrist, others to the elbow. The thighs of the cavalry were defended by small strips of iron plate laid horizontally over each other and riveted together, forming what were called *cuissarts* or thigh-pieces. Of these, some entirely enclosed the thighs; others only covered the front of them, the inside, next the horse, being unarmed. They were made flexible at the knees by joints, like those in the tail of a lobster. Tassets or shirts, hooked on to the front of the cuirass, were used by the infantry. For the defence of the legs, there were a sort of iron boots, called *greaves*. Plates of iron, covering the front of the leg, were also frequently worn over the stockings of mail. The greaves commonly covered the leg all round; with these they had broad-toed iron shoes, with joints at the ancle. Boots of jack-leather, called *curbouly (cuir bouillé)*, were also worn by horsemen. The different pieces of armour covering the body were called, collectively, a *coat of mail;* and a completely armed cavalier of the sixteenth century is shown in the engraving. Armour gradually continued decreasing, both from innovations and from its utility being diminished, till, in 1690, most of the defensive armour throughout Great Britain was returned to the Tower, whence it had been issued.

MAIN-MAST; the chief or middle mast of a ship. It is divided into four unequal sections, viz. the *main-mast*, properly so called, which rises from the deck; the *main-top-mast*, immediately rising from the main-mast; the *main-top-gallant-mast*, just above the main-top-mast; and the *main-royal-mast*, which crowns the whole. The form of the main-mast, like that of other masts, is taper. Each division of the mast has its particular sail, to which it gives name, as the *main-sail, main-top-sail*, &c.; and its particular yard, as the *main-yard, main-top-sail-yard, main-top-gallant-sail-yard*, &c.; besides its separate head or top, as the *main-top, main-top-mast-head*, &c. The ropes, tackling, &c., of each section are named in a similar manner.

MAJOR, in *military affairs;* the lowest of the staff-officers; a degree higher than captain. There appear

to have been officers called *majors* as early as 1560 in the German and Spanish troops; they were then the assistants of the colonels. At present, they are generally the commanders of battalions. The French, however, abolished this degree during the revolution; they have now *chefs de bataillon*. Their *gros major* is a half-invalid officer, who commands the depôt of the regiment.

MAJOR; an epithet applied to that of the two modern modes in which the third is four semitones above the tonic or key-note. Those intervals which contain the greatest number of semitones under the same denomination are also called *major*; as a third, consisting of four semitones, instead of three only, is termed a *major-third*; a sixth, containing nine semitones, instead of eight, is called a *major-sixth*.

MALLEABILITY; a property of metals, whereby they are capable of being extended under the hammer. (See DUCTILITY.)

MALLEUS, in *anatomy*; a bone of the ear, so called from its resemblance to a mallet, and in which is observed the head, the neck, and handle, which joins the membrane of the tympanum. (See EAR.)

MALMSEY WINE is a sweet wine, made from a grape originally brought from Monembasia, a small town on the south-east coast of the Morea. The English call the place by its Italian name, *Malvasia*, and the French, *Malvoisie*; hence the name of the wine, *Malmsey (vin de Malvoisie)*. Much of the Malmsey now used is made from a grape grown on rocky ground in Madeira, exposed to the full influence of the sun. It is left to hang about a month later than the grapes used for the dry wines, and is not gathered until partially withered.

MALT is the preparation of barley from which ale, beer, and porter, are brewed, all which are generally denominated *malt liquors*. For this purpose, the barley is steeped in water for three or four days. It is then taken out and suffered to lie until it begins to sprout or germinate. As soon as this process has advanced sufficiently, its further progress is prevented by drying it in a kiln, heated by coal or coke. The grain is now become mellow and sweet, and, after having been crushed in a kind of mill contrived for the purpose, its saccharine and mucilaginous portions are extracted by boiling water. The liquor thus produced has the name of *wort*, which, having undergone the process of fermentation, and having been flavoured by the addition of hops, &c., constitutes ale or beer. What remains of the malt after brewing is called the *grains*, which are used for feeding horses and cows. The tax upon malt constitutes a very important item in the revenue. The following document forms part of a parliamentary paper published last session (1832).

		From Barley at 20s. 8d. per Quarter.	From Bear, or Bigg, at 16s. per Qr	Total.	Duty.
Half Year ending Apr. 5, 1830.	England .	2,318,516	. . .	2,318,516	2,395,800
	Scotland .	258,848	55,614	314,463	311,968
	Ireland . .	201,587	. . .	201,587	208,306
Half Year ending Apr. 5, 1831.	England .	3,030,001	. . .	3,030,001	3,131,001
	Scotland .	251,874	60,326	312,200	308,531
	Ireland . .	157,670	17,516	175,186	176,938

MANCHINEEL; a West Indian tree, celebrated for the poisonous qualities of the milky juice which abounds in every part of it. When a drop of this juice is applied to the skin, it causes the same sensation as a burning coal, and quickly produces a vesicle. The Indians use it for poisoning the points of their arrows, which preserve their venom for a long time. The workmen employed in felling these trees first build a fire round the trunks, in order to make the juice evaporate, and cover their eyes with gauze; but, notwithstanding these precautions, they are subject to be incommoded by the dust. The accounts, however, which represent it as dangerous to sleep in the shade, or to come in contact with the rain which has fallen upon this tree, are highly exaggerated. The inhabitants of Martinique formerly burnt entire forests of the manchineel, in order to free their dwellings from its presence. It is said that drinking copiously of sea-water is the best remedy, when a portion of this fruit has been swallowed. It grows in the West Indies, and other parts of tropical America, in the immediate vicinity of the ocean.

MANDOLINE; an instrument, the name of which is much more musical than its tones. The Italian name is *mandola*. It has four strings, belongs to the lute and guitar species, and is played with a quill as well as with the finger. There are also instruments of this kind with six or more strings, which, therefore, approach nearer to the nature of the lute. It is chiefly in use in Italy, and is pleasing when it accompanies the easy song of the country people. The strings are of steel or brass.

MANEGE, or MANAGE, is used to denote the art of breaking and riding horses, or the place set apart for equestrian exercises. Most horses are, by nature, extremely docile, and, when proper means are used with them, they are very well disposed to obey their masters. These ought, therefore, to endeavour, from the commencement, to acquire the confidence of the animal by kind and gentle treatment, and by avoiding all unnecessary severity. Some horses, indeed, are naturally vicious or obstinate, and must be occasionally punished; but the chastisement should be inflicted with judgment and discrimination. Spirit has been sometimes mistaken for vice, and many horses, not naturally vicious, have been rendered so by severity and injudicious treatment.

A horse's education may commence between the ages of two and three years, and it will greatly facilitate future operations if he has been housed during the winter. About this age, a halter or cavesson (a noose-band) should be put upon the foal, that he may become familiar with it. The groom, too, when he cleans the animal, should lift each of his feet, and strike them gently with a piece of wood or a hammer, after which he will readily submit to be shod when necessary. Next, before feeding, the groom should put a saddle on the back of the foal, and remove it again with great caution. After a while, the girth may be bound over the saddle, and the foal left to stand and feed. Every thing should be taught gradually and gently, to avoid the danger of rendering the animal timid or vicious. The horse should now be made to run at the end of a long rein, held in the hand, a noose-band being put on his nose, and a man following him, if necessary, with a long whip. This exercise should be performed with great gentleness and but little at a time, that the horse may not be fatigued, stupified, or discouraged. After he has acquired a firm, regular, and determined motion, he may be mounted. Only a trench or snaffle and cavesson should be used at first. The bit and bridle should not be introduced till the horse has been taught to carry his head high, and is free in his motions. A fine carriage is to be given to the horse by

bringing his head in such a position as to form a perpendicular line from his forehead to his nose, after which his head should be brought a little more inwards by pulling the inward rein gently and by degrees, and crossing the outward rein a little over, whereby he acquires the most beautiful position, and is better able to go through his exercises.

The natural paces of a horse are a walk, a trot, and a gallop, to which some horses, of themselves, add an amble. In a walk, a horse lifts two legs on a side, one after the other, beginning with the hind leg first; in an amble, two legs on a side at the same time; in a trot, two at the same time and keeps two on the ground crosswise. In galloping straight forward, the horse may lead with either fore leg, but, unless the hind leg on the same side follows it, the legs are said to be disunited; in this pace all four legs are off the ground at the same time. In galloping in a circle, the innermost fore leg should lead, or he is said to gallop false. The canter or hand-gallop is not considered as a natural pace: it is an easier gallop, in which the hand presses on the bridle, to restrain the speed. When the horse has learned to go forward freely, he should be exercised for some time in the manner above pointed out, first at a walk, and then at a trot. The trot is to render him supple in the shoulders, and to make him go with a free, united, and determined action, for which no pace is so well adapted. A horse light in hand should be put to the extended trot. When he goes freely, he should be brought together by degrees, until he bends his legs, and goes unitedly and equally. If, when kept together, he slackens his pace, he should be pushed forward, though still kept gently in hand. If he be heavy in hand, he must be thrown back on his haunches, to shorten his steps and collect his strength. When he has been brought into a proper position, he should be made still more supple in the shoulders, by the lesson of the *épaule en dedans*, which is, perhaps, the most important lesson of any. For this purpose, the bend of the neck must be procured in the manner formerly described. When he has been ridden in this position till he goes with perfect steadiness and freedom, the rider should walk him forwards to the right, and endeavour, almost imperceptibly, to place him so that the hinder feet keep the straight line of a wall, while the fore feet come out about a foot and a half inwards, towards the centre. This must be effected by crossing the outward rein, in the right hand, towards the left, a little backwards, which compels the horse to bring the right shoulder forwards, and to cross the inward leg over the outward. The rider should also press his right leg to the horse's side, which brings in his shoulders. The same crossing should afterwards be effected in the hinder legs, by bringing in the fore legs, &c.

In every exercise, the rider should avoid all unsettled motion and wriggling with the legs. Every thing should be effected by the hands, and the legs should be used only in case of necessity. After the horse has been taught to go freely on this lesson to the right, the rider may change to the left. The horse should be ridden in the same manner across the course, and exercised alternately to the right and left, until he crosses his legs with perfect facility. He may then be taught to back. Whenever the rider stops, he should back a few paces, and then put the horse forwards by little at a time. In backing, if he attempts to rear, push him out immediately into a full trot.

Bits should not be used until the previous lessons have been well practised with the trench or snaffle. Horses should be taught to leap by degrees, beginning with small leaps. The rider must keep his body back, raise his hand a little, to help up the fore parts of the horse, and be very attentive to his balance, without raising himself in the saddle, or moving his arms. Horses should first leap standing, then walking, then trotting, then galloping. A low bar, covered with furze, is best to begin with, as it pricks the legs of the horse if he does not raise himself sufficiently, and prevents him from acquiring the dangerous habit of touching. In order to teach horses to stand fire, and to bear the sound of drums and other noises, they should be first accustomed to them in the stable at feeding time. All other things necessary to make a horse steady may be easily taught by good judgment, patience, and gentleness. Of all bad tempers and qualities in horses, those which are occasioned by ignorant riders and harsh treatment are the most common and the worst. For mounting, &c., see HORSEMANSHIP.

MANGANESE, in the condition of an ore, had been used in certain arts before its nature as a distinct metal was known. Scheele and Bergman, from an examination of this ore, inferred that it chiefly consisted of the oxide of a peculiar metal. To obtain the metal pure, the mineral is dissolved in muriatic acid, the oxide of iron precipitated by ammonia, and the solution evaporated to dryness; the residuum, after heating to expel the muriate of ammonia, is pure oxide of manganese, which is made into a paste, with a small quantity of oil and charcoal, and exposed, in a crucible, to the most intense heat of a powerful wind-furnace; the result of the process is the manganese in the metallic form. Hydrogen gas, passed over the heated oxide, will also reduce it. The metal is of a white colour, with a shade of gray, having a moderate lustre, which tarnishes, however, on exposure to the air. Its texture is granular; it is brittle and hard; specific gravity, eight; heated in oxygen or chlorine it takes fire, and forms an oxide or chloride.

The *protoxide* of manganese is best obtained by transmitting hydrogen gas over the deutoxide, peroxide, or carbonate of manganese, ignited by a spirit-lamp, in a glass tube. It is permanent in the air, but when heated to 600° Fahr. it absorbs oxygen very rapidly, and at a low red heat it passes from its green colour, almost instantaneously, into black. It consists of manganese 76.82, and oxygen 23.18. It is the basis of all the proper salts of manganese, which when pure are colourless.

The *deutoxide* is prepared by exposing the nitrate or peroxide of manganese, for a considerable time, to dull ignition. When heated with sulphuric acid, oxygen gas is extricated with effervescence, and a protosulphate results. The *peroxide* exists native and crystallized in perfect purity. It may be artificially prepared, by heating the dry proto-nitrate till a uniform black mass be formed, which must be pulverized, washed while hot with strong nitric acid, and again gently calcined with constant stirring. It contains twice as much oxygen as the protoxide.

The *red oxide* is formed by exposing the nitrate or peroxide of manganese to a white heat, out of the influence of smoky vapours. It has a brownish-red colour when cold, and is nearly black while warm. It consists of two proportionals of the protoxide and one of the peroxide. It dissolves in small quantities in dilute sulphuric acid, without disengagement of oxygen gas, forming an amethyst-red liquid. On heating this solution, or the red oxide, oxygen is evolved, the colour disappears, and a proto-sulphate remains. Strong muriatic acid dissolves the red oxide into a coloured solution, which exhales chlorine, and gradually passes into a colourless proto-muriate.

A compound, possessing very singular properties as respects the colours to which it gives rise when in solution, and which from this circumstance has received the fanciful name of the *mineral chameleon*, is formed by fusing together the native black oxide of manganese and potash, or its carbonate, which, on being dissolved in water, communicates to it a greenish-blue colour. The solution, on standing a little time exposed to the air, lets fall the oxide of iron which it contains, and the colour becomes blue; and, on the addition of warm water, or an acid, the solution assumes a violet colour, from which it soon passes to red, brown, black, and lastly becomes colourless. When the colour of the solution is bluish-green, the manganese is believed to be united with the alkali, in the condition of manganeseous acid; and when it is red the manganese is supposed to be in the state of manganesic acid. The manganeseous acid is, according to this view, very easy of decomposition. When combined with potash, it forms a submanganesite; and whenever the potash is saturated, or its action weakened, the manganeseous acid is decomposed into deutoxide of manganese and manganesic acid; hence the changes of the solution.

According to the experiments of Frommherz, the manganesic acid has a dark carmine-red colour, tastes sweetish at first, but afterwards bitter and astringent, and is destitute of smell. When heated with care, it volatilizes. It is decomposed by a current of hydrogen gas, the hydrogen acids, carburet of sulphur, the metals, and all organic substances. The salts of manganese are usually prepared from the black peroxide. The acids, which have a strong affinity to the protoxide, expel the excess of oxygen, especially if their action is aided by heat; with other acids, it is necessary to add a little carbonaceous matter, as sugar, to abstract a portion of oxygen from the peroxide. The principal salt is the *sulphate* of manganese, which may be thus prepared: the acid acts very slowly on the metal itself; if diluted, however, it acts more quickly, hydrogen gas being disengaged, of a fetid smell. The solution, when concentrated, is of a rose colour; when obtained neutral, it affords, on evaporation, granular crystals of a reddish colour, transparent and soluble. Its taste is styptic and bitter, and it is very soluble in hot water.

Nitrate of manganese may be formed from the carbonate. It is very soluble, and difficult to crystallize. It may also be formed by making the acid act on a mixture of peroxide of manganese and sugar or gum, the vegetable substance serving to reduce the manganese to the minimum of oxidizement, while much carbonic acid is evolved. The muriatic acid is equally incapable of combining directly with the black oxide, but, according to the usual law, it de-oxidates it: one part of the muriatic acid is decomposed; its hydrogen combines with the excess of oxygen of the black oxide to form water; the chlorine, the other element of this portion of the acid, is evolved; and the rest of the muriatic acid unites with the protoxide of manganese to form the *muriate*. The solution of muriate of manganese is of a rose colour when concentrated, and affords, by evaporation, small crystals of a pale rose colour, which are four-sided tables; they are deliquescent, very soluble in water, and, by a red-heat, are converted into a red chloride.

Carbonate and *phosphate* of manganese may be formed by double decomposition, being thrown down in the state of insoluble precipitates. The salts of manganese suffer decomposition from the alkalies, which precipitate the oxide: they are not decomposed, however, by the inflammables, or the other metals, which is a proof of the affinity of manganese to oxygen. Oxide of manganese combines with those earths which are capable of vitrification and with their compounds, and communicates to the glasses which they form a violet tinge; it imparts the same colour, also, to borax and other vitrifiable salts. When heated with these fluxes, by the blow-pipe, the colour soon disappears in the interior flame from de-oxidation, but appears again if a little nitre is added.

Sulphuret of manganese was obtained by Berthier by heating the sulphate in a charcoal crucible; it was of a gray colour and crystalline appearance. Manganese, from its infusibility, does not combine readily with many of the metals. It shows, however, considerable affinity to iron, occurring frequently combined with it in nature. It is contained, also, in those ores of iron which are best adapted to the fabrication of steel, and is supposed to improve the quality of steel. Gold and iron are rendered more fusible by a due addition of manganese; and the latter metal is rendered more ductile. Copper becomes less fusible, and is rendered whiter, but of a colour subject to tarnish. Manganese is applied to no use in its metallic form. The black oxide is employed by the chemist in preparing oxygen and chlorine gases. It has long been used in the art of glass-making, to counteract the green tinge communicated by the iron contained in the materials—an effect which it produces by yielding oxygen to the oxide of iron, and bringing it to a high degree of oxidation; in a larger quantity added to glass, it gives a purple colour. It is also used to give a black colour to earthen-ware.

MANGEL-WURZEL; a kind of beet, which does not afford fodder of as good quality nor in such abundance as was supposed at the time of its introduction; but it is valuable from its size and hardy nature. The leaves may be eaten as a substitute for spinach, and continue in season long after that plant has withered. In some parts of Germany, the farmers prefer it for their cattle to most vegetables: and, besides, it can be obtained at the latter part of the season, when green fodder is much wanted.

MANIFEST is a regular list of a ship's cargo, containing the mark and number of each separate package, the names of the persons by whom the different parcels of goods are shipped, and those of the persons to whom they are consigned, a specification of the quality of the goods contained in each package, as rum, sugar, tea, coffee, &c., and also an account of the freight that the captain is to receive from the consignee of such goods, on his arrival, correspond-

ing with the bills of lading which he has already signed. The manifest is usually signed by the ship-broker who clears the vessel out at the custom-house, and by the captain, and serves as a voucher for the latter, whereby to settle his account with his owners, &c.

MANIOC; a shrub allied to the castor plant, and interesting from its nutritious properties. This plant is easily cultivated, grows rapidly, and produces abundantly. It is much less subject to injury from the ravages of animals, or variations of the atmosphere, than most crops, and, besides, accommodates itself to almost every kind of soil. The roots require at least a year to bring them to perfection; neither can they be kept in the ground for a longer period than two years. The cultivated varieties are very numerous. It is said that an acre of manioc will nourish more persons than six acres of wheat. Every part of the plant is filled with the milky juice, which is a very violent and dangerous poison, bringing on death in a few minutes when swallowed; and it may well excite surprise that human ingenuity should have converted the roots into an article of food. For this purpose the roots were formerly rasped with rough pieces of stone; but they are now ground in wooden mills, and the paste is put into sacks, which are exposed for several hours to the action of a very heavy press. By this means it is deprived of all the poisonous juice, and the residue is called *cassava*. Cassava flour, when kept free from moisture, continues good for fifteen or twenty years. It is very nutritious, half a pound a day being sufficient for any one. The Creole women prefer the cassava to wheaten bread, but, to a European, the taste is rather insipid. It is also the basis of several different beverages, some of which are acid, agreeable, and even nutritive. The substance called *tapioca*, which is frequently imported into this country, and is used for jelly, puddings, and other culinary purposes, is separated from the fibrous part of the roots by taking a small quantity of the pulp, after the juice is extracted, and working it by hand till a thick white cream appears on the surface. This being scraped off and washed in water gradually subsides to the bottom. After the water is poured off the remaining moisture is dissipated by a slow fire, and the substance, being constantly stirred, gradually forms into grains about as large as those of sago. This is the purest and most wholesome part of the manioc.

MANIPULATION; work done with the hands. The word is used in pharmacy for the preparation of drugs; and in chemistry for the preparation of substances for experiments.

MANNA. This substance, which is so frequently employed in the *materia medica*, and which forms a considerable article of commerce, exudes naturally or from incisions made in the trunk and branches of a species of ash *(ornus rotundifolia)*. It first appears as a whitish juice, thickens on being exposed to the air, and, when dried, forms a whitish or reddish granular substance, which is the manna of commerce. The tree is a native of Italy, and is cultivated extensively in Sicily. June and July are the two months in which the manna is collected. It is detached from the trees with wooden knives, and is afterwards exposed to the sun for drying. A little rain, or even a thick fog, will often occasion the loss of the collections of a whole day. The taste of manna is sweet, and slightly nauseous. It is a mild purgative, and is principally administered to children. The *fraxinus virgata* also yields manna, but it cannot be obtained from any other species of *ornus*.

MANNER, *in the fine arts*, is used in two different meanings:—First, it signifies the habitual style of an artist or a school of artists. Secondly, *manner* (also *mannerism)* is used as a term of reproach, and designates those qualities of a work of art which do not proceed naturally from the subject treated, but from the individual character of the artist, or the false taste of an age. Such are the studied yet untrue performances of certain actors, the phraseology or conceptions of certain poets, the colouring or composition of certain painters, &c.

MANŒUVRE, in the *military art;* a movement given to a body of troops, according to the rules of tactics, by which it is intended to gain a decisive advantage over an enemy, or to regain advantages which the enemy has already won. A manœuvre may be executed by large or small masses, according to a preconcerted plan, or upon the sudden impulse of genius seizing upon a favourable moment: in general, it may be said that manœuvres have become more practicable in proportion as armies have grown larger, and discipline stricter. In an ancient battle, after the combat was well commenced, the commander lost, in a great degree, the direction of his troops: in modern battles he is enabled by manœuvres to exert a much more controlling influence, though there are still moments when he is obliged to let the battle rage. To execute effective manœuvres in the heat of battle requires great coolness and clear-sightedness in the commander, and thorough training in the troops. A manœuvre generally is a test of the excellence of the officers of all degrees.

One of the most important manœuvres is that of outflanking an enemy, in which the general keeps back part of his line, whilst the other part strives to turn the wing of the enemy, or to attack it with the assistance of a division particularly appointed to get round it, and thus to throw the enemy into confusion. The invention of this manœuvre is ascribed to Epaminondas; he owed to it his victories at Leuctra and Mantinea. Philip, Alexander, Cæsar at Pharsalia, Baner at Wittstock, Torstenson at Jankowitz, Frederic the Great at Hohenfriedberg and Leuthen, Napoleon, and other generals, owe their most brilliant successes to this manœuvre. In executing it, the attacking army always receives an oblique direction, and the attack is sometimes made *en échelon*, as at Leuthen. The breaking through the enemy's line—a chief manœuvre in naval warfare—is, in land-battles, one of the boldest and most dangerous. The retreat *en échequier* (chess-board) is one of the most advantageous and most fitted to preserve calmness and order among the troops. The change of front during the combat is very dangerous, and rarely succeeds. The issue of a battle, where the other circumstances are nearly equal, depends upon the capacity of the troops for manœuvring; hence manœuvring in peace with large bodies is very necessary, in which the chief movements of both parties must be laid down beforehand; but the details ought to be left to the moment, so that the judgment of the officers shall be exercised.

In the provinces of Prussia large bodies of troops are annually assembled for the purpose of manœuvring. In 1823, from September 5 to September 20, 40,000 troops were collected for this object near Ber-

lin. Gustavus Adolphus and Charles XII. exercised their troops so well that they were allowed to be the best in Europe; but Frederic the Great conceived the whole art of war from a new point of view; and from Potsdam, where he superintended the reviews and manœuvres of his guards, and the garrison of Berlin, may be said to have proceeded the new art of war. There he perfected the movements which were afterwards introduced into the army at large; and generals from all Europe were sent to study his manœuvres. But, as so often happens with the creations of genius, the application of his plans by inferior men was attended with a pedantic minuteness of detail with which the armies of Europe were embarrassed when the wars of the French revolution took place. The genius of the French generals now reformed the art of war anew; manœuvring on a great scale was invented by them. Napoleon developed it still further, and the rest of Europe learned it from him.

MANOMETER; an instrument to measure or show the alterations in the rarity or density of the air.

MANTELETS, in the *art of war;* a kind of movable parapets, made of planks about three inches thick, nailed one over another, to the height of almost six feet, generally cased with tin, and set upon wheels, so that in a siege they may be driven before the pioneers, and serve as blinds to shelter them from the enemy's small shot.

MANUFACTURES. Great Britain is essentially a trading country. Napoleon called us a "nation of shopkeepers," but he might more truly have characterised us as a nation of manufacturers. And yet, in the strict sense of the word, we had no claim to the title prior to the commencement of the last century. Our principal manufactures date their origin from the invention of the steam-engine; and it is most likely that we should have now been receiving the manufactures of other nations, instead of supplying *our own,* if this stupendous machine had never been improved by Mr. Watt. One of the principal reasons why so many more improvements are made in this country beyond what is found in the manufactures of any other arises from the circumstance that in Great Britain the masters have generally been workmen, whilst, among our continental rivals, they are almost invariably the possessors of the soil and the princes of the land. There are few manufactures on any very extended scale found either in the metropolis or its environs. It is only in the provincial districts that we observe the great principle of a "division of labour," by which prices are reduced, fully developed. Under these various divisions then our readers will best see the progress of the manufactures of Great Britain illustrated, and in our article COMMERCE will be found the results of that division of labour on a large scale, as it affects the commerce of the world.

MANURES; vegetable, animal, and mineral matters, introduced into the soil, to accelerate vegetation and increase the production of crops. If the soil to be improved be too stiff from excess of clay, it will require sand; if too loose from excess of sand, it will be benefited by clay; but, when sand is mixed with argillaceous soil, the latter must be broken and pulverized, which may be effected by exposing it to the frost, and afterwards drying it. *Marl* is a natural compound earth, used with great success in the amelioration of soils. It consists of a mixture of clay and lime, sometimes containing a little silica and bitumen. Those varieties of it which contain more clay than lime are advantageous for a dry sandy soil; while calcareous marl, or that in which the lime predominates, is suited to an argillaceous soil. The great advantage of marl is, that it dilates, cracks, and is reduced to powder, by exposure to moisture and air. Marl in masses would be totally useless in the ground; and it is necessary to begin by laying it on the ground in heaps; for the more it is heaped the more it dilates, splits, and crumbles to dust, in which state it is fit to spread upon the ground. Marl is sometimes formed into a compost with common manure, before it is laid on the soil; in this state, however, it should be applied sparingly at a time, and renewed frequently. It operates by subdividing the soil, and hastening decomposition, its calcareous particles disorganizing all animal or vegetable bodies, by resolving them into their simple elements, in which state they combine with oxygen, and facilitate this union. The best time for marling is the autumn.

Quick-lime, and especially that derived from fossil or living shells, is another excellent means of amending soils. It is particularly adapted to cold marshy soils, abounding in organic matters, as it assists powerfully in the conversion of animal and vegetable substances into nourishment for plants. *Ashes* are very beneficial to the soil, by attracting moisture from the atmosphere, in consequence of the alkali they contain, and thus accelerating vegetation. *Gypsum* is, however, the most universal mineral manure; but chemists are not agreed as to the manner in which it acts on vegetation. It is strewed, in the state of fine powder, over crops, when the leaves are in full vigour, towards the latter end of April or the beginning of May.

Common manure is composed of the remains of organized bodies, of every description, whether animal or vegetable, in a state of decomposition. The principal result of this decomposition is carbonic acid, which, becoming dissolved in water, finds its entrance into the plant by the pores in the fibres of the roots, and, being every where distributed through the vegetable tissue, deposits its carbon for the growth of the plant, while its oxygen escapes into the atmosphere, through the pores of the leaves. Manure which has not completely undergone the process of fermentation, so that the straw is not yet wholly decomposed, is best adapted to strong compact soils: the tubular remnants of straw answer the purpose of so many little props to support the earth, and afford a passage for the air, thus rendering the soil lighter; besides, the completion of the fermentation taking place after the manure is buried in the soil has the advantage of raising the temperature. Those bodies which are subject to the most rapid decomposition are most employed for manure. Of this description are animal manures in general, which require no chemical preparations to fit them for the soil. The great object of the farmer is to blend them with the earthy constituents, in a proper state of division, and to prevent their too rapid fermentation.

In maritime districts, *fish,* when sufficiently abundant, are sometimes used to manure the land. They afford a powerful manure, and cannot be ploughed in too fresh, though the quantity should be limited. Mr. Young records an experiment, in which herrings, spread over a field, and ploughed in for wheat, produced so rank a crop that it was entirely laid before harvest. Amongst excrementitious solid substances,

one of the most powerful is the *dung of birds* that feed on animal food, particularly the dung of sea-birds. The *guano*, which is used to a great extent in South America, and which is the manure that fertilizes the sterile plains of Peru, is a production of this kind. It contains a fourth of its weight of uric acid, partly saturated with ammonia, and partly with potash; some phosphoric acid, combined with the bases, and likewise with lime; small quantities of sulphate and muriate of potash; a little fatty matter; and some quartzose sand.

Night-soil, it is well known, is a very powerful manure, and very liable to decompose. Its disagreeable smell may be destroyed by mixing with quicklime, after which, if exposed to the atmosphere in layers, in fine weather, it speedily dries, is easily pulverized, and, in this state, may be used in the same manner as rape-cake, and delivered into the furrow with the seed. The Chinese, who have more practical knowledge of the use and application of manure than any other people existing, mix their night-soil with one-third of its weight of fat marl, make it into cakes, and dry it by exposure to the sun. In this state it is free from any disagreeable smell, and forms a common article of commerce of the empire. After night-soil, *pigeons' dung* comes next in order as to fertilizing power. If the pure *dung of cattle* is to be used as manure, like the other species of dung which have been mentioned, there seems no reason why it should be made to ferment, except in the soil; or, if suffered to ferment, it should be only in a very slight degree. A slight incipient fermentation is undoubtedly of use in the dunghills; for by that means a disposition is brought on in the woody fibre to decay and dissolve, when it is carried to the land, or ploughed into the soil; and woody fibre is always in great excess in the refuse of a farm. Too great a degree of fermentation is, however, very prejudicial; and it is better that there should be no fermentation at all before the manure is used than that it should be carried too far. In cases where farm-yard dung cannot be immediately applied to crops, the destructive fermentation of it should be prevented very carefully, by defending the surface of it, as much as possible, from the oxygen of the atmosphere: a compact marl, or a tenacious clay, offers the best protection against the air; but before the dung is covered over, or as it were sealed up, it should be dried as much as possible. If the dung be found to heat at any time, it should be turned over, and cooled by exposure to air. When a thermometer, plunged into it, does not rise above 100° Fahr., there is little danger of much aëriform matter flying off; if the temperature be above that point, the dung will require to be immediately spread open. Also, when a piece of paper, moistened in muriatic acid, held over the steams arising from a dung-hill, gives dense white fumes, it is a certain test that the decomposition is going too far; for this indicates that volatile alkali is disengaged. The situation in which dung is kept by farmers is often injudicious, it frequently being exposed to the direct influence of the sun; whereas it should always be kept under sheds, or at least on the north side of a wall. Less perishable substances, of animal origin, are sometimes used as manure, such as *horns*, *hair*, *feathers*, and *bones*; but, owing to their dry nature, they require a longer period for their decomposition. They are not calculated for annual harvests, but to fructify the soil for a produce of much longer duration, such as that of olive-trees, and of vineyards.

Vegetable manure does not undergo fermentation previous to being buried in the soil. Of this kind of manure, *green crops*, such as clover, lupins, and buckwheat, which are ploughed into the soil, are the best, since they contain a considerable quantity of water, and, when buried, serve to lighten the soil previous to decomposition. It is especially adapted to hot climates. *Rape-cake*, which is used with great success as a manure, contains a large quantity of mucilage, some albuminous matter, and a small quantity of oil. It should be used recent, and kept as dry as possible before it is applied. It forms an excellent dressing for turnip crops, and is most economically applied by being thrown into the soil at the same time as the seed. *Sea-weeds*, consisting of different species of *fuci*, *algæ*, and *frevæ*, are much used as a manure. This manure is more transient in its effects, and does not last for more than a single crop, which is easily accounted for from the large quantities of water, or the elements of water, which it contains. It decays without producing heat when exposed to the atmosphere, and seems, as it were, to melt down and dissolve away. *Soot*, which is principally formed from the combustion of wood and pit-coal, contains, likewise, substances derived from animal matters, and is a very powerful manure. It requires no preparation, but is thrown into the ground with the seed.

The foregoing species of manure have, for the sake of convenience, been described separately, though they are very rarely employed unmixed by the farmer; on the contrary, the most common manure consists of a mixture of animal, vegetable, and mineral substances, such as farm-yard litter, night-soil, mud from the streets, dust from the roads, or earth from the bottom of ponds and rivers, abounding with organic remains of fish, shells, and rotten plants. Before being laid upon land, it usually requires to be well turned up and exposed to the air for some time; but, as soon as it is spread, it should be ploughed in, to prevent loss by evaporation. As to the depth below the surface of the ground to which it should be deposited, it may be remarked that this should never be below the reach of the roots of the plants it is intended to nourish; for, in proportion as it is dissolved and liquefied, it will naturally descend. And it is better to manure lands in the spring than in autumn, lest the winter rains should dissolve it too much, and endanger its sinking below the roots of the crop. With regard to the quantity of manure, it is a commodity so scarce that it is not likely to be employed in excess. This occurs, however, sometimes in garden culture, and it produces a strong and disagreeable flavour in the vegetables. But the stock of manure is generally so limited that it has hitherto been the study of agriculturists rather to discover some means of compensation for a deficiency than to avoid danger from excess.

We cannot close this account of the best modes of applying manure without briefly adverting to the economical arrangements which have lately been made for effecting this object in Holland. It forms the principal feature in a system of rural economy, by means of which establishments called "pauper colonies" are enabled to support themselves, and yet return an annual interest to those who have established them. Mr Jacob furnishes the following facts:—

"When the house and barn are built, the soil formed, by mixing sand and clay to a consistence which makes it sufficiently retentive of moisture, the land manured, dug, and one crop sowed or planted on it, then a family consisting of from six to eight persons is fixed on it, at an expense of about 141*l*. To enable this household to subsist or pay the rent, and to save something, it is necessary that very intense manuring be persevered in. The directors therefore require, and by their enforcement of the prescribed regulations, indeed, compel each family to provide sufficient manure to dress the *whole* of the land every year. For this purpose each household must provide itself with three hundred fodder of manure, yearly; or, in English terms, one hundred and fifty tons, or at the rate of more than twenty tons to each acre. When it is considered that few of our best English farmers can apply one half that quantity of manure, it will not appear wonderful that seven acres should be made to provide for the sustenance of the same number of persons, and leave a surplus to pay rent and to form a reserve of savings. On each farm the live stock of two cows, or one cow and ten sheep, to which may be added pigs, would not nearly enable the cultivator to manure his small portion of land once even in four or five years.

"It hence becomes necessary to form masses of compost, the collecting the materials for which forms the greater part of the employment of the colonists. These masses are created almost wholly by manual labour, of that kind which, but for such an application of it, would be wholly lost to the community. As straw is at best, in the early period, not abundant, and as that from the corn must at first be chiefly used as food for the cattle or for covering to the houses, other materials, which the heaths furnish, are resorted to in order to make beds for the cattle. The heath land is pared, but the operation is to cut with the spade a very thin slice of the earth, and not to the bottom of the roots of the plants, that they may, as they soon will do, shoot again; the parings are not only made thin, but in narrow strips or small spots. Thus but little soil is taken away, and the roots, though cut, are not all of them destroyed; the parts that are left bare are protected from being too much dried up by the sun and wind, and the seed of the ripe heather is scattered over the spaces left bare near them, and soon bring forth the same plants. By this operation there is a constant succession provided of heathy material.

"This paring for the heath is a joint operation, performed by the men in a kind of military lines. The society pays each for the work he performs, and, when the average cost is ascertained, the sods are sold to the several households at the same price, and are carried to their respective farms in small one-horse carts, which are kept by the society for that and for similar purposes, to which mere manual labour cannot be so beneficially applied. When these sods are dried and conveyed to the barns of the colonists, they are piled in a kind of stack, and portions of it are pulled out, not cut out, to ensure their being broken into small fragments. With these the bedding of the cows or sheep, as the case may be, is formed.

"The use of bog turf or peat as one of the materials of compost is not approved. It impedes the process of fermentation, which is the most important part of the preparation of the heaps of manure. Another expedient is therefore adopted, by paring the second year's grass land, whether of clover, rye grass, or fiorin. These clods, containing a proportion of the roots of the plants which have been before harvested from them, and much garden mould, become useful auxiliaries to the heathy turf, and spare the use of that material, which if solely applied would require almost as much land to supply it as the farm itself.

"The bedding of the cattle with fresh material is performed every morning and evening, and remains under them seven days and nights, when it is wheeled to the dunghill. Each morning that which lies near the hinder part of the cow is thrown forward, and the part towards its head takes its place, and fresh heather, about a quarter of a fodder, or two hundred and fifty pounds, added to the bedding; the same is also done every evening. The sheep and pigs are only supplied with fresh heather once a day. It is reckoned that ten sheep make an equal quantity of dung with one cow. It must be obvious to every one that the changing and consequent turning over thirteen times must make the mixture of the animal and vegetable substances more equably rich; and the uniform treading of it must break it into small particles and give greater scope to the fermentative putrefaction.

"Each week the stalls are cleaned, and the dung conveyed to the place appointed at the back of the barn. This is of a round shape, from three to four feet in depth. The bottom and sides are walled with either clinkers or turf, and made water-tight. It is commonly from twelve to fourteen feet in diameter, and sufficiently capacious to contain the dung made by the cattle in the course of four weeks. The mass is thus composed of portions which have remained from four weeks to one day, over which the ashes from the household and all the sweepings of the premises are strewed. Adjoining to the dung-heap is the reservoir, into which the drainings of the stalls are conveyed. Equal care is taken that every other material for compost is preserved. In England, little attention is paid to these matters; and even in agricultural districts many of the most valuable ingredients for fertilizing the earth (soap-suds, for instance) are constantly thrown away. This cesspool, containing about a hogshead, is never allowed to run over; and, if it has not rained, is every other day filled up with water, and then with a scoop taken up and sprinkled over the heap of dung. As this heap contains four week's dung, or thirty fodder, or fifteen tons, the administering fourteen such portions of rich fermenting matter must vastly enhance the value of the whole for the purposes of vegetation." (See *Rotation of crops*.)

Map. See this word in Geographical Division.

Maple; a well-known American tree. It grows in moist situations, from lat. 49° to the gulf of Mexico, both in the Atlantic and western States. The bright red blossoms appearing at a time when there is no vestige of a leaf in the forest render this tree very conspicuous at the opening of spring; and again at the close of the season it is not less conspicuous, from the scarlet colour which the leaves assume when they have been touched by the frost. The leaves are cordate at base, unequally toothed, five-lobed, and glaucous beneath. It attains the height of seventy feet, with a diameter of three or four at the base. The wood is easily turned, and when polished acquires a silken lustre; it is hard and fine-grained,

and is employed chiefly for the lower parts of Windsor chairs, sometimes for saddle trees, wooden dishes, and similar purposes. The variety called *curled maple*, from the accidental undulation of the fibres, is one of the most ornamental woods known, and bedsteads made of it exceed in richness and lustre the finest mahogany. It is sometimes employed for inlaying, but its most constant use is for the stocks of rifles and fowling pieces. The sugar maple is one of the most valuable trees. Besides the sugar which is obtained from the sap, the wood affords excellent fuel, and from the ashes are procured four-fifths of the potash which forms such an important item in American exports. The sugar is superior in quality to the common brown sugar of the West Indies, and, when refined, equals the finest in beauty. It is, however, little used. The potash is exported from the two principal northern ports, New York and Boston. To the latter place the wood is brought in great quantities from Maine for fuel, and is esteemed hardly inferior to hickory. In Maine and New Hampshire, it is employed in ship-building for the keel, and likewise in the lower frame; for the axle-trees and spokes of wheels; and sometimes in the country for the frames of houses. A variety, with undulations, like the curled maple, and containing besides small spots, is called *bird's eye maple*, and forms exceedingly beautiful articles of furniture.

MARBLE, in common language, is the name applied to all sorts of polished stones employed in the decoration of monuments and public edifices, or in the construction of private houses; but, among the materials thus made use of, it is necessary to distinguish the true marbles from those stones which have no just title to such a designation. In giving a short but universal character of marble, it may be said that it effervesces with dilute acid, and is capable of being scratched with fluor, while it easily marks gypsum. These properties will separate it at once from the granites, porphyries, and silicious pudding-stones, with which it has been confounded on one side, and from the gypseous alabaster on the other. From the hard rocks having been formerly included under the marbles, comes the adage, "hard as marble."

Marbles have been treated of under various divisions by different writers. The most frequent division has been that of two great sections—*primitive* marbles, which have a brilliant or shining fracture, and *secondary* marbles, or those which are possessed of a dull fracture. This classification has grown out of the idea that the former class was more anciently created —an opinion which the deductions of geology for the most part sufficiently confirm, though occasionally we find a marble of a compact and close texture in old rocks, and, on the other hand, those which are highly crystalline in very recent formations. Daubenton has founded a classification of marbles upon the colours which they present; those of a uniform colour forming one class; those with two colours, another; those with three shades, a third; and so on. The best classification of these substances, however, is that of M. Brard, which divides all marbles into seven varieties or classes:—viz. 1. *marbles of a uniform colour*, comprehending solely those which are either white or black; 2. *variegated marbles*, or those in which the spots and veins are interlaced and disposed without regularity: occasionally, this variety embraces traces of organic remains; when these are disposed in star-like masses they are sometimes called *madrepore marbles*; 3. *shell marbles*, or those which are in part made up of shells; 4. *lumachelli marbles*, or those which are apparently wholly formed of shells; 5. *cipolin marbles*, or those which are veined with green talc; 6. *breccia marbles*, or those which are formed of angular fragments of different marbles, united by a cement of some different colour; 7. *pudding-stone marbles*, or those which are formed of reunited fragments, like the breccia marbles, only with the difference of having the pebbles rounded in place of being angular.

Parian marble; its colour is snow-white, inclining to yellowish-white; it is fine, granular, and, when polished, has somewhat of a waxy appearance. It hardens by exposure to the air, which enables it to resist decomposition for ages. Dipœnus, Scyllis, Malas, and Micciades, employed this marble, and were imitated by their successors. It receives, with accuracy, the most delicate touches of the chisel, and retains for ages, with all the softness of wax, the mild lustre even of the original polish. The finest Grecian sculpture which has been preserved to the present time is generally of Parian marble; as the Medicean Venus, the Diana Venatrix, the colossal Minerva (called *Pallas of Velletri*), Ariadne (called *Cleopatra*), and Juno (called *Capitolina*). It is also Parian marble on which the celebrated tables at Oxford are inscribed.

Pentelican marble, from Mount Pentelicus, near Athens, resembles, very closely, the preceding, but is more compact and finer granular. At a very early period, when the arts had attained their full splendour, in the age of Pericles, the preference was given by the Greeks, not to the marble of Paros, but to that of Mount Pentelicus, because it was whiter, and also, perhaps, because it was found in the vicinity of Athens. The Parthenon was constructed entirely of Pentelican marble. Among the statues of this marble in the royal museum at Paris are the Torso, a Bacchus in repose, a Paris, the throne of Saturn, and the tripod of Apollo.

Carrara marble is of a beautiful white colour, but is often traversed by gray veins, so that it is difficult to procure large blocks wholly free from them. It is not subject to turn yellow, as the Parian. This marble, which is almost the only one used by modern sculptors, was also quarried and wrought by the ancients. Its quarries are said to have been opened in the time of Julius Cæsar.

Red antique marble (rosso antico of the Italians; *Ægyptium* of the ancients). This marble, according to antiquaries, is of a deep blood-red colour, here and there traversed by veins of white, and, if closely inspected, appears to be sprinkled over with minute white dots as if it were strewed with sand. Another variety of this marble is of a very deep red without veins, of which a specimen may be seen in the Indian Bacchus, in the royal museum of Paris.

Green antique marble (verde antico of the Italians) is an indeterminate mixture of white marble and green serpentine. It was known to the ancients under the name *marmor Spartanum, or Lacedæmonium.—African breccia marble (antique African breccia).* It has a black ground, in which are imbedded fragments or portions of a grayish-white, of a deep red, or of a purple wine colour. This is said to be one of the most beautiful marbles hitherto found, and has a superb effect when accompanied with gilt ornaments.

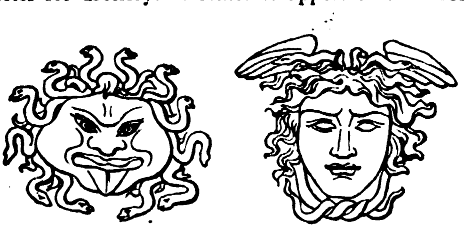
Its native place is not known with certainty; it is conjectured to be Africa. The pedestal of Venus leaving the bath, and a large column, both in the royal museum in Paris, are of this marble. (See NATURAL HISTORY Division of this work.)

MARCH; originally the first month of the Roman year, so named, according to tradition, by Romulus in honour of his father Mars. Till the adoption of the new style in England (1752), the 25th of March was new year's day; hence January, February, and the first twenty-four days of March have frequently two years appended, as January 1, 1701-2. (See CALENDAR.)

MARCH; a movement by regular steps in the manner of soldiers; also a journey performed by a body of soldiers either on foot or on horseback. Soldiers on a march are subject to certain rules, very necessary to keep them in good order, and fit to meet the enemy. The march in the first sense of regular step differs on different occasions. In the parade-march, from 75 to 95 steps, differing in different armies, are made in a minute; in the quick-march, from 108 to 115 steps; and, in the storming-march, 120 steps in the Prussian army.

March further signifies the music composed for such movements; it is composed in $\frac{4}{4}$ or $\frac{2}{4}$ time for the parade-march, and in $\frac{6}{8}$ for quick time. There are many sorts of such marches for festivals, funerals, &c., varying according to their different purposes.

MASK, or MASQUE; a cover to conceal the face. In the ancient revels the mask was considered an essential part of the costume; and even in the modern Italian carnival, as well as in our own masquerade attire, it retains all its peculiar character for drollery. Architects appear to have bor-



rowed some of their most singular and characteristic masques from the attire of those who were the principal actors in the "feasts of unreason." The left-hand sketch in the above engraving is copied from the porch of a Gothic edifice, and the lower part of the figure was dressed in the robes of a priest.

The other masque is copied from an ancient tomb; but the architects of the middle ages appear to have made most use of the mask in the erection of sacred edifices.

MASTIC; a resinous substance obtained from incisions made in the branches of the *pistachia lentiscus*, a small tree, or rather shrub, growing in the Levant and other countries bordering on the Mediterranean. This tree belongs to the natural family *terebinthaceæ*. It forms one of the most important products of Scio, and has been cultivated in this and some of the neighbouring islands from remote antiquity. Heat seems to exercise a great influence on the resinous product. Mastic is consumed in vast quantities throughout the Turkish empire, and is there used as a masticatory by women of all denominations, for the purpose of cleansing the teeth and imparting an agreeable odour to the breath. It was formerly in great repute as a medicine throughout Europe, but at the present time is very little used.

MATERIA MEDICA. See MEDICINE.

MATHEMATICS. If we call every thing which we can represent to our mind as composed of homogeneous parts a magnitude, mathematics, according to the common definition, is the science of determining magnitudes, i. e. of measuring or calculating them. Every magnitude appears as a collection of homogeneous parts, and may be considered in this sole respect; but it also appears under a particular form or extension in space, which originates from the composition of the homogeneous parts, and to which belong the notions of situation, proportion of parts, &c. Not only all objects of the bodily world, but also time, powers, motion, tones, &c., may be represented and treated as mathematical magnitudes. The science of mathematics has to do only with these two properties of magnitudes, the quantity of the homogeneous parts, which gives the numerical magnitude, and the form, which gives the magnitude of extension. This is one way, and the most common, of representing the subject: there are others more philosophical, but less adapted to the limited space which can allowed to so vast a subject, in a work like the present. In investigating these two properties of magnitudes, the peculiar strictness of the proofs of mathematics gives to its conclusions and all its processes a certainty, clearness, and general application, which satisfies the mind, and elevates and enlarges the sphere of its activity. According as a magnitude is considered merely in the respects above mentioned, or in connection with other circumstances, mathematics are divided into *pure* and *applied*. Pure mathematics are again divided into *arithmetic*, which considers the numerical quality of magnitudes, and *geometry*, which treats of magnitudes in their relations to space. In the solutions of their problems, the common mode of numerical calculations, and also *algebra* and *analysis*, are employed. To the applied mathematics belong the application of arithmetic to political, commercial, and similar calculations; of geometry to surveying, levelling, &c.; of pure mathematics to the powers and effects, the gravity, the sound, &c., of the dry, liquid, and aëriform bodies in a state of rest, equilibrium, or in motion—in one word, its application to the mechanical sciences; to the rays of light in the optical sciences; to the position, magnitude, motion, path, &c., of heavenly bodies in the astronomical sciences, with which the measurement and calculation of time, and the art of making sun-dials (see DIAL), are closely connected. The name of applied mathematics has sometimes been so extended as to embrace the application of the science to architecture, navigation, the military art, geography, natural philosophy, &c.; but in these connections it may be more conveniently considered as forming a part of the respective sciences and arts.

It is to be regretted that there is as yet no perfectly satisfactory work treating of the history of this science, so noble in itself, and so vast in its application: even Kästner and Montucla leave much to be desired. The establishment of mathematics on a scientific basis probably took place among the Indians and Egyptians. We find the first developement of the science among the Greeks, those great teachers of Europe in almost all branches. Thales, and more particularly Pythagoras, Plato, Eudoxus, investigated

mathematics with a scientific spirit, and extended its domain. It appears that geometry, in those ages, was more thoroughly cultivated than arithmetic. The ancients, indeed, understood by the latter something different from that which we understand by it. In fact, we have not a clear idea of the ancient arithmetic. Their numerical calculations were limited and awkward, sufficient ground for which might be found in their imperfect way of writing numbers, if there were no other reason. Euclid's celebrated *Elements* (a work of unrivalled excellence, considering the time of its origin), the ingenious discoveries of Archimedes, and the deep investigations of Apollonius of Perga, carried the geometry of the ancients to a height which has been the admiration of all subsequent times. Since then it has been made to bear more on astronomy, and has become more connected with arithmetic. Among the Greek mathematicians are still mentioned Eratosthenes, Conon, Nicomedes, Hipparchus, Nicomachus, Ptolemy, Diophantus, Theon, Proclus, Eutocius, Papus, and others.

It is remarkable that the Romans showed little disposition for mathematics; but the Arabians, who learned mathematics, like almost all their science, from the Greeks, occupied themselves much with it. Algebra and trigonometry owe them important improvements. Through the Arabians, mathematics found an entrance into Spain, where, under Alphonso of Castile, a lively zeal was displayed for the cultivation of this science. After this, it found a fertile soil in Italy; and in the convents a monk would sometimes follow out its paths, without, however, adding to its territory. This was reserved for later ages.

The science of mathematics owes much to Gmünden, Peuerbach, Regiomontanus, Pacciolo, Tartaglia, Cardanus, Macrolycus, Vieta, Ludolphus de Ceulen, Peter Nunez, Justus Byrge, and others. To this period, however, all mathematical operations of any extent required a weary length of detail; but, in the seventeenth century, Napier, by the introduction of logarithms, immensely facilitated the process of calculation; and Newton and Leibnitz, by their infinitesimal calculus, opened the way into regions into which no mathematician had previously attempted to penetrate. From this time, the science obtained a wonderful extension and influence, by the labours of such minds as Galilei, Torricelli, Pascal, Descartes, L'Hopital, Cassini, Huyghens, Harriot, Wallis, Barrow, Halley, James and John Bernouilli, and others. Thus it became possible for Manfredi, Nicoli, the two Bornouillis, Euler, Maclaurin, Taylor, Bradley, Clairaut, D'Alembert, Lambert, Tobias Mayer, Kästner, Hindenburg (the inventor of the combinatory analysis), Lagrange, Laplace, Legendre, Gauss, Bessel, and the later mathematicians in the eighteenth and in the present century, to make great advances, and to give us satisfactory conclusions, not only respecting our earth, but also the heavenly bodies, the phenomena and powers of nature, and their useful application to the wants of life, to establish firmly so many notions previously vague, and to correct so many errors.

The number of mathematical manuals increases daily, without, however, much surpassing the best of the earlier ones in perspicuity, novelty, and method, or rendering them unnecessary to the student.

May, the fifth month in the year, has thirty-one days. In the Salic laws, this month is called *Meo*, and it would appear that the idea of youthful beauty and loveliness, so naturally connected by northern nations with the month of May, gave rise to its name. In the Low Saxon, *Moj*, in Dutch, *Mooy*, is beautiful, agreeable; in Swedish, *Mio*, in Icelandic, *Mior*, small, pretty, agreeable; in ancient Swedish, *Mö*, a virgin (connected with *maid*, *maiden*). In Lower Brittany, *Mae* signifies green, flourishing, and *Maes*, a field, meadow; German, *Matte*; in Lorraine, *Io Mai*, and *Mé*, in ancient French, *Mets*, *Mès*, signify a garden. Whether all these must be referred to one Teutonic root, and whether this, again, is connected with the Indian *Maya*, the goddess of nature, cannot be investigated here.

Mean; the middle between two extremes: thus we say, the "mean motion of a planet," its "mean distance," &c., to signify a motion, or distance, which as much exceeds the least motion or distance as it is exceeded by the greatest. The *mean*, or *mean proportion*, is the second of any three proportions. In an arithmetical proportion, the *mean* is half the sum of the extremes; in a geometrical, the *mean* is the square root of the product of the extremes. *Mean time* is the mean or average of apparent time.

Measles; an exanthematic disease, which appears to have been unknown to the ancient physicians; the time of its first appearance in Europe is uncertain. It is communicated by the touch of infected persons or things. It is sometimes epidemic. Persons of all ages are liable to its attacks; but it is more common in infants, and rarely affects an individual a second time. The symptoms are hoarseness, cough, drowsiness, and, about the fourth day, an eruption of small red spots (hence the name *measles*; from the German *masern*, spots), which after three days end in scales. There is more or less of fever, attended with the usual febrile affections. The measles, even when violent, are not often of a putrid tendency, although such a disposition sometimes prevails. In the case of the simple measles, the best treatment is abstinence from food, and the use of mild, mucilaginous, sweetened drinks. Bleeding is proper only in the inflammatory measles. Some writers have treated the measles as an inflammation of the skin; but this is merely a symptom of the disease, and not the disease itself.

Measures. The general principle that simplicity and uniformity are the result of advancement in civilization is strikingly exemplified in the case of measures. Formerly every province, and almost every place of importance, had its own measures, which proved a most perplexing hindrance to commercial intercourse. In modern times, many attempts at uniformity have been made. Two modes most naturally suggested themselves, either to declare the measures of one place or province the universal measure (as has been done in this country, by an act of parliament, by which the standard London measures and weights are declared to be the standards for weights and measures throughout the realm), or to establish new measures, founded upon unalterable principles, upon the laws of nature, as has been done in France. Our standard yard is determined by the oscillations of a pendulum at London. This is still an arbitrary standard, as the oscillations vary in different parallels of latitude. It is not, indeed, so arbitrary as taking the foot of Louis XIV. for a measure, yet it is not so philosophical as the present French standard. The act already alluded to, for establishing uniform measures throughout the realm, and called the *act of uniformity*, took effect Jan. 1, 1826.

The system thus established is called the imperial

system. Its rationale is as follows :—Take a pendulum which will vibrate seconds in London, on a level parallel with the sea, in a *vacuum;* divide all that portion of the pendulum which lies between the axis of suspension and the centre of oscillation into 391,393 equal parts; then will 10,000 of those parts be an imperial inch, twelve whereof make a foot, and thirty-six whereof make a yard.

The standard yard is "that distance between the centres of the two points in the gold studs in the straight brass rod, now in the custody of the clerk of the house of commons, whereon the words and figures 'Standard yard, 1760,' are engraved, which is declared to be the genuine standard of the measure of length called a *yard;* and, as the expansibility of the metal would cause some variation in the length of the rod in different degrees of temperature, the act determines that the brass rod in question shall be of the temperature of 62° Fahrenheit. The measure is to be denominated the *imperial standard yard,* and to be the only standard whereby all other measures of lineal extension shall be computed. Thus the foot, the inch, the pole, the furlong, and the mile, shall bear the same proportion to the imperial standard yard as they have hitherto borne to the yard measure in general use."

The act also makes provision for the restoration of the standard yard, in case of loss, destruction, or defacement, by a reference to an invariable natural standard, which is to be that proportion which the yard bears to the length of a pendulum, vibrating seconds of time in the latitude of London, in a *vacuum* at the level of the sea; which is found to be as thirty-six inches (the yard) to 39.1393 (the pendulum); thus a sure means is established to supply the loss which might by possibility occur. Take a cube of one such inch of distilled water, at 62° of temperature by Fahrenheit's thermometer; let this be weighed by any weight, and let such weight be divided into 252,458 equal parts, then will 1000 of such parts be a troy grain; and 7000 of those grains will be a pound avoirdupois, the operation having been performed in the air. Ten pounds, such as those mentioned, of distilled water, at 62° of temperature, will be a gallon, which gallon will contain 277 cubic inches, and $\frac{274}{1000}$ parts of another cubic inch. The standard pound is determined to be that standard pound troy weight, made in the year 1758, in the custody of the clerk of the house of commons; such weight is to be denominated the *imperial standard troy pound,* and is to be "the only standard measure of weight from which all other weights shall be derived, computed, and ascertained; and one-twelfth part of the said troy pound is to be an ounce, and one-twentieth part of such ounce a pennyweight, and one twenty-fourth part of such pennyweight a grain; so that 5760 such grains shall be a pound troy, and 7000 such grains a pound avoirdupois, and one-sixteenth part of the said pound avoirdupois an ounce avoirdupois, and one-sixteenth part of such ounce a drachm."

If the standard pound shall be lost, destroyed, or defaced, the act directs that it shall be recovered by reference to the weight of a cubic inch of water; it having been ascertained that a cubic inch of distilled water, weighed in air by brass weights, at the temperature of 62° (Fahrenheit), and the barometer at thirty inches, is equal to 252,458 grains; and, as the standard troy pound contains 5760 such grains, it is therefore established that the original standard pound may be at any time recovered, by making another weight to bear the proportion just mentioned to a cubic inch of water.

The standard gallon is determined by the act to be such a measure as shall contain ten pounds avoirdupois of distilled water, weighed in air at the temperature of 62° (Fahrenheit), and the barometer at thirty inches; and such measure is declared to be the *imperial standard gallon,* and the unit and only standard measure of capacity to be used, as well for wine, beer, ale, spirits, and all sorts of liquids, as for dry goods not measured by heaped measure; and all other measures are to be taken in parts or multiples of the said imperial standard gallon, the quart being the fourth part of such gallon, and the pint one-eighth part, two such gallons making a peck, eight such gallons a bushel, and eight such bushels a quarter of corn, or other dry goods, not measured by heaped measure.

The standard for heaped measure, for such things as are commonly sold by heaped measure, such as culm, lime, fish, potatoes, fruit, &c., is to be "the aforesaid bushel, containing eighty pounds avoirdupois of water, as aforesaid, the same being made round with a plain and even bottom, and being nineteen and a half inches from outside to outside;" and goods thus sold by heaped measure are to be heaped "in the form of a cone, such cone to be the height of at least six inches, the outside of the bushel to be the extremity of the base of such cone."

Stricken Measure. The last-mentioned goods may be sold either by the heaped measure or by the standard weight, as before-mentioned; but for every other kind of goods not usually sold by heaped measure, which may be sold or agreed for by measure, the same standard measure is to be used, but the goods are not to be heaped, but stricken with a round stick, or roller, straight, and of the same diameter from end to end. Copies and models of the standard of length, weight, and measure, are to be made and verified under the direction of the treasury, and every county to be supplied with them for reference whenever required. Existing weights and measures may be used, being marked so as to show the proportion they have to the standard measures and weights; tables of equalization of the weights are to be made by the treasury; tables, also, for the customs and excise, by which the duties will be altered so as to make them equal to what they are at present, in consequence of the alterations in the weights and measures.

The measures now in use in the United States of America are precisely identical with our own; and it is creditable to the government of that country that they did not suffer any narrow-minded jealousy of the origin of this beautiful system to interfere with its adoption.

The following series of tables form a complete outline of our weights and measures, calculated from the London Standard.

1. MEASURE OF LENGTH.

12 inches	=	1 foot
3 feet	=	1 yard
5½ yards	=	1 rod, or pole
40 poles	=	1 furlong
8 furlongs	=	1 mile
$69\frac{1}{15}$ miles	=	1 degree of a great circle of the earth.

An inch is the smallest lineal measure to which a name is given, but subdivisions are used for many

purposes. Among mechanics, the inch is commonly divided into eighths. By the officers of the revenue, and by scientific persons, it is divided into tenths, hundredths, &c. Formerly, it was made to consist of twelve parts, called *lines;* but these have properly fallen into disuse.

Particular Measures of Length.

1 nail	= 2¼ inches		used for measuring cloth of all kinds.
1 quarter	= 4 nails		
1 yard	= 4 quarters		
1 ell	= 5 quarters		
1 hand	= 4 inches, used for the height of horses.		
1 fathom	= 6 feet, used in measuring depths.		
1 link	= $7\frac{92}{100}$ inches		used in land measure, to facilitate computation of the content, ten square chains being equal to an acre.
1 chain	= 100 links		

2. MEASURE OF SURFACE.

144 square inches	= 1 square foot
9 square feet	= 1 square yard
30¼ square yards	= 1 perch, or rod
40 perches	= 1 rood
4 roods, or 160 perches	= 1 acre
640 acres	= 1 square mile.

3. MEASURES OF SOLIDITY AND CAPACITY.

Division I.—Solidity.

1728 cubic inches	= 1 cubic foot
27 cubic feet	= 1 cubic yard.

Division II.

Imperial measure of capacity for all liquids, and for all dry goods except such as are comprised in the third division:

4 gills	= 1 pint	= 34⅔ cubic in., nearly
2 pints	= 1 quart	= 69⅓ ,, ,,
4 quarts	= 1 gallon	= 277¼ ,, ,,
2 gallons	= 1 peck	= 554½ ,, ,,
8 gallons	= 1 bushel	= 2218½ ,, ,,
8 bushels	= 1 quarter	= 10¼ cubic feet, nearly
5 quarters	= 1 load	= 51⅓ ,, ,,

The last four denominations are used for dry goods only. For liquids several denominations have been heretofore adopted, viz. for beer, the firkin of 9 gallons, the kilderkin of 18, the barrel of 36, the hogshead of 54, and the butt of 108 gallons.' These will probably continue to be used in practice. For wine and spirits, there are the anker, runlet, tierce, hogshead, puncheon, pipe, butt, and tun; but these may be considered rather as the names of the casks in which such commodities are imported than as expressing any definite number of gallons. It is the practice to gauge all such vessels, and to charge them according to their actual content.

Division III.

Imperial measure of capacity, for culm, lime, fish, potatoes, fruit, and other goods commonly sold by heaped measure :—

2 gallons	= 1 peck	= 704 cubic in., nearly
8 gallons	= 1 bushel	= 2815½ ,, ,,
3 bushels	= 1 sack	= 4 8-9 cubic feet, nearly

(For measures of weights, see Weights.)

5. ANGULAR MEASURE,

or Divisions of the Circle.

60 seconds	= 1 minute
60 minutes	= 1 degree
30 degrees	= 1 sign
90 degrees	= 1 quadrant
360 degrees, or 12 signs	= 1 circumference.

Formerly the subdivisions were carried on by sixties; thus the second was divided into 60 thirds, the third into 60 fourths, &c. At present, the second is more generally divided decimally into tenths, hundredths, &c. The degree is frequently so divided.

6. MEASURE OF TIME.

60 seconds	= 1 minute
60 minutes	= 1 hour
24 hours	= 1 day
7 days	= 1 week
28 days	= 1 lunar month
28, 29, 30, or 31 days	= 1 calendar month
12 calendar months	= 1 year
365 days	= 1 common year
366 days	= 1 leap year.

In 400 years, 97 are leap-years, and 303 common. The second of time is subdivided like that of angular measure. We shall now give a table of itinerary measures of different countries, exhibiting the number of each answering to 100 English miles; also the length of a single measure of each sort in English yards :—

		No. of each = 100 Eng. miles.	Length of a single meas. in Eng. yds.
Arabia,	Miles	81.93	2148
Bohemia,	,,	17.36	10137
Brabant,	,,	28.93	6082
Burgundy,	,,	28.46	6183
China,	Lis	279.80	629
Denmark,	Miles	21.35	8244
England,	,,	100.00	1760
	Geographical	86.91	2025
Flanders,	Miles	25.62	6869
France,	Leagues astronomical*	36.21	4860
	Do. marine	28.97	6075
	Do. legal, of 2000 toises	41.28	4263

A day's journey	33	172	4.0

The following comparative view of the weights and measures of England and France was published by the Royal and Central Society of Agriculture in Paris in their *Annuary* for 1829; and it may be proper to add that the above work contains a greater quantity of useful information than any other periodical in France.

MEASURES OF LENGTH.

English.	French.
1 inch (1-36th of a yard)	2 539954 centimetres
1 foot (1-3d of a yard)	3.0479449 decimetres
1 yard imperial	0.91438348 metre
1 fathom (2 yards)	1.82876696 metre
1 pole, or perch (5½ yd.)	5.02911 metres
1 furlong (220 yards)	201.16437 metres
1 mile (1760 yards)	1609.3149 metres
French.	**English.**
1 milimetre	0.03937 inch
1 centimetre	0.393708 inch
1 decimetre	3.937079 inches
1 metre	39.37079 inches
	3.2808992 feet
	1.093633 yard
1 myriametre	6.2138 miles

SQUARE MEASURE.

English.	French.
1 yard square	0.836097 metre square
1 rod (square perch)	25.291939 metres square
1 rood (1210 yards square)	10.116775 ares
1 acre (4840 yards square)	0.404671 hectares
French.	**English.**
1 metre square	1.196033 yard square
1 are	0.098845 rood
1 hectare	2.473614 acres

SOLID MEASURE.

English.	French.
1 pint (1-8th of a gallon)	0.567932 litre
1 quart (1-4th of a gallon)	1.135364 litre
1 gallon imperial	4.84345794 litres
1 peck (2 gallons)	9.0869159 litres
1 bushel (8 gallons)	36.347664 litres
1 sack (3 bushels)	1.09043 hectolitre
1 quarter (8 bushels)	2.907813 hectolitres

MECHANICS is the science which treats of forces and of motion. It had, probably, its origin in the construction of machines, and an important branch of it, practical mechanics, investigates their construction and effects. Forces acting upon bodies may either produce rest or motion. In the former case they are treated of under statics, in the latter under dynamics. Hydrostatics and hydraulics respectively treat of *fluids*, at rest or in motion.—When a body is acted on by two or more forces which counteract each other, so that no motion is produced, the body and the forces are said to be in a state of *equilibrium*. The conditions of equilibrium form the subject of statics. 1. A body acted upon by two equal and opposite forces will remain at rest. In this case either of the two opposite forces may be made up of several parallel forces. It is then said to be the *resultant* of those forces. 2. If two forces act with reference to each other obliquely upon a body, they may be counteracted by a third (called also their *resultant*). If the two forces be represented in direction and intensity by two contiguous sides of a parallelogram, their result will be represented in direction and intensity by its diagonal. This is called the *parallelogram of forces*. 3. If several forces, acting at once upon a polygon, can be represented in direction and intensity by several sides of a polygon, they may be counteracted by a single force, acting in a direction and with an intensity represented by the side which would be necessary to complete the polygon.

All the changes which come under our observation in this science are the consequence of motions produced by the action of a few great elementary forces. The consideration of the motions which take place among the particles only of one or of several bodies comes within the department of chemistry. Those motions which affect masses are the appropriate subject of the second part of mechanics.

All motions are found to take place in conformity to a few universal principles deduced from observation and confirmed by experiment. These principles have often been placed at the beginning of treatises on mechanics, under the name of the *laws of motion*. If not expressed in this manner, the truths they declare, making an essential part of the principles of the science, are necessarily introduced under some other form. Their comprehensiveness adapts them to our purpose, and they are here quoted in the language of Newton. I. "Every body perseveres in its state of rest, or of uniform motion in a right line, unless it is compelled to change that state by forces impressed thereon." This is called the law of *inertia*, and expresses the entire indifference of matter to motion or rest. The proposition that a body will never begin to move of itself needs no proof: it is the conclusion of universal observation. Wherever we observe motion we conclude that there is a power in action to produce it. The other part of the law, that motion is, in its nature, as permanent as rest, and that it is in a right line, is far from being a self-evident, or even an obvious truth. Limited observation would lead to the conclusion that all matter has a tendency to rest, and such has long been, and still is, a common error. The same limited observation led some of the ancient astronomers to imagine that all bodies when forced into a state of motion naturally moved in curved lines. There is, however, abundant proof of the permanence of motion; and if friction and the resistance of the air, the two most universal obstacles to the motion of bodies near the surface of the earth, could be entirely removed, instances of permanent motion would be still more numerous. In proportion as they are removed, or as bodies are beyond their influence, we observe a tendency in the motions of those bodies to become more and more permanent. A marble, rolled on the grass, soon stops; on a carpet, it moves longer; on a floor, still longer; and on smooth level ice, where the wind is not unfavourable, it continues very long in motion. In a vacuum where the resistance of air is not felt, two windmills, whose pivots have equal friction, and which are set in motion by equal forces, continue to move equally long whatever be the position of their vanes. In the air, the one whose vanes cut the air will move much longer than the one whose vanes are opposed to it. A pendulum in a vacuum, having only the stiffness of the riband by which it is suspended to overcome, will vibrate for a whole day. A spinning top in the same situation, retarded only by the friction of its point, is said to continue spinning for hours. In all these cases the continuance of the motion is proportioned to the diminution of friction and resistance. We can hardly avoid the conclusion that a body once put in motion would, if left to itself, continue to move with undiminished velocity.

The heavenly bodies, moving in free space, subject to no opposing influence, keep on in their path with a velocity which has remained unabated since first they were launched from the hand of the Creator. They move not, indeed, in straight lines, but in curves, as they are drawn towards each other and towards a centre by the universal force of gravity. This force does not diminish their velocity, but deflects them continually from the right line in which they tend to move. If this central force were suspended, they would all shoot forwards into space, and the harmony of their motions would cease. Some force similar to this central tendency is always in action whenever we see bodies move in curve lines.

The stone to which a boy gives accumulated force by whirling it round in a sling is, for a time, kept in its circle by the central force represented by the string; when let loose it darts forward in the air, turning not to the right or left, until the atmospherical resistance destroys its motion, or the force of gravity bends it to the ground. A full tumbler of water placed in a sling, and made to vibrate with gradually

increasing oscillations, may at last be made to revolve in a circle about the hand, each drop tending to move out in a straight line from the centre, and therefore remaining safe in the tumbler, whose bottom is always farthest from the centre. In a corn mill the grain is poured gradually into a hole in the centre of the upper mill-stone. The weight of the stone pulverizes the corn, while its circular motion throws it out as fast as it is ground into a cavity around the stone.

When a vessel, partly full of water, is suspended by a cord, and made to turn rapidly round, the water, in its tendency to move out in a straight line, recedes from the centre, and is gradually heaped up against the sides of the vessel, sometimes even leaving a portion of the bottom dry. Water moving rapidly in the stream of a river, or the tide of the sea forced violently through a narrow passage between opposite rocks, not unfrequently forms a whirlpool on the same principle. Bent out of its course by a projecting ledge, it departs, as if reluctantly, from a straight line, and heaps itself up towards the circumference of the circle in which it is compelled to move. To this cause, too, it is owing, however little we might expect such a consequence, that a river, passing through an alluvial soil, and once turned from its onward channel, continues to pursue a meandering course to the sea. Driven, by any cause, to one side, it strikes the bank with all its violence, is repelled, and rebounds with the same force to the opposite side, continually wearing the two banks, and leaving a larger space on the inner side of the bends.

The force with which a body constrained to move in a circle tends to go off in a straight line is called the *centrifugal force*. Advantage is taken of it in many processes of the arts, and in all circular motions of machinery. The clay of the potter is placed on the centre of a swiftly revolving table, and while his hand shapes it the centrifugal force causes it to assume the desired dimensions. A globe, or sheet of molten glass, is in a similar manner made to expand itself. The legs of a pair of tongs, suspended by a cord, and made to revolve by its twisting or untwisting, will diverge in proportion to the velocity of the revolution.

The *steam governor* of Watt is constructed and acts on this principle. Weights are attached to two rods, to which a circular motion is communicated by the machinery which is to be governed. If the motion be so rapid as to cause these rods to diverge from each other beyond a certain angle, they act upon a valve which partly closes and diminishes the supply of steam. With a slower motion the rods collapse, and the valve is opened.

In consequence of the centrifugal force occasioned by the rotation of the earth, the weight of bodies at the equator is diminished the 289th part. If the earth revolved on its axis in eighty-four minutes, the loose parts near the equator would be projected from the surface. Another consequence or particular of the law of inertia is, that motion is communicated gradually. A force which communicates a certain quantity of motion in one second will impart double the quantity in two seconds. A ship does not yield at once to the impulse of the wind when the sails are set; its motion increases as new portions are successively imparted. A horse does not start at once with a carriage into his utmost speed; his force is at first spent in giving motion to the inert mass. Afterwards, with far less exertion, he keeps up the motion, being required to supply that portion only which is destroyed by the obstacles of the road. The motion communicated to a body, if not destroyed by some force, is accumulated. Thus a nail is driven in by all the force of the hand, accumulated through the whole time of the descent of the hammer. The knowledge of this fact gives the means of increasing the effective force of a moving power in a very great degree. A force of fifty pounds communicated every second to a loaded wheel will, if not diminished by friction or other cause of waste, enable it to overcome a resistance of five hundred pounds once in every ten seconds. Such a wheel is called a *fly wheel*.

II. "The alteration of motion is ever proportioned to the motive force impressed, and is made in the direction of the right line in which that force is impressed." This is only a statement that a double force generates a double motion; that motion cannot increase or diminish itself, nor turn to the right or left without cause. In consequence of this, two or more forces acting at once on a body in different directions cause it to take a direction different from that of either force, and, if one of them is a variable or constantly acting force, to move in a curve line. This is called the *composition of forces*, the single motion impressed upon the body being considered as composed of the several motions which the forces acting separately would have produced. A boat, rowed at the rate of three miles an hour directly from the bank of a river which runs at the rate of two miles an hour, is acted on at once by the force of the rowers and that of the current, and will be found, at the end of an hour, three miles from the bank, and two miles below the point from which it started, having moved in a diagonal line between the directions of the two forces.

The *resolution* of forces is the reverse of this. A single force is considered as resolved into two or more others. A ship, sailing on a side wind, is sent forward by a part only of its force. The other part has no effect, or that only of driving her out of her course.

III. "To every action there is always opposed an equal reaction; or the mutual actions of two bodies on each other are equal and in opposite directions." If you press a stone with your finger, the finger is equally pressed by the stone. A horse drawing upon a load is drawn backward by its whole weight, and, if he succeed in moving it, it can only be with a velocity proportioned to the excess of his strength over the reaction of the load. A magnet and piece of iron attract each other equally; and if, when in the sphere of mutual attraction, one is fixed and the other free, whichever is free will be drawn to the other. Two equal boats, drawn towards each other by a rope, act in the same manner; if both are free, they meet in the middle. When a gun is discharged it recoils with a force equal to that with which the ball is propelled, but with a velocity as much less as its weight is greater. If, in the side of a vessel of water, hanging perpendicularly by a cord, a hole be opened, the vessel will be pushed back from the perpendicular by the reaction of the jet of water, and will remain so while it flows. A consequence of this law is, that the earth is attracted by each body on its surface as much as it attracts, and that when a stone falls towards the earth the earth rises to meet it.—The force with which a body acts is estimated by its velocity and mass conjointly, and is called its *mo-*

mentum. Thus, if two balls of one and two pounds weight respectively be moving with the same velocity, the larger has twice the momentum of the smaller, since each pound of the larger has the same velocity as the ball of a single pound. A body of small weight may therefore be made to produce the same mechanical effect as a large one, by sufficiently increasing its velocity. The cannon ball of modern times is not less effectual in battering down walls than the massy battering-ram of the ancients.—The forces which may be employed to give motion to machines are called *mechanical agents* or *first movers*. They are water, wind, steam, gunpowder, and the strength of man and other animals. They may be indirectly referred to three independent sources—gravity, heat, and animal strength.

Gravity. A body falling from a state of rest descends 16 feet, nearly (16.095), in one second; but, as all the motion which is communicated by gravitation remains in it, and it receives an accession of motion every indefinitely small portion of the first second, it is moving more rapidly at the end of the second than at any previous time, and with that motion alone, if it continued uniform, would descend through twice sixteen or thirty-two feet in the next second; but during this next second as much motion is communicated as during the first, and consequently the body descends through three times sixteen or forty-eight feet in this next second. The whole of this accumulated motion would alone carry it through four times sixteen or sixty-four feet in the third second, and the continued action of gravitation carries it once sixteen; so that it actually descends five times sixteen or eighty feet during the third second. In the fourth second it would, in the same manner, descend seven times sixteen feet; in the fifth, nine times sixteen, &c., the series of odd numbers expressing the distances passed through in the successive seconds. By adding these numbers we find that at the end of two seconds the body will have descended four times sixteen feet; at the end of the third, nine times sixteen; at the end of the fourth, sixteen times sixteen, &c.; the whole distance fallen through at the end of any number of seconds being found by multiplying the square of that number by sixteen feet. Such is the simple and remarkable law of the descent of bodies by the uniformly accelerated velocity produced by gravitation. The velocity acquired in one second is sufficient of itself to carry a body through twice sixteen feet; that acquired in two seconds would carry it four times sixteen feet; that acquired in three seconds, through six times sixteen feet, &c., the velocities possessed at the end of any number of seconds being represented by twice that number multiplied by sixteen feet. The following table exhibits, 1. the space fallen through in the successive seconds; 2. the whole space fallen through at the end of a number of seconds; and, 3. the final velocity:—

Time, - - - -	1	2	3	4	5	6	7	8	9	10	seconds.
1. Successive spaces,	1	3	5	7	9	11	13	15	17	19	times 16 ft.
2. Total spaces, -	1	4	9	16	25	36	49	64	81	100	„ „
3. Final velocity, -	2	4	6	8	10	12	14	16	18	20	„ „

By means of this table, a traveller standing on the summit of a cliff might ascertain its height above the plain or torrent below, with considerable accuracy, by letting fall a stone and observing the time of its fall. It would only be necessary to make allowance for the resistance of the air, which, for small velocities, is not very great.

The same cause which communicates motion to a falling body would gradually destroy that of a body ascending. A ball projected upwards with the velocity of 1000 feet per second would, therefore, rise with a uniformly retarded motion to the height from which a body must fall to acquire that velocity. The phenomena of accelerated and retarded motion are beautifully exhibited by Atwood's machine for that purpose. In moving down an inclined plane, a solid body is urged by a portion of the force of gravitation, which is continually smaller as the plane is nearer to a horizontal position. When it is horizontal, the whole weight of the body is sustained by the plane. The velocity acquired by bodies moving down planes of different inclinations is the same as they would have acquired by falling freely through a distance equal to the perpendicular height of the plane. It is necessary, in the construction of machines, carriages, buildings, bridges, and ships, and in many other cases, to ascertain exactly the centre of gravity of the whole and of each part; since, if the centre of gravity, in any body or system of bodies, be supported, the whole must remain firm, and in a state of rest, in every possible position. The various problems arising from this necessity have been solved with great accuracy, and on fixed principles. In all regular solids of uniform density, whether bounded by straight or curve lines, the centre of gravity coincides with the centre of magnitude.

If a body of any shape be suspended freely from any one point of its surface, the straight line extending from that point to the centre of the earth will pass through the centre of gravity. This line is called the *line of direction*. The centre of gravity may, therefore, sometimes be found, practically, by suspending a body successively from two of its points, and observing the point where the lines of direction cross each other. The centre of gravity of a triangle is at one-third the distance from the middle of the base to the vertex; that of a cone and of a pyramid at one-fourth the same distance.

Stability, in every case, depends upon the position of the centre of gravity in reference to the base. The nearer it is to the base, and the further the line of direction falls from each part of the perimeter of the base, the greater is the stability. The sphere rests equally in every position, because the centre of gravity is at the same distance from every part of the surface; it is unstable in every position, as it rests on a single point of the plane; and it yields to the smallest force, as the centre of gravity does not rise when the sphere revolves. In order that the pyramid or cone may be overturned, the centre of gravity must rise almost perpendicularly, and move for a great distance before it ceases to tend to fall back to its place. Hence their stability, and hence the propriety of giving to steeples, monuments, and other buildings of great height, a pyramidical or conical figure. Those carriages are most secure which are hung low, and have the wheels far apart. Whatever raises the centre of gravity or narrows the base allows the line of direction more easily to pass without it, and consequently diminishes stability. Hence we see the imprudence of rising in carriages or boats which are in danger of being overset, and hence the danger of high loads on waggons, where the roads are not perfectly level. The force of gravity is not often employed directly as a mechanical agent, or prime mover. Those most fre-

quently employed to give motion to machinery are water, wind, heat, and the strength of animals.

Water acts by its *weight* and by the *velocity* which it acquires from falling, in consequence of its weight. *Wind* acts by its *volume* or *mass* and its velocity. Both these agents are variable, and both act in a straight line. *Heat*, as given out by combustible materials, produces steam or gas, or gives motion to air by making it lighter, and thus causing it to rise. The steam or gas, when formed, has a tendency to expand itself, presses against the sides of the vessel which contains it, and endeavours to escape with a force proportioned to the heat and pressure to which it is exposed. When allowed to escape in only one direction, it necessarily generates motion in a straight line. Steam, as usually employed, generates motion, which is alternately in one direction and the opposite. The strength of animals is commonly made to act upon some centre of resistance, by drawing, pushing, or pressing, and produces variable motions, naturally in a straight line, but often in a curve. The motions or pressures produced by all these agents are capable of being compared with those produced by weights. They might all be referred to a common standard, the unit of which should be the force required to raise a given weight a certain number of feet in a given time.

The mechanical agents are employed to measure time, to move ships and carriages, to raise weights, to shape wood and work metals, to overcome the resistance of air, of water, and of cohesion, to draw out and form materials, and to combine them into new fabrics. To apply them to accomplish any one of these effects requires the intervention of some mechanical contrivance. Such a mechanical contrivance, whether consisting of a few or of many parts, is called a *machine*. A machine has been defined, "a system of bodies, fixed or movable, so connected together that a movement impressed on one of them shall be transmitted to the others." The object of a machine is often vaguely supposed to be to produce or augment power. It can never have this effect. The resistance of the fixed and the friction of the movable parts will always consume a part of the power of the prime mover. The real object of every machine is to increase or diminish the velocity of the moving force, to change its direction, to accumulate its action and expend it at a single effort, to distribute the force among a great number of small resistances, or to divide the force of a resistance so that it may be overcome by a series of actions, or by the continued action of the moving power. A machine may combine the action of several movers, and employ one to regulate the others, so that the final effect shall be perfectly uniform. The pendulum, the governor, and the fly-wheel are employed for this purpose.

By the *mechanical powers* are signified the simple machines to which all machines, however complex, may be referred. They are essentially three in number, but usually considered as six; 1. The *lever*, and the *wheel* and *axis*; 2. the *inclined plane*, the *screw*, the *wedge*; 3. the *pulley*.

The *lever* is a bar, resting on a support, called a *fulcrum* or prop, for the purpose of raising, by a *power* applied to one end, a *weight* at the other. An iron crow, used by workmen to raise heavy stones, affords a good instance of a lever. The stone is the weight; the block on which the crow rests is the fulcrum; the strength of the men, the power. To gain any advantage by its use, the fulcrum must be nearer to the weight than to the power. If the distance from the power to the fulcrum be five times greater than the distance from the weight to the fulcrum, a force of one pound in the power will balance a pressure of five pounds in the weight. But in this case the end of the long arm of the lever will, as it turns on the prop, pass through a space five times greater than that of the short arm. By such a lever a man could raise 1000 pounds with the same exertion as would be required to raise 200 without a lever, but he could raise it only a fifth part so high in the same time. What he would gain therefore in power would be lost in time. In theory, a lever is considered inflexible and without weight. There is an equilibrium when the power and weight are inversely as their distances from the fulcrum.

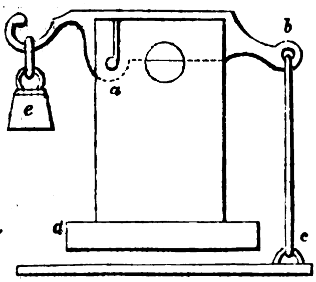
Leverage is the distance of the power from the fulcrum. The *mechanical advantage* or *purchase* is proportional to this distance compared with that of the weight from the fulcrum. Levers are of three kinds, according to the relative position of the power, the prop, and the weight. In the first, the prop is between the power and the weight. To it belong scissars, snuffers, pincers (in which the pivot or joint is the prop), the hand-spike, the brake of a pump, &c. A hammer with its claw is a bent lever of this kind. In the second, the weight lies between the fulcrum and the power. This includes the oar, where the boat is the weight to be moved; the door, of which the hinge is the fulcrum; the wheel-barrow, nut-crackers, bellows, and the knife attached at one end, used to chip dye-woods. In a lever of the third kind, the resistance is at one end and the fulcrum at the other. To this belong the pitchfork and spade, the one end being the power and the other the fulcrum, sheep-shears, with a bow at one end, giving a greater facility of motion. The bones of animals are levers of this kind, and are moved by muscles so attached as to give rapidity of motion at the expense of power. The ox-yoke is of this kind, the neck of each ox being the fulcrum with reference to the exertion of the other. The stronger of two oxen must have the short arm of the lever, that they may be able to pull together. So a load supported on a pole and borne by two men must divide the pole unequally, if either is to be favoured.—The mechanical advantage may be multiplied to any extent by a combination of levers of the first kind. Such a combination is used to *prove* the strength of iron cables.—To the lever are referred the various instruments employed for weighing. The most perfect of these is the common *balance*. For entire accuracy, the arms should be of precisely the same length, and as nearly as possible inflexible, light, and strong. The axis on which it turns, and the points of suspension at the ends of the arms, should be sharp, and rest upon polished plates of steel.

If we wish to construct a balance with the least possible degree of friction, this form of the lever should be adopted, but, instead of allowing it to rest on a flat plane, the fulcrum should be formed of steel and suspended by a magnet. By adopting this plan, the friction diminishes as the weights placed in the scale-pans are increased, an effect exactly the reverse of that which results from the use of the ordinary balance.

The Editor of this work has a specific gravity balance arranged upon this principle, which turns

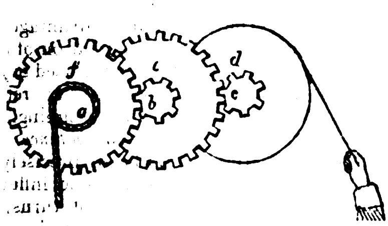
freely with the eight hundredth part of a grain, and yet the first cost was little more than that of a common pair of scales.

In the accompanying figure we give a view of a combination of levers in which great power is obtained. It is intended for pressing and cutting of metal. The principal lever, placed at the top of the machine, revolves on the axis or fulcrum *a*, which must be immovable and of great strength. The point *b* is just three times as far from the axis *a* as the pressing orifice is. A rod descends from the point *b*, and carries the mechanical advantage thus obtained to the lever beneath, and, as that turns on an axis placed at the extremity, a pressing power applied at the end of the longer arm *d* will act with an amazing force on the cutting part of the machine. The weight *e* is intended merely to raise the levers after the power is withdrawn.



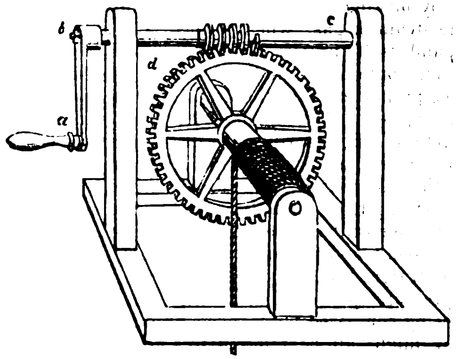
The *wheel* and *axle* consist of a wheel attached to a smaller cylinder, and moving on the same axis. The weight to be raised has a cord winding round the cylinder, and the power is attached to the circumference of the wheel. It may be regarded as a continual lever, each spoke of the wheel representing the long arm, and the radius of the cylinder the short arm. The mechanical advantage depends on the ratio of the cylinder. In the *ship's windlass*, movable bars or hand-spikes are substituted for a wheel. The *capstan* is a vertical wheel and axle used on board ships to weigh the anchor.

The wheel and axle may turn on different centres, and have their circumferences connected and made to act on each other, by means of a strap or belt, or by a system of cogs or teeth. The latter plan is adopted in this arrangement, and is called *wheel and pinion work*.



The weight to be raised is supported by a flexible cord coiled round the axis *a*; and, as the teeth of the wheel are three times as far from the centre as the cord, one pound will raise three pounds. In the wheel and pinion *e b* a similar advantage is obtained, and nine pounds may be elevated. Passing on to the third in the series, twenty-seven pounds may be raised by a maintaining power of one pound applied by the hand.

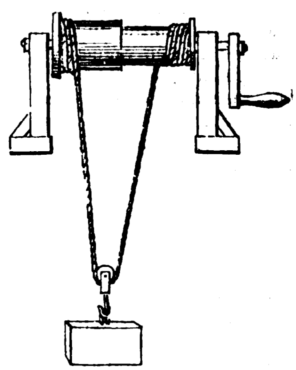
Another example, and a still more striking one, is given in the wheel and axis *a b c d*. The power is in the first instance applied at the handle *a*, which acts on the screw *b c* with great force. The screw turns the wheel *d*, and that gives motion to the small barrel. The handle at *a* will raise a weight of ten pounds at the screw, and, if that make forty revolutions to one of the wheel, four hundred pounds may be raised. It may hardly be necessary to add that, as the barrel is smaller than the wheel, the mechanical advantage is proportionably increased.



The efficacy of the wheel and axle may be increased either by enlarging the diameter of the wheel or diminishing that of the cylinder.

The *Chinese capstan* furnishes the means of increasing the mechanical efficacy to any degree. It consists of two cylinders of nearly equal diameters, turning upon the same axis, the weight being supported by the loop of a very long cord, one end of which unwinds from the smaller cylinder, while the other end is coiled upon the larger. The elevation of the weight by each revolution is equal to half the difference of the two circumferences, the mechanical advantage depending upon the smallness of this difference.

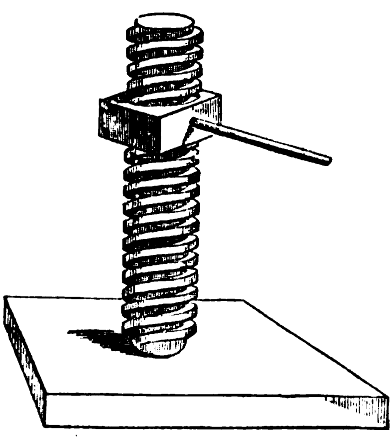
An arrangement of this kind is shown in the accompanying figure. One end of the cord coils round the first cylinder, and descending passes under the pulley to which the weight is attached. It is then carried around the smallest cylinder, and the apparatus may either be made to draw in a horizontal or vertical direction.



Inclined plane.—When a drayman lays a plank from the street to the higher level of the floor of a store-house, that he may be able to roll in a heavy cask, he employs the principle of the *inclined plane*; and the more gradual the inclination of the plank the more easily will he effect his purpose: that is, the advantage gained by the inclined plane is greater the more the length of the plane exceeds its height. A road which is not level is an inclined plane. When a road mounts over a hill, instead of winding round its foot, a team of horses with a load of a ton weight must exert strength sufficient to lift the load perpendicularly into the air, to a height equal to that of the top of the hill, instead of that moderate

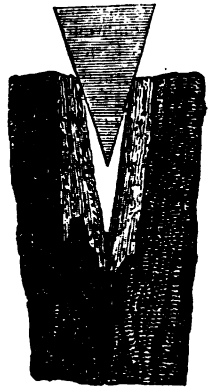
exertion which is necessary to overcome the friction of the axis of the waggon and the slight inequalities of a level road. Hence the absurdity of constructing roads in hilly countries to pass directly over the tops of hills, instead of winding by small circuits along their base. A body descending freely on an inclined plane moves with a velocity as much less than that with which it falls freely as the height of the plane is less then the length. If the elevation were one-sixteenth of the length, the body would roll down one foot in the first second, and four in twice that time. It is on this principle that the equality in the vibrations of a pendulum may be explained. A long vibration takes no more time than a short one, because the body begins to fall in this case down a steep plane, and acquires great velocity. In a short vibration, the beginning of its path is a very gradual descent. A short pendulum vibrates more rapidly than a long one, because it has a shorter distance to move in a path of the same steepness. A body moving down an inclined plane moves four times as far in two seconds as in one. A pendulum, to vibrate once in two seconds, must be therefore four times as long as one which beats seconds. The most remarkable application of the inclined plane is in the construction of the *marine rail-way*, on which, by the power of a few horses, a ship of 600 tons is drawn, with all its cargo, out of the water, high enough to allow workmen to pass under its keel. An example of this species of mechanical power has already been given under INCLINED PLANE.

The *screw*. Imagine an inclined plane to pass round an immense building like the tower of Babel, affording means of ascending to the top, and you have the first idea of the *screw*. It is an inclined plane wrapped spirally round a solid cylinder. The advantage gained by it depends on the slowness of the ascent, that is, on the number of turns, or *threads* as they are called, in a given distance. It is always used in combination with a lever. It is a machine of great power, commonly employed to produce compression or to raise heavy weights. In the screw beneath, the threads which form the path of the inclined plane are flat, instead of being sharp as in the common wood screw, and this form is well fitted for heavy work, as it materially reduces the friction.



Hunter's screw is a compound of two screws with threads of different degress of fineness, one moving within the other, the end advancing at each revolution through a distance equal to the difference of the threads. (See SCREW.)

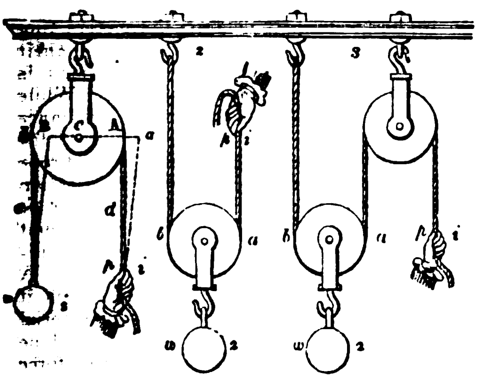
The *wedge* is a double inclined plane, used commonly to cleave wood or stone, and sometimes to elevate a large mass, as part of a building or a ship. The effect of a wedge depends apparently upon friction, elasticity, and the slowness with which motion is communicated to a mass of matter. When a wedge is driven in the particles immediately in contact with it are, for a moment, displaced: the friction against it prevents it from receding, and when the displaced particles endeavour to resume their relative position the rift is lengthened, as is shown in the wood cut. To the wedge may be referred various cutting tools, such as axes, knives, swords, chisels, and nails and spikes to be driven into wood, as well as pins, needles, awls, &c. The saw and the file and rasp are modifications still more remote. The colter of a plough, the blade of a spade, and other instruments to penetrate the earth, are in the shape of a wedge.



The *pulley*. If a rope be stretched horizontally between two fixed points by equal weights attached to the ends, any very small weight applied to the rope between these points will bend the rope and thus raise the weights. If we suppose the rope to have been perfectly horizontal, the weight applied acts upon those at the ends with a mechanical advantage which may be considered infinite, as it acts at right angles to the directions of the opposite actions of those weights. This is a necessary consequence of the principles of the resolution of forces. The action of one or two forces can have no effect in counteracting a third, unless they act in such a direction that their action can be resolved into two, one of which is opposite to the direction of the third force. While the rope is horizontal the two weights counterbalance each other, but produce no further effect until the rope is bent into an angle. A bending of the rope must therefore take place in consequence of the action of any force, however small. By bending the rope it must raise the weights and support them at a point above their former position, thus producing an equilibrium with them however great they may be. A necessary consequence of the principle on which it depends is, that when a rope or chain of any material whatever is stretched horizontally its weight alone will prevent its being perfectly straight, and no force is sufficient to straighten a rope unless it hangs perpendicularly. Advantage is often taken of this power by seamen in tightening ropes, which have previously been drawn as closely as possible by the direct action of their strength.

The flexible rope to which we have adverted is an essential part of the pulley, which is a small wheel, moving on an axis or pin, fixed in a frame called a *block*. The circumference of the wheel has a groove for the rope to move in. The pulley is said to be *fixed* or *movable*, according as its block admits of motion or not. A fixed pulley gives no mechanical ad-

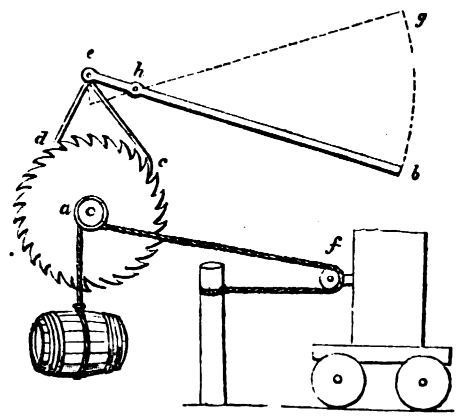
vantage, but it enables us to apply force more conveniently, by changing its direction. A man standing on the deck of a ship is able, by means of one fixed at the top of the mast, to raise a weight to that point by drawing downwards. In the same manner ore is raised from mines, and water from deep wells. The wheel in the grooved circumference round which the rope passes gives facility to its motion by preventing the necessity of its bending suddenly round a sharp edge, and diminishes the friction by transferring it from the rope to the axis of the wheel. One or more grooved wheels, called *sheaves*, set in a block, and moving freely round an iron axis, constitute a pulley, and the combination of pulley and ropes a *tackle*. If the rope, instead of being attached to the weight, passes through a movable pulley attached to the weight, and terminates in a hook or ring in the upper block, the tackle becomes an engine by which another advantage is gained. As, in this case, the weight is supported by two parts of a rope, each part sustaining one-half, the power necessary to support one of these parts is equal to only one-half the weight supported, and, by drawing upon one end of the rope with a power a little greater than one-half of the weight, the whole weight will be raised. It is on this principle that advantage is gained by the pulley. If the weight were supported by the four parts of a rope, which passed through two fixed and two movable pulleys, each part sustaining one-fourth of the weight, a power equal to one-fourth part of the weight, attached to the free end of the rope, would balance the whole weight, and something more than one-fourth would raise it. This advantage is purchased by the space through which the power must move, and the time occupied by the motion. To raise a weight fifty feet, by the combination last mentioned, the power must move over a space of 200 feet. The pulley is employed to elevate large weights to the tops of buildings, or to upper lofts in store-houses. Its numerous varieties are chiefly used on board ships.



An example of the simplest form of the pulley is given at B A, in which a weight, *w i*, is supported by the hand *p i*. The pulley in this case serves merely to change the direction of motion. If we suppose a second pulley to be attached to the first, as much larger as is shown by the dotted line, or rope *a*, the effect would be doubled, as in the common wheel axle. In figure 2, the same mechanical advantage is obtained by a single pulley. The cord passes round the pulley *a b*, and the weight of two pounds is supported by a power of one applied by the hand at *p i*. To understand this, it will only be necessary to bear in mind that the axis of the pulley to which the weight is really attached is only half the distance from the flexible fulcrum *b* that the point *a* is to which the power is applied. In the third series we have the same arrangement of the left-hand pulley, but the power is applied through the medium of a roller at top, which is employed only to change the direction of motion.

A great many experiments made by Rondelet have shown that, for most purposes, the best proportions for the wheel of a pulley are, 1. that its diameter should be five times its thickness; 2. that the diameter of the pin should be one-twelfth of that of the wheel; 3. that the wheel should have about one-twelfth of its thickness on each side for its play in the block.

In concluding our account of the mechanical powers, it may be advisable to take one machine in which several are combined. The lever *b*, by moving through the arc *b g*, tends to elevate the barrel attached to the cylinder *a*. This is effected by the two arms *d* and *c*, which are attached by a flexible joint to the end. When the end of the lever *b* is elevated, then the arm *d* carries forward the wheel a single tooth. When it is depressed, *c* moves the wheel. The same machine may be employed to do other work, and when combined with a pulley, as at *f*, its power is doubled.



MEDALLIONS. The term *medallion* is applied to those productions of the mint which, if gold, exceed the *aureus* in size; if silver the *denarius*; and if copper the first or large brass coin. Antiquaries have long differed as to the purposes for which they were designed; they are generally, however, supposed to have been struck, like the medals of our time, to commemorate some remarkable event. Yet circumstances are not wanting to render it probable that they were intended for circulation as money. Perhaps both objects were united, at least in many instances, a large number of pieces, of a definite value, being coined in memory of a great event, and thus adapted, at the same time, for current use. Medallions are not numerous. The Greek, or those struck in the Greek provinces of the Roman empire, are more common than the Roman, but of inferior workmanship. A gold medallion exists of Augustus, and one of Domitian; but few, in any metal, are found prior to the reigns of Adrian and Antonine; those in brass are

the largest, many of them being several inches in diameter.

MEDALS. See NUMISMATICS.

MEDICINE; the science of diseases, and the art of healing or alleviating them. It is founded on the study of man's physical and moral nature, in health and in disease. Like other sciences, medicine has gained more from the single discoveries of close observers than from centuries of theory. For the few hundreds of years in which men have begun to apply themselves more to actual observation, and the human body has been carefully studied, medicine, like all the natural sciences to which it is so near akin, has made great progress.

The higher kinds of skill and knowledge, in the earlier stages of nations, are in general exclusively appropriated by the priests, and this has been the case with medicine and the other branches of natural science. The knowledge of medicine was a secret of the Egyptian priests, and, in Greece, it was carefully concealed, and transmitted from father to son by the family of the Asclepiades, an order of priests of Æsculapius. To these belonged the great Hippocrates. He undertook, in the fifth century B. C., after making himself master of the medical knowledge preserved in the temples at Cos and Cnidos, to become the founder of scientific medicine, by separating the results of actual experience from vain speculation. His doctrine may be called the *empiric rationalism*; and numerous as are the systems that have flourished since, in ancient and modern times, mankind has always returned to his principle of making observation the only rule in the treatment of diseases. The doctrine of Hippocrates was blended, by his immediate successors, with the Platonic philosophy, whereby was formed the (so called) *ancient dogmatic system*. In Alexandria, which was, from 300 B. C., the seat of learning, medicine was one of the branches studied, but soon degenerated into mere dialectics and book-learning. Hence we find it soon followed by the empiric school (286 B. C.), the methodic school (100 B. C.), the pneumatic school (68 B. C.), and at length by the eclectic school (A. D. 81), which took from all the others. A philosophical and great mind was required to put an end to so confused a state of medical science, and such a mind appeared in Galen of Pergamos. His system acquired an almost undisputed preëminence during the middle ages, and down to the sixteenth century.

For some time the intellectual Arabians cultivated the sciences, and with them medicine. They also founded their medicine on that of Galen, but fashioned the science according to their notions, and left it not unimproved in respect of practical application and pharmacology. Arabian medicine reached its highest point under Avicenna (born 980), who was esteemed even higher than Galen; the opinion of the latter's superiority, however, eventually revived. Western medicine begins with the medical school of Salerno, perhaps existing as early as in the ninth century, but well established in 1143 and 1238, when medicine was taught according to the principles of the Greeks. During the rest of the middle ages there existed a Galeno-Arabian science of medicine, mostly fostered by ignorant monks, and only gradually struggling on, after suffering, perhaps more than any other science, from every superstition and every misconception of nature. In the fourteenth century anatomy was improved by Mondini; later, the knowledge of medicaments by the discovery of new and distant countries, practical medicine by the appearance of new diseases, and not a little by the frightful syphilis. The love of Greek literature was revived by the scholars driven from Greece by the conquest of Constantinople (in 1453); and men having begun to read the Greek medical writers, especially Hippocrates, in the original language, a more scientific and liberal spirit of investigation took the place of slavish adherence to antiquated prejudice. Thus the fall of the Galenic system was prepared, which was completed in the sixteenth century, and forms the essential part of the reformation produced by Theophrastus Paracelsus (1526). Soon after Harvey's great discovery of the circulation of the blood (in 1619) the medico-mathematical doctrine, under Alphonso Borelli (who died in 1679), developed itself, which finally took the shape of the dynamic system of Fr. Hoffman, from which the dynamic schools of modern times proceeded. For the newest systems, as the homœopathic system of Hahnemann (see HOMŒOPATHY), or that of M. Broussais, a Frenchman, who strives to trace all diseases to inflammation of the bowels, we must refer to the publications of those authors, and to the medical periodicals. The various medical sciences, or those closely connected with them, and more or less requisite for a thorough knowledge of medicine, may be thus enumerated:—The whole range of natural sciences, as zoölogy (including comparative anatomy and physiology, mineralogy, geology, botany, natural philosophy, chemistry, &c.)—psychology, which teaches the various phenomena of soul and mind—anatomy, which teaches the form and situation of the organs by the examination of dead bodies, and is divided into osteology, treating of the bones; syndesmology, of the ligaments; myology, of the muscles; splanchnology, of the intestines; angiology, of the vessels; neurology, of the nerves; and adenology, of the glands—organic physics, treating of the mechanical operations of the human body, the power, gravity, &c., of its parts—physiology, which treats of all the phenomena of life in connection. Such is the basis of all those branches of science which may be more particularly called *medical*, and which we will now enumerate. The science of health, that is, of that in which it consists, its conditions, and its signs, is called *hygiene*, or, as far as it relates to the regulation of the diet, *diætetics*. *Pathology*, on the other hand, is the science of disease, of that in which it consists, its origin, &c. *Nosology* treats of the various sorts of diseases, their origin and symptoms, and strives to arrange diseases into one whole. *Pathological anatomy* teaches the mechanical alterations and changes of structure. *Semiotics* teaches to infer from the various symptoms the nature of the disease; *diagnostics*, to distinguish the symptoms of different diseases; and *prognostics*, to infer from the past and present state of a disease its future course. *Therapeutics* is the science of the cure of diseases, often divided into *general*, treating of the subject of cure in general, its character, &c., and *special*, of the cures of the particular diseases.

Surgery treats of mechanical injuries, and the mode of relieving diseases and derangements by mechanical means. *Obstetrics* treats of the modes of facilitating delivery. *Materia medica* is the science of medicines, their external appearance, history, and effects on the

human organization. *Pharmacy* teaches how to preserve drugs, &c., and to mix medicines.

Clinics, or medical practice, applies the results of all these sciences to real cases. We should mention in this connection the history and literature of medicine; the history of diseases; a very interesting branch, political medicine, which is divided into medical police and forensic medicine, that branch which enables the physician to give to courts and other legal authorities proper explanations in regard to personal injuries, particular appearances of the body, &c., as whether a wound was mortal, how inflicted, whether a child was dead before born, &c. In many countries physicians are appointed by the government for this purpose.

Mellitic Acid; discovered by Klaproth in the mellite, or honey-stone. It is procured by reducing the mellite to powder, and boiling it with about seventy-two times its weight of water; the alumine is precipitated in the form of flakes, and the acid combines with the water. By filtration and evaporation, crystals are deposited, in the form of fine needles, or in small short prisms. It is composed of carbon, hydrogen, and oxygen. In combination with the earthy alkalies and metallic oxides, it forms compounds called *mellates*.

Melody; in the most general sense of the word, any successive connection or series of tones; in a more narrow sense, a series of tones which please the ear by their succession and variety; and, in a still narrower sense, the particular air or tune of a musical piece. By melody, in its general, musical sense, the composer strives to express particular states of feeling or disposition, which, in pieces of several voices, is chiefly effected by the principal melody, or chief voice, to which the other voices, with their melodies, are subordinate. The elements by which the composer is enabled to express a beautiful variety of sentiments and feelings, by means of the melodious connection of tones, are the variety of tones in themselves, and the variety of transitions from one tone to another, to which is still to be added the variety of the movements in which the music proceeds.

Melody and rhythm are the true means to awaken delight, and, where they are wanting, the greatest purity of harmony remains without effect. The proper essence of melody consists in *expression*. It has always to express some internal emotion, and every one who hears it, and is able to understand the language, must understand the feeling expressed. But as melody, in the hands of the composer, is a work of art and taste, it is necessary that, like every other work of art, it should form a whole, in which the various means are combined to produce one effect. This whole must be such that the hearer is kept constantly interested, and can give himself up, with pleasure, to the impressions which he receives. The particular qualities of a good melody are these:—It is indispensable that it should have one chief and fundamental tone, which receives proper gradations by a variation adapted to the expression. This can be effected only by letting the tones proceed according to a certain scale; otherwise there would be no connection between them. The chief tone, again, must be appropriate to the general idea to be expressed, because every kind of tone has its own character, and the finer the ear of the composer is the better will he always discover the tone wanted.

In very short melodies, or tunes consisting merely of a few chief passages, the same fundamental tone may remain throughout, or perhaps pass over into its *dominante*; but longer pieces require change of tone, that the harmony also may receive modifications according to the feeling. Thirdly, a good melody requires rhythm. A regular advance from one part to another, whether in music or motion (dancing), affects the mind agreeably, whilst an irregular progress fatigues. The love of rhythm is one of the most general feelings of human nature. We find rhythm every where, and to music it is indispensable, as tones without regularity of measure would distract and weary. Hence music is divided into portions or bars; these, again, are divided so as to prevent monotony, without disturbing the general regularity. Accents are given to certain parts, and it is possible greatly to assist the expression of feeling by slow or quick, gay or solemn movements, and by the variety of accents, and even or uneven time.

Much might be said respecting the skill of the composer to adapt his music, not only in general to the idea to be expressed, but also, in song, to the single words, to the pause which the hearer wishes here, or the speedy movement which he desires in other places; the necessity of the repetition of words, if the feeling is long and varied, while the word is short; the childish impropriety of representing, as it were by imitative sounds, the ideas presented by particular words, which is much the same as if a declaimer, every time that he pronounces the word *ocean*, were to endeavour to represent the roaring of the waves; the parts where dissonances are admissible, &c.; but it would carry us much beyond our limits.

Menses; periodical discharges to which females are subject during a certain portion of their life.

Mensuration is the art of ascertaining the contents of superficial areas or planes, of solids or substantial objects, and the lengths, breadths, &c., of various figures, either collectively or abstractedly. The mensuration of a plane superficies or surface lying level between its several boundaries is easy: when the figure is regular, such as a square or a parallelogram, the height, multiplied by the breadth, will give the superficial contents. In regard to triangles, their bases, multiplied by half their heights, or their heights by half their bases, will give the superficial measure. The height of a triangle is taken by means of a perpendicular to the base, let fall from the apex or summit. Any rectangular figure may have its surface estimated, however numerous the sides may be, by simply dividing it into triangles by drawing lines from one angle to another, but taking care that no cross lines be made: thus, if a triangle should be equally divided, it may be done by one line, which must, however, be drawn from any one point to the centre of the opposite face. A four-sided figure will be divided into two triangles by one oblique line connecting the two opposite angles; a five-sided figure (or pentagon) by two lines, cutting, as it were, one triangle out of the middle, and making one on each side; a six-sided figure (or hexagon) will require three diagonals, which will make four triangles; and so on, to any extent, and however long or short the several sides may be respectively.

The most essential figure is the circle, of which mathematicians conceive it impossible to ascertain the area with perfect precision, except by the aid of logarithmic and algebraic demonstration. It may be

sufficient in this place to state that 8$\frac{86}{100}$ of the diameter will give the side of a square whose area will be correspondent with that of a circle having ten for its diameter. Many circular or cylindrical figures come under the measurer's consideration—mirrors, arched passages, columns, &c. The contents of a pillar are easily ascertained, even though its diameter may be perpetually varying; for if we take the diameter in different parts, and strike a mean between every two adjoined measurements, and multiply that mean area by the depth or interval between the two, the solid contents will be found.

The contents of pyramids are measured by multiplying the areas of their bases by half their lengths, or their lengths by half the areas of their bases. Cones whose sides are straight are equal to one-third the solid contents of cylinders equal to them in base and altitude. Solids which have a certain degree of regularity may be easily measured: thus a cube is computed by multiplying first its width by its length, then their product by its height: thus a cube measuring four feet each way would be $4 \times 4 = 16 \times 4 = 64$. This is the meaning of what is called the *cube root*.

Parallelopipedons, or solids of a long form, such as squared timbers, are measured by the same means.

For the mensuration of growing timber various modes have been devised. After a tree has been felled its girth is usually taken at each end and at the middle, when there is no particular swell or the top extremity does not suddenly decrease. But where the irregularity is great it is better to take many more girths, and, summing up the whole, to divide their amount by the number of girths taken, so as to establish a mean measurement. Divide that mean measurement by four to find the side of a square to which the tree will be reduced when prepared for the sawyer. If the whole solid contents are to be estimated, divide by three instead of four, and taking the third part, thus given, for a diameter, proceed in the way already shown to find the side of a square equal to the circle of which that ascertained third part is the diameter. Solid bodies or areas, such as hay-stacks, interiors of barns, granaries, &c., come under the rule laid down for cubes, &c. When any sides fall in regularly, as in garrets, &c., the inclined part must be treated as a pyramid, or as a quoin (or wedge), and the whole be summed up together. The contents of casks, tubs, &c., are found by the process of gauging. (For that part of the subject which appertains to the admeasurement of lands, as also to the distances, heights, &c., of remote objects, accessible or otherwise, see SURVEYING.)

MENTAL DERANGEMENT, INSANITY. By these general terms we understand every form of intellectual disorder, whether consisting in a total want or alienation of understanding, as in idiocy, or in the diseased state of one or several of the faculties. Medical writers have adopted different systems of classification in their treatment of this subject; but perhaps the most convenient is that which comprises all mental diseases under the four heads of mania, melancholy, demency or fatuity, and idiocy. Lunacy, in its proper sense, implies an influence of the changes of the moon on the state of the mind or body, of which modern science cannot recognize the existence. It is true that many diseases are periodical in their returns, and it is not improbable that paroxysms of violence among insane persons may be really increased at the time of a full moon, by the effect of the shadows of clouds, and other objects, as ghosts are generally seen by moonlight; but any other lunar influence neither experience nor science can discover. The causes of insanity are divided, by modern writers, into physical and moral. Every excess of passion, joy, grief, anger, fear, anxiety, &c., becomes a moral cause of insanity.

Great political or civil revolutions have always been observed to be attended with numerous cases of mental derangement. Pinel observed this phenomenon in France, after the revolution of 1789; and Dr. Rush describes similar effects in the United States of America, after the war of the revolution. Strong religious excitement often produces similar results, although, in many cases, religious enthusiasm is only a form of the malady, and not a cause. Madden states that insanity is rare among the Mohammedans, and attributes it to their consoling belief in the certainty of their salvation. Dr. Rush thinks that the disease is more common among civilized communities than with savages, on account of the greater influence of moral causes on the former. The physical causes of insanity are various and numerous; diseases of various kinds and of different organs, bodily injuries or wounds, excessive indulgence in eating, drinking, and other sensual pleasures, privation, exposure to extreme cold or heat, &c., are among them. Insane persons are often, however, in good health, and dissection does not always detect a disordered condition of the organs. Philosophy is not sufficiently acquainted with the mutual action and re-action of the body and the mind on each other to decide how far the disordered state of the one is consistent with the sanity of the other; nor is it certain that there is any one organ or function which must be diseased to affect the mind.

Climate, age, occupation, and sex, are often mentioned as causes influencing insanity. But climate does not appear to be an exciting cause, although the moral, civil, religious, or physical condition of a nation may have rendered the disorder more frequent in some countries than in others. The seasons, however, appear to exercise an influence, and it is generally observed that the cases of insanity are most numerous in the hottest part of the year. Suicides are most frequent when the thermometer is above 84°.

Although many circumstances, both physical and moral, might seem to render the female sex most liable to insanity, it does not appear that the number of insane females is greater than that of males: drunkenness being more prevalent among the latter may be one cause of this. In both sexes, the most active period of life, from thirty to forty, presents the greatest number of cases. In regard to occupation, sufficient data do not exist to show that there is any decided predominance of cases in any particular employment. Idiocy is either a congenital or an acquired defect of the intellectual faculties, or, as Pinel defines it, an obliteration, more or less absolute, of the functions of the understanding and the affections of the heart. Congenital idiocy may originate from a malformation of the cranium, or of the brain itself; the senses are often wanting or defective, and life is commonly of short duration. Acquired idiocy proceeds from mechanical injury of the cranium, or from an injury or a disease of the brain, from excess in sensual indulgences, intemperance, fatigue, and from moral causes. In this, the senses may be par-

tially affected or quite destroyed, and life often continues to old age. Absolute idiocy admits of no cure; but it should not too hastily be concluded that a patient is in this state.

Mania is a species of mental derangement characterized by the disorder of one or several of the faculties, or by a blind impulse to acts of fury. Adults are the principal subjects. A nervous temperament, or an irritable constitution, predisposes to it. Females are more exposed to it than males, particularly at the period when menstruation begins or ceases, during pregnancy, and after delivery. Violent emotions, a dissipated life, excess in any indulgence, sometimes produce it. The disorder of the intellectual faculties is manifested by extravagant, gay, gloomy, or furious emotions; the gestures and words seem automatic. Sometimes the conversation is rational, but the patient bursts out at intervals into paroxysms of rage, attacking every thing which he meets; the moral affections also seem deadened, and the most ferocious hatred is displayed towards the most natural objects of love. It is sometimes cured, at other times remains stationary, and sometimes is converted into demency. Repeated bleeding, hellebore, cold water poured upon the head, scourging, and other means of terror were formerly employed as remedies. At present, solitude, warm baths, low diet, &c., are more commonly applied.

Melancholy, called also *monomanie;* a species of mental disorder, consisting in a depression of spirits. Some dark or mournful idea occupies the mind exclusively, so that, by degrees, it becomes unable to judge rightly of existing circumstances, and the faculties are disturbed in their functions. The powers of the soul become weakened, we might say crippled. If these feelings are allowed to attain a height at which the power of self-control is lost, a settled gloom takes possession of the mind. Consciousness, however, may still continue; the person knows his state. But if consciousness is also lost, if this state becomes continual, the melancholic patient is insensible to the world around him; he lives only within himself, and there only in the circle of one fixed idea. In this disordered state of the feelings, the other faculties may still continue to act, although the mode and result of their operation will necessarily be influenced by the existing disease. There may be reflection in the actions of the patient, but the reflection proceeds from false premises. Several kinds of melancholy are distinguished; the distinctions are founded, however, mostly on the cause of the disease. A very common cause of melancholy is love. He who loses the great object of his wishes and affections, which has absorbed, we might almost say, the whole activity of his soul, feels more than jealousy at the success of a fortunate rival; existence appears to him a blank, and himself the most unhappy of men. Another frequent cause of melancholy is gloomy views of religion. A constant excitement of the feelings by the awful picture of the eternal punishment of sin often produces absolute despair. The use of such means, to prepare the mind for the reception of deep religious principle, has not unfrequently led to distraction and suicide. Repeated failures in enterprises pursued with anxious zeal may also reduce the faculties of a man so much that he becomes wrapt up solely in the idea of his misfortune.

Melancholy patients often flee from men, haunt solitary places, such as grave-yards, and are given to nocturnal rambles. The course of the disease is various; sometimes it lasts a series of years; sometimes it ceases of itself, or is cured by medical aid; more frequently it passes over into other kinds of insanity, or into bodily diseases, as dropsy of the chest, consumption, dropsy in the head, apoplexy, &c. It is said that melancholy people rarely suffer from the gout or are attacked by epidemic diseases. Several physical causes are enumerated as inducing it, particularly a superfluity of black bile. Various derangements in the physical system tend to occasion it, as debility of the nerves, violent flow of the blood to the heart, superfluity of thick blood. Burton's *Anatomy of Melancholy* consists chiefly of extracts from ancients authors illustrating the causes, effects, and cure of that morbid affection. The author's own reflections are few, but they are original, ingenious, and striking. The subject of insanity is fully treated in the following works:—Burrow's *Commentaries on the Causes, Forms, Symptoms, and Treatment of Insanity* (London 1828); Pinel, *Traité sur l'Aliénation Mentale;* Voisin, *Des Causes Morales et Physiques des Maladies Mentales* (1826).

MEPHITIC is used to signify those kinds of air which will not support combustion or animal life, or, more generally, offensive exhalations of any sort. Modern chemistry has given particular names to many of these. (See CARBON and SULPHUR.)

MERCANTILE SYSTEM is one that prevails to a greater or less extent in every country of Europe. It was introduced into France by Colbert. As originally understood and acted upon, it embraces some fallacious doctrines, and carries some just ones to excess. The notion, for example, that wealth is derived mostly from foreign commerce, and depends upon an annual importation of specie, called the *balance of trade*, is erroneous. This balance was understood to be the bullion or coin received by a country in exchange for a part of its exports, and the foreign trade was supposed to be advantageous and promotive of the national wealth in proportion as the returns of trade were made in the precious metals, instead of other merchandise; whereas an exchange for iron, tin, leather, or any other useful merchantable commodity, is quite as advantageous as the importation of specie. It will depend upon the wants of the community whether the importation of one or another article will most promote the national wealth. It would be quite absurd, therefore, to attempt, by legislation, to force trade to yield a balance in specie. As far as this was a direct object of the commercial system, it was accordingly mistaken. If a nation needs other things more than specie, such prices will be offered as will induce their importation. But this notion of the importance of the balance of exports and imports is not without its truth in a certain respect. It is undoubtedly an evil for one nation to be constantly indebted to another. It will be found true between individuals, between different districts of the same country, and also between different nations, that the indebted party is the one most liable to make sacrifices. If a people or district, or an individual, will keep in advance of their means, and anticipate the income of the coming year, the consequence will be a perpetually straitened and embarrassed state. This was always the case with the British American colonies, and even of the United States for many years after the

establishment of American independence. The liberal credits in England enabled them to anticipate their income, and they were, accordingly, always largely indebted to this country, and thus constantly straitened and distressed, notwithstanding the country was during the same time rapidly growing in population and wealth. It is desirable that the commerce of a country should be so conducted as not to keep the country constantly indebted. If we were, therefore, to consider the balance of trade to be a constant standing balance of debt due to or from a country, in this sense it would be a subject of great importance. The consequence of large foreign credits, and of the desire to consume more of foreign products than the people have present produce of their labour sufficient to pay for, is occasionally to drive specie from the country; and the more extensive the credits the more complete and exhausting will be this drain when it happens.

MERCURY, or QUICKSILVER. The name *quicksilver* is derived from the alchemists, who regarded this metal as silver in a fluid state, quickened by some inherent principle, which they hoped either to fix or expel. It was known to the ancients, especially to the Greeks and Romans, who employed it in gilding and in the extraction of the precious metals. It is distinguished from all other metals by its extreme fusibility, which is such that it does not take the solid state until cooled to the thirty-ninth degree below 0 (Fahrenheit), and, of course, is always fluid in the temperate climates of the earth. Its colour is white, and rather bluer than that of silver. In the solid state it is imperfectly malleable; specific gravity, 13.6. It is volatile, and rises in small portions at the common temperature of the atmosphere. At the temperature of 656° it boils rapidly, and rises copiously in fumes. When exposed to such a heat as may cause it to rise quickly in the vaporous form, it gradually becomes converted into a red oxide, provided oxygen be present. This was formerly known by the name of *precipitate per se*. A greater heat than 600°, however, revives this metallic oxide, at the same time that the oxygen is again liberated, and we may thus procure a plentiful supply of oxygen gas for chemical experiments.

Mercury, if quite pure, is not tarnished in the cold by exposure to air and moisture; but, if it contains other metals, the amalgam of those metals oxidises readily, and collects as a film upon its surface. It is said to be oxidised by long agitation in a bottle half full of air, and the oxide so formed was called by Boerhaave *Ethiops per se;* but it is very probable that the oxidation of mercury observed under these circumstances was solely owing to the presence of other metals. The oxides of mercury are two. The *protoxide*, which is a black powder, insoluble in water, is best prepared by mixing calomel briskly in a mortar with pure potassa in excess, so as to effect its decomposition as rapidly as possible. The protoxide is then to be washed with cold water, and dried spontaneously in a dark place. The *peroxide*, which is commonly known under the name of *red precipitate*, is prepared, as already mentioned, from the combined agency of heat and air, or by dissolving mercury in nitric acid, and exposing the nitrate so formed to a temperature just sufficient to drive off the whole of the nitric acid. It contains double the quantity of oxygen found in the protoxide. It is acrid and poisonous, and carries these qualities into its saline combinations; whereas the protoxide is relatively bland, and is the basis of all the mild mercurial medicines.

Of the combustibles, mercury unites only with phosphorus and sulphur. The *phosphuret* is formed by heating either of the oxides along with phosphorus in a retort filled with hydrogen gas, or under water, with frequent agitation: the oxide is reduced, and a phosphuret is the result. It is of a black colour, is easily cut with a knife, and, in the air, exhales vapours of phosphorus. There are two sulphurets, the black and the red, or the *proto-sulphuret* and the *deuto-sulphuret*. The first is formed by rubbing vigorously in a glass or porcelain mortar three parts of sulphur and one of mercury, or by adding mercury at intervals, and with agitation, to its own weight of melted sulphur. The second, which is commonly called *cinnabar*, or *vermilion*, is formed by subliming the proto-sulphuret. Large quantities of it are manufactured in Holland. The ordinary process consists in binding together 150 lbs. of sulphur and 1080 of quicksilver, and then heating the mixture in a cast-iron pot, two feet and a half in diameter, and one foot deep, precautions being taken that the mixture does not take fire. The calcined Ethiops is then ground to powder, and introduced into pots capable of holding twenty-four ounces of water each, to which are attached subliming vessels, or bolt-heads of earthenware. The sublimation usually takes thirty-six hours, when the sublimers are taken out of the furnace, cooled, and broken.

The acids sustain an important relation to mercury. All of them either dissolve the metal or unite with its oxides. Sulphuric acid exerts little or no action upon it in the cold; but, if heat is applied, it is decomposed, the mercury is oxidated, sulphurous acid is disengaged, and the oxide combines with the remaining acid. This *proto-sulphate* of mercury crystallizes in slender prisms, forming a mass, soft, and partly liquid. It is very acrid, deliquescent, and soluble in water. If it is urged with a heat gradually raised until the mass becomes dry, the metal is more highly oxidated, and a portion of the acid is dissipated. On pouring boiling water on this dry mass, it acquires a lively yellow colour, forming an insoluble powder, known by the appellation of *turbith mineral*, or yellow sulphate of mercury. The water, in this process, produces the usual effect which it has when it decomposes metallic salts. Exerting a stronger attraction to the acid than to the metallic oxide, it combines principally with the former; but, from the influence of quantity on chemical affinity, the acid carries with it a portion of the oxide, and conversely, from the operation of the same force, the oxide which is precipitated retains a portion of the acid combined with it. The neutral sulphate is thus resolved into a super-sulphate, which the water dissolves, and a sub-sulphate, which remains undissolved. This sub-sulphate is chiefly used in preparing corrosive sublimate and calomel.

Nitric acid acts on mercury with facility, oxidating it, and combining with the oxide, forming a perfect solution. The product of this action varies considerably, particularly with regard to the state of oxidation, according to the circumstances under which it is exerted. If the acid is diluted with rather more than an equal part of water, and if the action is not accelerated by heat, the protoxide only

is formed, and the salt is the *proto-nitrate of mercury*. If the acid is less diluted, and if its action on the metal is promoted by heat, the peroxide is produced, and the compound is the *per-nitrate of mercury*. Both these solutions, when concentrated, crystallize, a mass being deposited, consisting of a congeries of slender prisms. Both salts are corrosive, deliquescent, and soluble in water. If the solution of the per-nitrate is poured into water, a partial decomposition happens, similar to that of sulphate of mercury, and a yellow insoluble sub-per-nitrate of mercury is precipitated.

Nitrate of mercury is decomposed by the alkalies and earths; and in these decompositions are well displayed the differences which arise from different states of oxidation of the metal. By potash, soda, or lime, added to the solution of the proto-nitrate, a precipitate of a grayish colour, with a tinge of yellow, is thrown down: from the solution of the per-nitrate the precipitate is yellow, more or less bright. These precipitates are sub-nitrates, the oxide, separated by the alkali, retaining a portion of the acid combined with it. The action of ammonia on these solutions is more peculiar. From the solution containing the mercury at a high state of oxidation, it throws down a white precipitate, which is a ternary combination of the oxide, with portions of the acid and alkali. From the solution at which the metal exists at the *minimum* of oxidation, it throws down a precipitate of a dark gray or blue colour.

A *fulminating* preparation of mercury is obtained by dissolving 100 grains in one and a half ounce by measure of nitric acid. This solution is poured cold into two ounces by measure of alcohol in a glass vessel, and heat is applied till effervescence is excited, though it ordinarily comes on at common temperatures. A white vapour undulates on the surface, and a powder is gradually precipitated, which is immediately to be collected on a filter, well washed, and cautiously dried. This powder detonates loudly by gentle heat or slight friction. It has been very much used of late as the match-powder, or priming, for the percussion caps of the detonating locks of fowling-pieces. Two grains and a half of it, mixed with one-sixth of that weight of gunpowder, form the quantity for one percussion cap, according to the researches of Aubert, Pelissier, and Gay-Lussac. In preparing this powder in quantities, the fulminating mercury should be moistened with thirty per cent. of water, then triturated in a mortar, and afterwards mingled with the sixth part of its weight of gunpowder. Matches of this kind resist damp very well, and take fire after several hours' immersion in water. The detonating match, or priming powder, made with chlorate of potash, sulphur, and charcoal, has the inconvenience of rusting and soiling the fowling-pieces, and thence causing them to miss fire; whereas, with the above fulminating powder, 100 shots may be discharged successively. The mercurial percussion caps are sold now in Paris for three francs and a half per thousand.

The acetic and most other acids combine with the oxide of mercury, and precipitate it from its solution in the nitric acid. Muriatic acid does not act on mercury. When mercury is heated in chlorine, it burns with a pale-red flame, and the substance called *corrosive sublimate* is formed. This *deuto-chloride* may also be formed by mixing together equal parts of dry bi-deuto-sulphate of mercury and common salt, and subliming. The corrosive sublimate rises, and incrusts the top of the vessel, in the form of a beautiful white semitransparent mass, composed of very small prismatic needles. Its specific gravity is 5.14. Its taste is acrid, stypto-metallic, and eminently disagreeable. It is a deadly poison. Twenty parts of cold water dissolve it, and less than one of boiling water. It is composed of 73.53 mercury and 26.47 chlorine. It may be recognized by the following characters:—It volatilizes in white fumes, which seem to tarnish a bright copper-plate, but really communicate a coating of metallic mercury, which appears glossy white on friction. When caustic potash is made to act on it with heat in a glass tube, a red colour appears, which by gentle ignition vanishes, and metallic mercury is then found to line the upper part of the tube in minute globules.

Solution of corrosive sublimate reddens litmus paper, but changes syrup of violets to green. Bicarbonate of potash throws down from it a deep brick-red precipitate, from which metallic mercury may be procured, by heating it in a tube. Lime-water causes a deep yellow precipitate, verging on red. Water of ammonia forms a white precipitate, which becomes yellow on being heated. With sulphureted hydrogen and hydrosulphurets, a black or blackish-brown precipitate appears. Nitrate of silver throws down the curdy precipitate characteristic of muriatic acid; and the proto-muriate often gives a white precipitate. From six to twelve grains were the mortal doses employed by Orfila, in his experiments on dogs: they died in horrible convulsions, generally in two hours; but when, with a larger quantity, the whites of eight eggs were thrown into the stomach, the animals soon recovered after vomiting. The effect of this antidote is to convert the corrosive sublimate into calomel. Sulphureted hydrogen may also be employed along with emetics. The *proto-chloride* of mercury (*mercurius dulcis*, or *calomel*), is usually formed from the deuto-chloride, by triturating four parts of the latter with three of quicksilver till the globules disappear, and subjecting the mixture to a subliming heat. By levigating and edulcorating with warm water the sublimed grayish-white cake, the portion of soluble corrosive sublimate which had escaped decomposition is removed. It may also be made by adding solution of proto-nitrate of mercury to solution of common salt; the proto-chloride, or calomel, precipitates. The following is the process used at Apothecaries' Hall:—Fifty pounds of mercury are boiled with seventy pounds of sulphuric acid to dryness, in a cast-iron vessel; sixty-two pounds of the dry salt are triturated with forty pounds and a half of mercury until the globules disappear, and thirty-four pounds of common salt are then added. This mixture is submitted to heat in earthen vessels, and from 95 to 100 lbs. of calomel are the result. It is washed in large quantities of distilled water, after having been ground to a fine and impalpable powder. When proto-chloride of mercury is very slowly sublimed, four-sided prisms terminated by prisms, are obtained. It is nearly tasteless and insoluble, and is purgative in doses of five or six grains. Its specific gravity is 7.176. Exposure to air darkens its surface. It is not so volatile as the deuto-chloride.

Nitric acid dissolves calomel, converting it into corrosive sublimate. Proto-chloride of mercury is composed of mercury 84.746, and chlorine 15.254. There are two *iodides* of mercury; the one yellow, the

other red; both are fusible and volatile. The yellow, or *protiodide*, contains one half less iodine than the deutiodide; the latter, when crystallized, is a bright crimson. They are both decomposed by concentrated sulphuric and nitric acids. The metal is converted into an oxide, and iodine is disengaged. They are likewise decomposed by oxygen, at a red heat.—Mercury, on account of its fluidity, readily combines with most of the metals, to which it communicates more or less of its fusibility. When these metallic mixtures contain a sufficient quantity of mercury to render them soft at a mean temperature, they are called *amalgams*. It very readily combines with gold, silver, lead, tin, bismuth, and zinc; more difficultly with copper, arsenic, and antimony; and scarcely at all with platina or iron. It does not unite with nickel, manganese, or cobalt; and its action on tungsten and molybdena is not known. Looking-glasses are covered on the back side with an amalgam of tin. The amalgamation of the precious metals, water gilding, the making of vermilion, the silvering of looking-glasses, the construction of barometers and thermometers, are the principal uses to which this metal is applied. Scarcely any substance is so liable to adulteration as mercury, owing to its property of dissolving completely some of the baser metals. This union is so strong that they even rise along with it in vapour when distilled. Its impurity, however, can generally be detected by its dull aspect; by its tarnishing, and becoming covered with a coat of oxide, on long exposure to the air; by its adhesion to the surface of glass; and, when shaken with water in a bottle, by the speedy formation of a black powder. Lead and tin are frequent impurities, and the mercury becomes capable of taking up more of these, if zinc or bismuth be previously added. In order to discover lead, the mercury may be agitated with a little water, in order to oxidize that metal: pour off the water, and digest the mercury with a little acetic acid; this will dissolve the oxide of lead, which will be indicated by a blackish precipitate, with sulphureted water; or to this acetic solution add a little sulphate of soda, which will precipitate a sulphate of lead, containing, when dry, seventy per cent. of metal. Bismuth is detected by pouring a nitric solution, prepared without heat, into distilled water; a white precipitate will appear, if this metal be present. Tin is manifested, in like manner, by a weak solution of proto-muriate of gold, which throws down a purple sediment; and zinc by exposing the metal to heat.

The medicinal virtues of this mineral were almost totally unknown to the ancients, who considered it as a poison. It was first employed for purposes of medicine by the Arabians, who made use of it in the form of ointments for the skin and the killing of vermin. In modern times mercury is one of the most important articles of the materia medica. It has an advantage over all others in being a specific remedy for a disease which tends more than any other to the destruction of the human species, and which, without this inestimable discovery, would probably have continued incurable to the present day.

Mercury, taken into the stomach in its metallic state, has no action on the body, except what arises from its weight or bulk. It is not poisonous as is vulgarly supposed, but perfectly inert. But, in its various states of combination, it produces certain sensible effects. It quickens the circulation, and increases all the secretions and excretions.

The metallic oxide of mercury differs very much in its effects on the system. Sometimes, it more particularly increases one secretion; sometimes another; but, its most characteristic effect is the increased flow of saliva, which it generally excites, if given in sufficient quantity.

Mercury; the finest plant in order from the sun. (See Astronomy.)

Meridian, in *astronomy*, is a great circle of the celestial sphere, passing through the pole of the earth and the zenith and nadir, crossing the equator at right angles, and dividing the sphere into an eastern and western hemisphere. When the sun is on this circle, it is noon or mid-day to all places situated under that meridian.

Meridian, in *geography;* a corresponding terrestrial circle in the plane of the former, and which, therefore, passes through the poles of the earth. All places situated under the same meridian have their noon or midnight at the same time; but, under different meridians, it will arrive sooner or later, according as they are situated to the eastward or westward of each other; viz. the sun will be upon that meridian soonest which is most to the eastward, and that at the rate of an hour for every 15°.

First Meridian is that from which all the others are reckoned, which, being totally arbitrary, has been variously chosen by different geographers. Ptolemy makes his first meridian pass through the most western of the Canary Islands; others have chosen Cape Verd; some the Peak of Teneriffe; others the Island of Ferro, &c.; but most nations now consider that the first meridian which passes over their metropolis, or their principal observatory. Thus we reckon from the meridian of Greenwich; the French from Paris; the Spanish from Madrid; the Americans from Washington, &c.

Meridian of a Globe is the brazen circle in which it turns, and by which it is supported. *The brazen meridian* is divided into 360 equal parts, called *degrees*. In the upper semicircle of the brass meridian these degrees are numbered from 0 to 90, or from the equator towards the poles, and are used for finding the latitudes of places. On the lower semicircle of the brass meridian they are numbered from 0 to 90, from the poles towards the equator, and are used in the elevation of the poles.

Meridian Line is a line running due north and south, the exact determination of which is of the greatest importance in all cases relating to astronomy, geography, dialling, &c., because on this all the other parts have their dependence. The most celebrated meridian line is that on the pavement of the church of St. Petronio, in Bologna, which was drawn to the length of 120 feet, by the celebrated Cassini. Without knowing the meridian line of a place, it would be impossible to make a dial, set a clock, or measure degrees on the earth's surface.

Meridian Line, on a dial, is the same as the twelve o'clock hour line.

Magnetic Meridian; a great circle passing through the magnetic poles. (See Magnetism.)

Meridian Altitude; the altitude of any of the heavenly bodies when they are upon the meridian.

Merlon, in *fortification*, is that part of a parapet which is terminated by two embrasures of a battery. Its height and thickness are the same with that of the parapet; but its breadth is generally nine feet on the

inside, and six on the outside. It serves to cover those on the battery from the enemy; and it is better when made of earth, well beat and close, than when built with stones, because they fly about and wound those they should defend.

MESENTERY; a membrane in the cavity of the abdomen, attached to the lumbar *vertebræ*, and to which the intestines adhere. Its uses are to sustain the intestines in such a manner that they may possess both mobility and firmness to support and conduct the blood-vessels, lacteals, and nerves, to fix the glands, and give an external coat to the intestines.

MESS, in *sea* language, denotes a particular company of the officers or crew of a ship, who eat, drink, and associate together, whence *messmate*, one of the number thus associated. In military language, *mess* denotes a sort of military ordinary, for the maintenance of which every officer who takes his meals there gives a certain proportion of his pay. These associations of officers in the English armies exist not merely in time of peace, but even in the field; and foreigners are surprised at the degree to which the national love of comfort prevails, even amid the fatigues of service, leading the officers to carry with them loads of table equipage, thereby adding to the cumbrous baggage of an English army. In all the descriptions of English military life the mess is conspicuous; and it may easily be imagined that these social meetings, when the toils of service are suspended, and the pleasures of the table are heightened by music—when the restraints of military etiquette are relaxed, and a soldier-like frankness prevails—when the young express their hopes, and the older relate their experiences—are among the bright spots of British military life. Several armies, particularly the Prussian, have attempted in time of peace to imitate the English mess, but without being able to copy it fully.

MESTRE DE CAMP; formerly the title of the commanding officer of a regiment of cavalry in the French service. He was distinguished by this appellation on account of there being a colonel-general in the cavalry. The chief of a regiment of infantry was also formerly so called.

METAL; the most numerous class of undecompounded chemical bodies, distinguished by the following general characters:—1. They possess a peculiar lustre, which continues to be seen in the smallest fragments. 2. They are fusible by heat, and in fusion retain their lustre and opacity. 3. They are all (except selenium) good conductors both of electricity and caloric. 4. Many of them may be extended under the hammer, and are called *malleable*; or under the rolling-press, and are called *laminable*; or drawn into wire, and are called *ductile*. 5. When their saline combinations are electrized, the metals separate at the negative pole. 6. When exposed to the action of oxygen, chlorine, or iodine, at an elevated temperature, they generally take fire, and, combining with one or other of these three elementary dissolvents, in definite proportions, are converted into earthy or saline-looking bodies, devoid of metallic lustre and ductility, called *oxides*, *chlorides*, or *iodides*. 7. They are capable of combining in their melted state with each other, in almost every proportion, constituting alloys. 8. Most of them combine in definite proportions with sulphur and phosphorus, forming bodies frequently of a semi-metallic lustre; and others unite with hydrogen, carbon, and boron, giving rise to peculiar gaseous or solid compounds. Their names are as follows:—1. platinum, 2. gold, 3. silver, 4. palladium, 5. mercury, 6. copper, 7. iron, 8. tin, 9. lead, 10. nickel, 11. cadmium, 12. zinc, 13. bismuth, 14. antimony, 15. manganese, 16. cobalt, 17. tellurium, 18. arsenic, 19. chromium, 20. molybdenum, 21. tungsten, 22. columbium, 23. selenium, 24. osmium, 25. rhodium, 26. iridium, 27. uranium, 28. titanium, 29. cerium, 30. potassium, 31. sodium, 32. lithium, 33. calcium, 34. barium, 35. strontium, 36. magnesium, 37. yttrium, 38. glucinum, 39. aluminum, 40. zirconium, 41. silicium, 42 thorinum, 43 vanadium. The first twelve are malleable, and so are the 30th, 31st, and 32nd, in their congealed state. The first sixteen yield oxides, which are neutral salifiable bases. The metals 17, 18, 19, 20, 21, 22, and 23 are acidifiable by combination with oxygen. Of the oxides of the rest, up to the 30th, little is known. The remaining metals form, with oxygen, the alkaline and earthy bases.

A very curious test of the state of metals has lately been brought before the scientific world, which must be noticed in the present place. It is well known that Dr. Wollaston devised a beautiful little arrangement to ascertain the conducting power of certain crystals having metallic characters, and which, ultimately, proved to be titanium. If a plate of copper be in contact with a plate of zinc, and part of both plates be immersed in a dilute acid, the copper, by its electric condition, decomposes water, and becomes covered with bubbles of hydrogen. If a piece of paper or a card be interposed where the two metals were in contact, the copper loses this power altogether, and no bubbles appear on it; but if a small hole be made in the paper or card, and a little piece of metallic matter put there so as to touch at once both the zinc and copper, then the latter has its full power restored. M. Macaire Prinsep has applied this test more generally; and he found, in the first place, that a metal was necessary to restore the effect; lead, bismuth, tin, &c., re-produced the bubbles; but sulphuret of arsenic, rutulite, or oxide of titanium, gray cobalt ore, and the sulphuret of antimony, iron, tin, or lead, produced no effect. Portions of meteoric stone from Aigle and Barbosan, by producing bubbles, showed that they contained uncombined metal; and the method seemed competent to indicate, in all cases, whether the metals were free or in a combined condition.

As lead gave bubbles, but the sulphuret of lead none, experiments were made with lead, to which sulphur, in increasing proportions, had been added. 1-100th, 1-50th, 1-32d, 1-16th, and 1-12th of sulphur did not take away the property from lead, but when 1-8th of sulphur was used no bubbles appeared upon the copper; then, ascertaining the proportions in the definite sulphuret of lead, he found them to be exactly those which caused the evolution of bubbles to cease (eighty-six lead and fourteen sulphur). The same effect occurred with the sulphuret of tin; and hence it was concluded that chemical combination, in determinate proportions, was necessary to prevent this electric decomposition, and that mixtures had no influence on the phenomena.

METALLOID, in *chemistry*; a name given at first to the metals which have been obtained from the fixed alkalies and some of the earths. These bodies having been found to be completely metallic are now classed with the other metals, and no distinction is necessary.

METALLURGY, METALLURGIC CHEMISTRY, is that

part of chemistry which teaches the combinations and analyses of metals. It has been much cultivated of late.

Meteorology; that science which investigates the phenomena of our atmosphere (commonly called *meteors*), giving an account of the circumstances attending each, and explaining the causes from which they arise.

In considering this science, we find the objects of it naturally divided into two classes, viz. those which rise high in the heavens, seemingly without any connection with this earth; and others which are more particularly connected with the earth, or are perceptible only in the lower regions of the atmosphere. The former, which may properly be called *celestial meteors*, are only three in number, viz. the large fire-balls, falling stars, and aurora borealis. The second class is much more numerous, including the phenomena of the ordinary winds, rain, hail, snow, clouds, and vapours of all kinds, thunder and lightning, hurricanes, whirlwinds, water-spouts, ignes fatui, and other wandering luminous appearances, not excepting the various changes of the atmosphere itself, with regard to its specific gravity, rarefaction, heat, and moisture, as indicated by the barometer, thermometer, and hygrometer.

To treat of all these in a satisfactory manner, it is plain that we ought to have an intimate acquaintance with the constitution of the atmosphere, with the nature of those powerful agents by which it appears to be principally influenced, viz. fire, light, and electric fluid, and with their peculiar modes of operation and action upon one another and upon the atmosphere, and this in every possible variety of circumstances. Nor is even all this sufficient: the various phenomena of rain, wind, snow, thunder, heat, cold, &c., are known to depend very much upon the situation of different places on the surface of the earth; and their occasional variations are with great reason *suspected* to proceed, partly at least, from changes which take place in the bowels of the earth: whence a meteorologist ought not only to be perfectly well acquainted with geography, but with mineralogy chemistry, the analysis of metals, and the general principles of natural philosophy.

In a science so very difficult, it is not to be supposed that any thing like a certain and established theory can be laid down: our utmost knowledge in this respect goes no further as yet than to the establishment of a few facts; and, in reasoning even from these, we are involved every moment in questions which seem scarcely within the compass of human wisdom to resolve.

In considering the subject of meteorology, it will readily be admitted that the whole atmospherical phenomena depend, some how or other, upon the action of the sun upon the earth, and the annual and diurnal revolutions of the latter. As these causes, however, are always invariably the same, why do we not find the same regularity in meteors that we do in other phenomena of nature? The eclipses of the sun and moon, for instance, which depend on the different positions of the earth and moon with regard to the great luminary, are found to follow a certain and regular course; so that the very same eclipses both as to quantity and duration, which happened before will happen again. But with meteors the case is quite different. Most of the atmospherical phenomena are so various and uncertain that no person can pretend to reduce them to any kind of rule. Every succeeding year, for instance, differs in a vast number of particulars from that which preceded it, even in such as are the most similar to one another. Sometimes we find a number of years successively similar to one another, and another set quite different taking place immediately after them; and some have even fancied that this succession took place every nineteen years, nearly the time of the revolution of the moon's nodes, though the observations on which this opinion is built are far from being sufficient to establish it: at any rate, the dissimilarity between the phenomena of different years may sufficiently warrant us to conclude that other causes besides the regular action of the sun and revolution of the earth are concerned. Some of these causes may be supposed to be chemical changes and other commotions within the bowels of the earth itself; but as all chemical change is a regular process, and takes place only in certain circumstances, of which heat is a very considerable one, why is there not annually a certain quantity of this fermentation excited, and why are not regular effects observed in proportion? It does not, indeed, appear that the immense variety which occurs in meteorological appearances can by any means be accounted for but by the interference of some causes in their own nature *irregular*; that is, capable of such endless variety that no assignable space of time is sufficient to exhaust it. These causes, as they cannot be proved to exist either on the surface of the earth or in its internal parts, must be sought for in the celestial expanse itself. Sir Isaac Newton supposed the planets to be influenced by the comets, and that from the tails of the latter some of the finer parts of our atmosphere were produced. He even supposed that from these bodies a quantity of water, imagined to be wasted in the various operations of nature, might be supplied. But, if it is not unreasonable to suppose that *comets* answer some such purposes in nature, it is as little unreasonable to think that the *planets* may influence the atmospheres of one another. That this must be the case indeed is very probable, not only on account of the light they reflect upon one another, but also by reason of their spheres of mutual attraction, which extend an immense way, and are so powerful in the planets Jupiter and Saturn that they disturb the motions of each other's satellites as they pass. But, besides even these causes, if we allow them to be such, there are others which take place in the immense void betwixt the celestial bodies, and which has with great impropriety been determined an absolute vacuum. That changes do take place in this space is evident from what is related of the temporary disappearance of some of the satellites of Saturn, and their sudden re-appearance, without any perceptible change in our atmosphere so as to affect our view of other celestial objects. It may appear ridiculous to think that a change in such distant regions should have any influence upon the atmosphere of the earth; but we must remember that if the universe is connected together as one vast system, which we have every reason to believe it is, as impossible that a change can take place in any part without affecting the whole in some degree as it is impossible to change any part of a clock or watch without in some measure affecting the whole movement.

But, of all the changes which take place in the

celestial regions, those which affect the sun seem most likely to produce changes in our atmosphere, and to be the hidden cause of many meteorological phenomena. That the sun is not exempt from those changes is evident from the spots which are always, or for the most part, to be seen on his disc when viewed through a telescope. It has been observed in some years that the sun has seemed to lose his influence, and even to the naked eye appeared much dimmer than usual. In such cases it is impossible but our atmosphere, and even the whole solar system, must have been affected; and not only must the seasons for the present time have felt the malign influence of those spots, but the atmosphere itself may have acquired such a disposition as to produce seasons of a peculiar nature for a number of years afterwards. If it be true, according to the hypothesis of some, that the sun is supplied with fuel by comets falling into his body, it is plain that every new accession of this kind must have a proportionable effect upon all the bodies exposed to his light. If the comets do not perform any such office, still it is very probable that they answer some such purpose to the planets, as they are never seen beyond the planetary regions; and, though their influence be not immediately perceptible, it is impossible to prove that they have none, nor indeed is it probable that they have not; for we are very certain that the influence of any object extends as far as its light, and how much further we cannot tell. Considering the matter in this view, therefore, there is not a spot which can obscure the sun, a comet that can appear in the celestial regions, a planet that can approach the earth, nor, perhaps, a belt or spot which can take place on Mars, Jupiter, or Saturn, which may not be productive of important changes in our atmosphere, and affect the meteors produced by it in many different ways.

It would no doubt be an error to have recourse to so many obscure causes, were there any plain and obvious ones from which the phenomena could be deduced. But the endless variety of meteors which occur throughout every part of the globe plainly show that the causes, whatever they are, must be infinitely varied also. The principal one is no doubt the action of the sun upon the earth and atmosphere in its various positions; but this is regular, and, did nothing else interfere, would produce regular effects. Secondary causes probably are the action of the moon and planets; but these also are regular, though much more diversified than the former; so that we are at last obliged to have recourse to causes still more obscure and remote, as comets, spots on the sun, and changes taking place in the effects of those rays which pervade the whole celestial expanse. These we must either assign as the remote causes of the phenomena of our atmosphere, or admit others equally obscure, or we must be contented to own our ignorance, as, indeed, must at all events be frequently the case.

But though, to satisfy ourselves, such conjectures may occasionally be indulged, it is not from them that we are to derive any knowledge of the regular phenomena of nature; for these are evidently owing to the settled and established action of heat, light, and electric matter, which have already been enumerated as the great powers influencing and indeed in a great measure forming the substance of our atmosphere. The most remarkable effects of these are—

1. *Evaporation*. This, which is the principal cause of almost all the meteors of our atmosphere, may be reckoned in a more particular manner the effect of heat. Upon this principle vapour is shown to be a compound of water and fire; and such it is supposed to be by M. de Luc, in his *Treatise on Meteorology*, as well as by other philosophers of the highest rank. In considering this operation, however, as carried on by nature, we shall soon find that it proceeds in a manner very different from what takes place in our chemical operations. In the latter, evaporation is merely the effect of heat, and the process cannot go on without a considerable degree of it, especially if the vessel containing the fluid be close. In the natural way, on the contrary, the process goes on under almost every degree of cold we know; the vapours ascend to a height which has never yet been determined, and, from the extreme cold which they sustain, show evidently that they are connected with our atmosphere by means of some other agent besides heat. From the continual ascent of vapour, indeed, if the operations of nature were of the same kind with those of art, the upper parts of our atmosphere would be always involved in a fog, by reason of the condensation of the vast quantity which continually ascends thither; but so far is this from being the case that in those elevated regions to which the vapours continually ascend the air is much drier than at the surface of the ground. This was experienced by M. de Saussure and M. de Luc in their journeys up the Alps. The air was there found to be excessively dry, and evaporation to go on much more rapidly than below; so that the surface of their bodies was parched up, and an excessive thirst took place by reason of the great absorption of the moisture. The same dryness was manifested by the hygrometer, which could scarcely ever be brought to indicate any moisture, even when our travellers were surrounded with clouds, hail, and rain. From many experiments, indeed, it is evident that water, after being reduced into a state of vapour, is capable of undergoing a certain change, by which it partially lays aside its fluidity, and even, to appearance, its specific gravity; so that it becomes, as far as regards its mechanical character, totally different from what it was before. This may be familiarly understood from the common operation of slaking lime; for in that case the water unites with the lime so intimately that the whole assumes the form of a dry powder, extremely greedy of moisture, and which cannot be reduced to its former state of quicklime without undergoing a much greater degree of heat than the water by itself could bear. The same thing is manifest from mixing dry plaster of Paris with water; for thus a vast quantity of the water is fixed, and becomes in a manner solid. A still more remarkable instance is in sending the steam of water over red-hot iron; for there the oxygen of the water unites in such a manner with the metal that the other element, hydrogen, is entirely liberated. Here we are to consider the changes which the element undergoes after being reduced to the state of vapour. The first of these is its assuming the appearance of smoke or fog when mixed with the common atmosphere, which smoke, when examined by a very powerful microscope, appears to be composed of an infinite number of spherules of water. They are no doubt expanded by heat, and thus rendered lighter than air, by which means they ascend in it. As long

as the aqueous vapour retains this visible form, it retains also its humidity, and will again become a liquid, and wet whatever comes in its way; and this the more readily, while it retains any sensible degree of heat. As the vapour cools in the atmosphere, it gradually assumes an aërial state, mixing itself with the air, so as to be no longer distinguishable from it. In this state the air itself does not by any means appear to become more moist, but continually drier the more water it receives. This, however paradoxical it may seem, is a certain fact; for in summer, though we are assured that evaporation goes on very rapidly from the surface both of the sea and land, yet the air, so far from being moist, is much drier than at any other time; and yet we know that the whole quantity evaporated is, some how or other, received by the atmosphere. After the water has attained to this state, our enquiries concerning it must assume a new course.

On this subject M. de Luc has some very curious observations, built principally upon the chemical character of water, which was then first developed. As this gentleman is still considered as a good authority in matters of fact, we may embody his statements as nearly as possible in his own words. Our author first began to alter his sentiments concerning the *aqueous* existence of vapour in the atmosphere from the circumstance already mentioned concerning the great *dryness* of the upper atmospherical regions already taken notice of. A very remarkable instance of this was that the ferule of his cane dropped off during his journey up one of the Alpine mountains, which he never had observed it to do before. It is observed, likewise, that the air in these elevated regions is somewhat drier in the night than in the day-time; for which M. de Luc gives the following reason, viz. that the air on the plains being condensed by the cold, the superior air must subside, and the air on the mountains of course be replaced by the drier air from above them; though he thinks that this dryness may also be imputed in part to some other cause. This increase of dryness in the night, however, seems less constant than that in the day-time. Our author has often arrived at the tops of mountains before sunrise, and sometimes found the grass covered with dew, though he never had the good fortune to be able to determine the state of the air, for want of an hygrometer: nor, indeed, could the appearance of dew be any certain indication of the state of the atmosphere, there being strong reasons to believe that dew is occasioned, in a great measure, by vegetables themselves; for grass, when covered with glass plates, was found to become moist as well as that which had been exposed to the open air. In this case the plates became moist both on the upper and under sides; but when suspended a foot above the ground, they were found to be covered with dew only on the upper part.

The dryness of the air on the tops of high mountains was otherwise accounted for by M. Saussure.—When on Mont Blanc, at the height of 7200 feet above the level of the sea, he found that from six in the evening till half-past five next morning his hygrometer moved twenty-one degrees (the whole scale containing one hundred) towards dryness. But this he accounts for by saying that from sunrise to three or four in the afternoon, the quantity of vapours in the neighbourhood of the earth is continually diminishing, because they *ascend* in the atmosphere, either in virtue of their own levity, or by means of a vertical wind, which he supposes to be produced by the heat of the sun; that, from the time just mentioned till next morning, their quantity increases in the lower strata, because the upper vapours re-descend in proportion as they condense; and that in the higher regions of the atmosphere the reverse ought to be the case, as the upper strata are then left drier by the previous descent of the vapours. This argument, however, is contradicted by M. Saussure himself in another part of his work, where he says that in the middle of the day, when the sun is hottest, the air in the neighbourhood of the earth contains really more *water* than it does at the moment when a refreshing dew falls. It is besides impossible that a *vertical* wind can ever be occasioned by the heat of the sun; for this produces only a general expansion of the whole body of the atmosphere, as a condensation of it is occasioned by the action of cold, neither could any considerable quantity of vapour (supposing with M. Saussure that it is a chemical solution of water in air) descend in the night-time; for, according to him, this compound differs very little from common air in its capacity of being expanded and condensed. Neither, according to M. Saussure himself, can any part of the water with which the air is combined descend at all, until some portion of the former becomes supersaturated with it, that is, till it has received more than it can hold in solution. But, if this should happen to be the case, the superfluous quantity would then appear in the form of a mist or cloud, and the hygrometer would indicate extreme humidity; whereas the contrary indication constitutes the difficulty.

It is besides evident, from innumerable instances, that mere cold will not by any means occasion the condensation of aërial vapour. A most remarkable example of this is given by M. de Luc, in an account of a storm in which he was involved on one of the Alps. "Though the hygrometer (says he) was within 33½ degrees of extreme dryness, or 66½ from extreme humidity, thick clouds formed around us, which obliged us to think of retreating; in a little time the summit of the mountain was surrounded by them: they spread and covered the whole horizon: a premature night surprised us in a very dangerous road; and we suffered one of the most violent tempests I ever experienced of wind, rain, hail, and thunder. The storm lasted great part of the night, and extended all over the neighbouring mountains and plains; and after it had ceased the rain continued, with only a few intermissions, till next day at noon. In one of these intervals I examined the hygrometer on the outside of our cabin; it showed only $1\frac{8}{10}$ degrees more humidity than before; and even this increase was no more than what the difference of heat was capable of producing. Nevertheless, new clouds continually rolled around us; and the rain, which presently began again, accompanied us as it were by fits to the bottom of the mountain. When arrived there, we saw the clouds disperse entirely. I observed the hygrometer again in the open air; and though the earth was all drenched with water, and the heat of the sun much less, the hygrometer was $1\frac{7}{10}$ degrees drier than it had been two days before, after a course of fine weather. Where was all this water, and all the ingredients of the storm, while the hygrometer showed such a degree of dryness in the very stratum where it was formed?"

M. de Luc considers vapour as a combination of

fire with water. By *vapour*, however, he does not mean "the visible steam issuing from heated liquids, but that invisible and subtile fluid which is found to be formed even *in vacuo*, and which," he adds, "disproves the hypothesis of those who hold that vapour is a solution of water in air." Our author, however, gives a solution of the difference betwixt what he calls *fog* or *mist* and vapour which seems scarcely founded upon any evident principle. According to him, this vapour cannot subsist unless the particles of water united to the fire be at a certain distance from one another. When this distance is lessened a decomposition takes place, by reason of the attraction of the aqueous particles to one another; and they then appear in their proper form of a liquid, the fire dissipating itself through the atmosphere. The smallest distance to which the particles can be brought without any decomposition varies according to the temperature, but is always constant in the same degree. When the thermometer stands at temperate or thereabouts, watery vapours, compressed into the smallest space they can bear, are found to have between $\frac{1}{18}$th and $\frac{1}{38}$th of the elasticity of air; but have less than $\frac{1}{135}$th of its weight. If such vapour, however, be mixed with air, the minimum distance is greatly increased, by reason of the interposition of aërial particles; and thus it can subsist under a much greater pressure than it could otherwise endure. In the heat of boiling water it can, without any mixture of air, bear the pressure of the atmosphere; for ebullition, under any given pressure, cannot take place until the vapour produced in the liquor has acquired a degree of expansive force sufficient to raise the liquor into bubbles under that pressure; and as long as the vapour retains this heat it must continue capable of resisting the same pressure. As the heat abates, a decomposition begins; hence the opaque steam over boiling water, which, by becoming vapour again by uniting with the fire it meets within a larger space, is diffused by its expansibility. Thus vapours are continually undergoing decompositions and new vaporifications. This evaporation of the clouds after they were once formed M. de Luc states he observed very evidently, some parts being continually detached and gradually diminishing and disappearing, while new ones are formed; so that the clouds do not continue the same for two moments together, and the evaporation goes on so fast that a cloud could not subsist without constant and large supplies.—"These phenomena appear to be independent of heat and cold; for sometimes clouds form suddenly in the middle of a hot day, and after they have poured down their water all is clear again, and sometimes they evaporate after sunset, gradually vanishing in the calmest weather without any change of place.—The appearances are such as would be produced by a large mass of water in violent ebullition, suspended invisibly in the atmosphere; and the similarity of effect naturally points out an analogy in the cause; that is, a source of vapour in the atmosphere itself. It is only when the vapour is produced too abundantly and too rapidly to be dispersed by evaporation that rain is formed, the vesicles in this case running together, and the water falling to the lower part, as it does in soap-bubbles, till they become thin enough to burst."

Heat and cold are very powerful agents in producing various meteors; but these are only relative and different modifications of the same principle. Though we do not know what connexion there is between heat, cold, and what we call electricity, yet we know that this last is very much affected by them; for heat makes bodies more pervious to electricity than otherwise they would be, and cold makes them less so. Hence the most violent electrical phenomena are observed in hot countries; while in the colder regions those which depend on a more moderate electrification, as auroræ boreales, are more frequent. The prevalence of heat and cold in particular places, however, depends upon circumstances which are altogether unknown to us, and therefore we cannot investigate the modes of their operation in such a particular manner as could be wished. From what has been already said, however, respecting the nature of the different agents concerned in meteorology, both in this article and in other parts of the work, we may take the following view of the causes of meteors in general:—

1. Evaporation, combined with electricity, produces all the phenomena of vapour, fog, clouds, rain, &c.; and according as these two are joined to certain degrees of heat or cold they produce dew, hoar-frost, rain, hail, or snow.

The phenomena of dew and hoar-frost seem to proceed from a quantity of aqueous vapour which always exists in the atmosphere, and which, being raised by mere heat, is condensed by mere cold, without undergoing any other process. Hence it both ascends and descends; for, if we cover a small space of ground with plates of glass, they will be wetted both above and below. The reason of this is, that the evaporation from the ground does not stop immediately after the air begins to cool, especially if it be covered with any thing which prevents the access of the cold air, as the glass plates do in this case. The cold air, therefore, acting upon the glass, condenses the vapour below it in the same manner that the head of a still or the receiver of a retort condenses the vapours which rise from the matter to be distilled. If the cold be very intense, hoar-frost appears instead of dew, which is nothing more than the dew frozen after it falls upon the ground, in the same manner that the vapour in a warm room congeals on the inside of the windows in a frosty night. As this seems to be the whole process, it has not been observed that any electricity is concerned in the production of dew.

When the vapour has been thoroughly decomposed, and become invisible, it very frequently returns back to its pristine state, so far as to assume the appearance of mist or fog. In this case, electricity appears evidently to be concerned; for Mr. Cavallo observed that all fogs were electrified. When the process has advanced further, and the water begins to collect into drops, the electricity is still more remarkable; and it is by some supposed that it is by means of electrical repulsion that the drops of rain keep at a regular distance from one another. When the cold is intense, and the electricity strong, the drops of water are frozen, and hail is produced: but snow indicates a more moderate degree of electricity; and a very violent cold, accompanied with a strongly electrical atmosphere, produces that excessively disagreeable vapour in the polar regions called *frost-smoke*, which is a general congelation of all the aqueous moisture contained in the atmosphere.

2. By highly excited electricity alone are produced the phenomena of thunder, lightning, fire-balls, ignes fatui, and the aurora borealis. In the phenomena of

lightning, evaporation and the other agents by which rain and hail are produced are also concerned; though temperature is most remarkably so, and thunder and lightning frequently occur without any rain. The aurora borealis, large fire-balls, and the smaller ones called *falling-stars*, seem to depend upon a change in the electrical equilibrium alone, without any aid from evaporation. The aurora borealis, indeed, is most common in the northern and southern parts of the world, where the cold is intense, though this seems to be owing, not to the cold, but to the natural emission of the electrical fluid from the polar regions in much greater quantities than from others. The fire-balls commonly appear collected on the very extreme boundaries of the atmosphere. The ignis fatuus sometimes arises from the strong electricity of a certain portion of atmosphere, and at other times from the emission of gas.

3. By the action of heat and electricity combined are produced the phenomena of hurricanes, whirlwinds, and water-spouts. It is not, indeed, known in what manner those agents combine themselves to produce such tremendous effects; but it seems evident that electricity is concerned in them, as the sea-water becomes unusually clear before a hurricane, and many signs of electricity are usually observed in the heavens.

4. The winds are supposed to proceed mostly from the heat of the sun rarefying the atmosphere, and occasioning a continual influx of fresh air to fill up the vacuum; but very violent winds are frequently observed where no such cause can be supposed to exist. Thus on the tops of high mountains the winds are commonly very violent; and mountainous countries, especially when cold, are for the most part also subject to high winds. As the tops of mountains, however, are known to be strongly electrified by their attracting and repelling the clouds, we must suppose that this electricity has a considerable share in producing the winds which are generally so violent on their tops. This will appear the more probable when we consider that frequently storms of wind, and those of the most violent kind, seem to be brought along with clouds; as, for instance, that which happened at Malta, in 1780, in which a dreadful tempest, brought along with a large cloud, almost destroyed the whole town.

Thus we have endeavoured to give a general sketch of the doctrine of Meteorology: a more particular detail of the causes by which meteors are produced is given under the names of each of them as they occur in the order of the alphabet. With regard to their uses, those of the more magnificent and extensive kind seem to be destined to preserve the balance of the electric fluid in the atmosphere, the want of which would be productive of the most fatal effects to the world in general. The effects of the inferior ones are more confined, and are of use only to particular districts, scarcely ever extending their influence over a whole country. Thus the clouds, which produce rain for the purposes of vegetation, do not extend themselves over a whole country at once, but transitorily fly over different parts of it; so that when it rains, for instance, in one place, the sun may shine in another, thunder be heard in a third, &c. It is, however, surprising to observe how equally these act over the whole of a very large tract of land; so that though there is never precisely the same weather in two places twenty miles distant from one another, yet vegetation goes on without any perceptible difference in the one as well as the other; neither, unless there be some very remarkable difference in the weather of one year from that of another, will there be any perceptible difference in the crop. For a more particular investigation of this point, however, see the articles WINDS and WEATHER.

For the application of meteorology to the foreknowledge of the weather, see the articles WEATHER and BAROMETER.

METOPE, in *architecture;* the interval or square space between the triglyphs in the Doric frieze. The ancients were in the habit of ornamenting these parts of their buildings with carved works, or with paintings representing the heads of oxen, vessels, and other articles used in heathen sacrifices. The difficulty of disposing the triglyphs and metopes in symmetrical proportion may have been the cause of their omission in the Ionic and Corinthian orders.

METOPOSCOPY; the pretended art of divining from the wrinkles of the forehead. The Romans, believing in every kind of divination, practised this, but not so much as the people of the middle ages. It seems singular that metoposcopy never was so much in vogue as chiromancy, though there might be some possibility of divining, in part, the character of a man from his forehead and its wrinkles, while the lines in the hand have no connexion with it.

METRE; the French unit of measure. See MEASURES.

MEXICAL, or MESCAL; a spirituous drink, extracted from the aloe, which is consumed in large quantities by the Mexicans. It is also called *aguardiente de Maguey.*

MEZZO; an Italian adjective, which means *half,* and is often used in musical language, as *mezzo forte, mezzo piano, mezzo voce,* which imply nearly the same thing, viz. a middle degree of piano, or soft. *Mezzo soprano,* a pitch of voice between the soprano or treble and counter-tenor.

MIASMA; a term used in the doctrine of contagious and epidemic diseases, with different meanings. Some authors use it precisely like *contagion*· with others it signifies the contagious matter of chronic diseases; with others, that contagious matter which collects in the atmosphere—flying contagion. Some understand by *miasma,* the vehicle of contagion; for instance, the pus of small-pox, which contains the proper contagious matter.

Miasma also signifies certain matter in the atmosphere, owing its origin to putrefied animal or vegetable bodies, or to the exhalation of animal bodies, and producing specific diseases. It would be well to contradistinguish *miasma* from *contagion,* and designate by the former term all the poisonous matter of disease which is not generated in living animal bodies, but has in some other way entered the atmospheric air. One of the most powerful correctors of miasmatic effluvia is chloride of lime, which is getting much into use among surgeons and other persons exposed to such effluvia.

MICROMETER; an instrument by the help of which the apparent magnitudes of objects viewed through telescopes or microscopes are measured with great exactness.

1. The first *telescopic* micrometers were only mechanical contrivances for measuring the image of an object in the focus of the object-glass. Before these

contrivances were thought of, astronomers were accustomed to measure the field of view in each of their telescopes by observing how much of the moon they could see through it, the semidiameter being reckoned at fifteen or sixteen minutes; and other distances were estimated by the eye, comparing them with the field of view. Mr. Gascoigne, however, suggested a much more exact method, by which he could mark above 40,000 divisions in a foot.

Mr. Gascoigne's instrument being shown to Dr. Hooke, he gave a drawing and description of it, and proposed several improvements in it, which may be seen in the *Philosophical Transactions, Abr.*, vol. i., p. 217. Mr. Gascoigne divided the image of an object, in the focus of the object-glass, by the approach of two pieces of metal ground to a very fine edge, in the place of which Dr. Hooke substituted two fine hairs, stretched parallel to one another. An account of several curious observations that Mr. Gascoigne made by the help of his micrometer, particularly in the mensuration of the diameters of the moon and other planets, may be seen in the *Phil. Trans.*, vol. xlviii. p. 190.

Mr. Huygens, as appears by his *System of Saturn*, published in 1659, used to measure the apparent diameters of the planets, or any small angles, by first measuring the quantity of the field of view in his telescope, and then preparing two or three long and slender brass plates, of various breadths, the sides of which were very straight, and converging to a small angle. In making use of these pieces of brass he made them slide in two slits, that were made in the sides of the tube, opposite to the place of the image, and observed in what place it just covered the diameter of any planet, or any small distance that he wanted to measure. It was observed, however, by Sir Isaac Newton, that the diameters of planets, measured in this manner, must appear larger than they should be, as is the case with all lucid objects when they are viewed upon dark ones.

In the *Ephemerides* of the Marquis of Malvasia, published in 1662, it appears that he had a method of measuring small distances between fixed stars and the diameters of the planets, and also of taking accurate drawings of the spots on the moon; and this was by a net of silver wire, fixed in the common focus of the object and eye-glasses. He also contrived to make one of two stars to pass along the threads of this net, by turning it, or the telescope, as much as was necessary for that purpose; and he counted by a pendulum-clock, beating seconds, the time that elapsed in its passage from one wire to another, which gave him the number of the minutes and seconds of a degree contained between the intervals of the wires of his net, with respect to the focal length of his telescope.

In 1666, Messrs. Azout and Picard published a description of a micrometer, which was nearly the same with that of the Marquis of Malvasia, excepting the method of dividing it, which they performed with more exactness by a screw. In some cases they used threads of silk, as being finer than silver wires. Dechales also recommends a micrometer consisting of fine wires, or silken threads, the distances of which were exactly known, disposed in the form of a net, as peculiarly convenient for taking a map of the moon.

M. de la Hire says that there is no method more simple or commodious for observing the digits of an eclipse than a net in the focus of the telescope. This, he says, was generally made of silken threads, and for this particular purpose six concentric circles had also been made use of, drawn upon oiled paper; but he advises to draw the circles on very thin pieces of glass with the point of a diamond. He also gives several particular directions to assist persons in the use of them. In another memoir he shows a method of making use of the same net for all eclipses, by using a telescope with two object-glasses, and placing them at different distances from one another.

Different constructions of Micrometers.—The first we shall describe is that by Mr. Huygens. Let A B C D, *Plate* MICROMETER, *fig.* 1, be a section of the telescope at the principal focus of the object-glass, or where the wires are situated, which are placed in a short tube containing the eye-glass, and may be turned into any position by turning that tube; *m n* is a fine wire extended over its centre; *v w*, *x y*, are two straight plates, whose edges are parallel and well defined, and perpendicular to *m n*; *v w* is fixed, and *x y* moves parallel to it by means of a screw, which carries two indexes over a graduated plate, to show the number of revolutions and parts of a revolution which it makes. Now, to measure any angle, we must first ascertain the number of revolutions and parts of a revolution corresponding to some known angle, which may be thus done:—1st, Bring the inner edges of the plates exactly to coincide, and set each index to 0; turn the screw, and separate the plates to any distance, and observe the time a star, *m*, is in passing along the wire *m n* from one plate to the other; for that time, turned into minutes and seconds of a degree, will be the angle answering to the number of revolutions, or the angle corresponding to the distance. Thus, if $d =$ cos. of the star's declination, we have $15'\ dm$, the angle corresponding to this distance; and hence, by proportion, we find the angle answering to any other. 2dly, Set up an object of a known diameter, or two objects at a given distance, and turn the screw till the edges of the two plates become tangents to the object, or till their opening just takes in the distance of the two objects upon the wire *m n*; then from the diameter, or distance of the two objects from each other, and their distance from the glass, calculate the angle, and observe the number of revolutions and parts corresponding. 3dly, Take the diameter of the sun on any day, by making the edges of the plates tangents to the opposite limbs, and find from any astronomical almanac what is his diameter on that day. Here it will be best to take the upper and lower limbs of the sun when on the meridian, as he has then no motion perpendicular to the horizon. If the edges do not coincide when the indexes stand at 0, we must allow for the error. Instead of making a proportion, it is better to have a table calculated to show the angle corresponding to every revolution and part of a revolution. But the observer must remember that when the micrometer is fixed to telescopes of different focal lengths a new table must be made. The whole system of wires is turned about in its own plane by turning the eye-tube round with a hand, and by that means the wire, *m n*, can be thrown into any position, and consequently angles in any position may be measured. Dr. Bradley added a small motion by a rack and pinion to set the wires more accurately in any position.

The divided object-glass micrometer was originally contrived by the late Mr. John Dollond, and by him adapted to the object-end of a reflecting telescope. The principle is this:—The object-glass is divided into two segments in a line drawn through the centre; each segment is fixed in a separate frame of brass, which is movable, so that the centres of the two segments may be brought together by a handle for that purpose, and thereby form one image of an object; but when separated they will form two images, lying in a line passing through the centre of each segment; and consequently the motion of each image will be parallel to that line, which can be thrown into any position by the contrivance of another handle to turn the glass about in its own plane. The brass-work carries a vernier to measure the distance of the centres of the two segments. Now let E and H, *fig.* 2, be the centres of the two segments, F their principal focus, and P, Q, two distant objects in the line of FE, FH, or the opposite limbs of the same object PBQD; then the images of P and Q, formed by each segment, or the images of the opposite limbs of the object PBQD, coincide at F: hence two images *m z* F, *n x* F, of that object are formed, whose limbs are in contact; therefore the angular distance of the points P and Q is the same as the angle which the distance EH subtends at F, which, as the angles supposed to be measured are very small, will vary as EH or nearly so; and consequently, if the angle corresponding to one interval of the centres of the segments be known, the angle corresponding to any other will be found by proportion. Now to find the interval for some one angle, take the horizontal diameter of the sun on any day, by separating the images till the contrary limbs coincide, and read off by the vernier the interval of their centres, and look into the *Connoissance de tems* for the diameter of the sun on that day, and you have the corresponding angle. Or, if greater exactness be required than from taking the angle in proportion to the distances of the centres, we may proceed thus:—Draw FG perpendicular to EH, which therefore bisects it; then one half EH, or EG, is the tangent of half the angle EFH; hence, half the distance of their centres is to the tangent of half the angle corresponding to that distance as half any other distance of the centres is to the tangent of half the corresponding angle.

Hence the method of measuring small angles is manifest; for we consider P, Q, either as two objects whose images are brought together by separating the two segments, or as the opposite limbs of one object PBQ, whose images, formed by the two segments F, H, touch at F: in the former case, EH gives the angular distance of the two objects; and, in the latter, it gives the angle under which the diameter of the object appears. Hence, to find the angular distance of two objects, separate the segments till the two images which approach each other coincide; and, to find the diameter of an object, separate the segments till the contrary limbs of the images touch each other, and read off the distance of the centres of the segment from the vernier, and find the angle as directed in the last article. From hence appears one great superiority in this above the wire micrometer; as, with this, any diameter of an object may be measured with the same ease and accuracy; whereas with that we cannot with accuracy measure any diameter, except that which is at right angles to its apparent motion.

But, besides these uses to which the instrument seems so well adapted, Dr. Maskelyne has shown how it may be applied to find the difference of right ascensions and declinations. For this purpose, two wires at right angles to each other, bisecting the field of view, must be placed in the principal focus of the eye-glass, and movable about in their own plane.—Let HCR*c*, *fig.* 3, be the field of view, HR and C*c* the two wires; turn the wires till the westernmost star (which is the best, having further to move) runs along ROH; then separate the two segments and turn about the micrometer till the two images of the same star lie in the wire C*c*; and then, partly by separating the segments, and partly by raising or depressing the telescope, bring the two innermost images of the two stars to appear and run along ROH, as *a*, *b*, and the vernier will give the difference of their declinations: because, as the two images of one of the stars coincided with C*c*, the image of each star was brought perpendicularly upon HR, or to HR in their proper meridian. And, for the same reason, the difference of their times of passing the wire CO*c* will give their difference of right ascensions.

These operations will be facilitated if the telescope be mounted on a polar axis. If two other wires KL, MN, paralled to C*c*, be placed near H and R, the observation may be made on two stars whose difference of meridian is nearly equal to HR, the diameter of the field of view, by bringing the two images of one of the stars to coincide with one of these wires. If two stars be observed whose difference of declination is well settled, the scale of the micrometer will be known.

Hence the true place of a planet in the sun's disk may at any time of its transit be found; and consequently the nearest approach to the centre and the time of ecliptic conjunction may be deduced although the middle should not be observed.

But, however valuable the object-glass micrometer undoubtedly is, difficulties sometimes have been fouud in its use, owing to the alteration of the focus of the eye, which will cause it to give different measures of the same angle at different times.

In the *Philosophical Transactions* for 1779, Mr. Ramsden has described two new micrometers, which he contrived with a view of remedying the defects of the object-glass micrometer.

1. One of these is a *catoptric* micrometer, which, besides the advantage it derives from the principle of reflection, of not being disturbed by the mixed character of light, avoids every defect of other micrometers, and can have no aberration, nor any defect arising from the imperfection of materials or of execution, as the extreme simplicity of its construction requires no additional mirrors or glasses to those required for the telescope; and the separation of the image being effected by the inclination of the two specula, and not depending on the focus of any lens or mirror, any alteration in the eye of an observer cannot affect the angle measured. It has peculiar to itself the advantages of an adjustment to make the images coincide in a direction perpendicular to that of their motion, and also of measuring the diameter of a planet on both sides of the zero, which will appear no inconsiderable advantage to observers who know how much easier it is to ascertain the contact of the external edges of two images than their perfect coincidence.

A, *fig.* 4, represents the small speculum divided into two equal parts, one of which is fixed on the end of the arm B; the other end of the arm is fixed on a steel axis, X, which crosses the end of the telescope C. The other half of the mirror A is fixed on the arm D, which arm at the other end terminates in a socket, *y*, that turns on the axis X; both arms are prevented from bending by the braces *a*, *a*. G represents a double screw, having one part, *e*, cut into double the number of threads in an inch to that of the part *g*, the part *e* having 100 threads in one inch, and the part *g* fifty only. The screw *e* works in a nut F in the side of the telescope, while the part *g* turns in a nut H, which is attached to the arm B; the ends of the arms B and D, to which the mirrors are fixed, are separated from each other by the point of the double screw pressing against the stud *b*, fixed to the arm D, and turning in the nut H on the arm B. The two arms B and D are pressed against the direction of the double screw *e g* by a spiral spring within the part *n*, by which means all shake or play in the nut H, on which the measure depends, is entirely prevented.

From the difference of the threads on the screw at *e* and *g*, it is evident that the progressive motion of the screw through the nut will be half the distance of the separation of the two halves of the mirror; and consequently the half mirrors will be moved equally in contrary directions from the axis of the telescope C.

The wheel V fixed on the end of the double screw has its circumference divided into 100 equal parts, and numbered at every fifth division with five, ten, &c., to 100, and the index I shows the motion of the screw with the wheel round its axis, while the number of revolutions of the screw is shown by the divisions on the same index. The steel screw at R may be turned by a key, and serves to incline the small mirror at right angles to the direction of its motion. By turning the finger-head T (*fig.* 5), the eye-tube P is brought nearer to or further from the small mirror, to adjust the telescope to distinct vision; and the telescope itself has a motion round its axis for the conveniency of measuring the diameter of a planet in any direction. The inclination of the diameter measured with the horizon is shown in degrees and minutes by a level and vernier on a graduated circle, at the breech of the telescope.

"It is necessary to observe," says Mr. Ramsden, "that, besides the table for reducing the revolutions and parts of the screw to minutes, seconds, &c., it may require a table for correcting a very small error which arises from the eccentric motion of the half-mirrors. By this motion their centres of curvature will (when the angle to be measured is large) approach a little towards the large mirror: the equation for this purpose in small angles is insensible; but when angles to be measured exceed ten minutes it should not be neglected. Or the angle measured may be corrected by diminishing it in the proportion of the versed sine of the angle measured, taking into account the focal length of the small mirror."

Mr. Ramsden preferred Cassegrain's construction of the reflecting telescope to either the Gregorian or Newtonian, because, in the former, errors caused by one speculum are diminished by those in the other. From a property of the reflecting telescope (which, he observes, has not been attended to), that the apertures of the two specula are to each other very nearly in the proportion of their focal lengths, it follows that their aberrations will be to each other in the same proportion; and these aberrations are in the same direction if the two specula are both concave; or in contrary directions if one speculum is concave and the other convex. In the Gregorian construction, both specula being concave, the aberration at the second image will be the sum of the aberrations of the two mirrors; but in the Cassegrain construction, one mirror being concave and the other convex, the aberration at the second image will be the difference between their aberrations. By assuming such proportions for the *foci* of the specula as are generally used in the reflecting telescope, which is about as one to four, the aberration in the Cassegrain construction will be to that in the Gregorian as three to five.

2. The other is a *dioptric* micrometer, or one suited to the principle of refraction. This micrometer is applied to the erect eye-tube of a refracting telescope, and is placed in the conjugate focus of the first eye-glass; in which position, the image being considerably magnified before it comes to the micrometer, any imperfection in its glass will be magnified only by the remaining eye-glasses, which in any telescope seldom exceeds five or six times. By this position also the size of the micrometer glass will not be the $\frac{1}{100}$ part of the area which would be required if it were placed in the object-glass; and, notwithstanding this great disproportion of size, which is of great moment to the practical optician, the same extent of scale is preserved, and the images are uniformly bright in every part of the field of the telescope.

Fig. 6 represents the glasses of a refracting telescope; *x*, the principal pencil of rays from the object-glass O; *t t* and *u u*, the axis of two oblique pencils; *a*, the first eye-glass; *m*, its conjugate focus, or the place of the micrometer; *b*, the second eye-glass; *c*, the third; and *d*, the fourth, or that which is nearest the eye. Let *p* be the diameter of the object-glass, *e* the diameter of a pencil at *m*, and *f* the diameter of the pencil at the eye; it is evident that the axis of the pencils from every part of the image will cross each other at the point *m*; and *e* the width of the micrometer-glass is to *p* the diameter of the object-glass as *m a* is to *g o*, which is the proportion of the magnifying power at the point *m*; and the error caused by an imperfection in the micrometer glass placed at *m* will be to the error had the micrometer been at O as *m* is to *p*.

Fig. 7 represents the micrometer; A, a convex or concave lens, divided into two equal parts by a plane across its centre; one of these semi-lenses is fixed in a frame B, and the other in the frame E; which two frames slide on a plate H, and are pressed against it by thin plates *a*; the frames B and E are moved in contrary directions by turning the button D. L is a scale of equal parts on the frame B; it is numbered from each end towards the middle with 10, 20, &c. There are two verniers on the frame E, one at M and the other at N, for the convenience of measuring the diameter of a planet, &c., on both sides the zero. The first division on both these verniers coincides at the same time with the two zeros on the scale L; and, if the frame is moved towards the right, the relative motion of the two frames is shown on the scale

L by the vernier M; but, if the frame B be moved towards the left, the relative motion is shown by the vernier N.—This micrometer has a motion round the axis of vision for the convenience of measuring the diameter of a planet, &c., in any direction, by turning an endless screw, F; and the inclination of the diameter measured with the horizon is shown on the circle *g* by a vernier on the plate V. The telescope may be adjusted to distinct vision by means of an adjusting-screw, which moves the whole eye-tube with the micrometer nearer or further from the object-glass, as telescopes are generally made; or the same effect may be produced in a better manner without moving the micrometer, by sliding the part of the eye-tube *m* on the part *n*, by help of a screw or pinion. The micrometer is made to take off occasionally from the eye-tube that the telescope may be used without it.

The late Sir W. Herschel, having had much occasion for micrometers that would measure exceeding small distances exactly, was led to direct his attention to the improvement of these instruments; and the result of his endeavours has been a very ingenious instrument called a *lamp-micrometer*, which is not only free from the ordinary imperfections, but also possesses the advantages of a very large scale. This instrument is described in the *Philosophical Transactions* for 1782; and the construction of it is as follows:—

ABG, *fig*. 8, is a stand nine feet high, upon which a semicircular board, *qhogp*, is movable upwards or downwards, in the manner of some fire-screens, as occasion may require, and is held in its situation by a peg, *p*, put into any one of the holes of the upright piece AB. This board is a segment of a circle of fourteen inches radius, and is about three inches broader than a semicircle, to give room for the handles *rD*, *eP*, to work. The use of this board is to carry an arm L, thirty inches long, which is made to move upon a pivot at the centre of the circle, by means of a string, which passes in a groove upon the edge of the semicircle *pgohq*; the string is fastened to a hook at *o* (not shown in the figure, being at the back of the arm L), and passing along the groove from *o b* to *a* is turned over a pulley at *a* and goes down to a small barrel *e*, within the plane of the circular board, where a double-jointed handle, *e P*, commands its motion. By this contrivance, we see, the arm L may be lifted up to any altitude from the horizontal position to the perpendicular, or be suffered to descend by its own weight below the horizontal to the reverse perpendicular situation. The weight of the handle P is sufficient to keep the arm in any given position; but, if the motion should be too easy, a friction-spring applied to the barrel will moderate it at pleasure.

In front of the arm L, a small slider, about three inches long, is movable in a rabbet from the end L towards the centre backwards and forwards. A string is fastened to the left side of the little slider, and goes towards L, where it passes round a pulley at *m*, and returns under the arm from *m*, *n*, towards the centre, where it is led in a groove on the edge of the arm, which is of a circular form, upwards to a barrel (raised above the plane of the circular board) at *r*, to which the handle *rD* is fastened. A second string is fastened to the slider, at the right side, and goes towards the centre, where it passes over a pulley *n*; and the weight *w*, which is suspended by the end of this string, returns the slider towards the centre, when a contrary turn of the handle permits it to act.

At *a* and *b* are represented two small lamps, two inches high, 1½ in breadth by 1¼ in depth. The sides, back, and top, are made so as to permit no light to be seen, and the front consists of a thin brass sliding door. The flame in the lamp *a* is placed three-tenths of an inch from the left side, three-tenths from the front, and half an inch from the bottom. In the lamp *b* it is placed at the same height and distance, measuring from the right side. The wick of the flame consists only of a single very thin lamp-cotton thread: for, the smallest flame being sufficient, it is easier to keep it burning in so confined a place. In the top of each lamp must be a little slit lengthways, and also a small opening in one side near the upper part, to permit air enough to circulate to feed the flame. To prevent every reflection of light, the side opening of the lamp *a* should be to the right, and that of the lamp *b* to the left. In the sliding door of each lamp is made a small hole with the point of a very fine needle just opposite the place where the wicks are burning, so that when the sliders are shut down, and every thing dark, nothing shall be seen but two fine lucid points of the size of two stars of the third or fourth magnitude. The lamp *a* is placed so that its lucid point may be in the centre of the circular board, where it remains fixed. The lamp *b* is hung to the little slider which moves in the rabbet of the arm, so that its lucid point, in an horizontal position of the arm, may be on a level with the lucid point in the centre. The movable lamp is suspended upon a piece of brass fastened to the slider by a pin exactly behind the flame, upon which it moves as a pivot. The lamp is balanced at the bottom by a leaden weight, so as always to remain upright when the arm is either lifted above or depressed below the horizontal position. The double-jointed handle *rD*, *eP*, consists of light deal rods, ten feet long, and the lowest of them may have divisions marked upon it near the end P, expressing exactly the distance from the central lucid point in feet, inches, and tenths.

From this construction we see that a person at a distance of ten feet may govern the two lucid points, so as to bring them into any required position south or north, preceding or following from 0 to 90° by using the handle P, and also to any distance from six-tenths of an inch to five or six and twenty inches by means of the handle D. If any reflection or appearance of light should be left from the top or sides of the lamps, a temporary screen, consisting of a long piece of pasteboard, or a wire frame covered with black cloth, of the length of the whole arm, and of any required breadth, with a slit of half an inch broad in the middle, may be affixed to the arm by four bent wires, projecting an inch or two before the lamps, situated so that the movable lucid point may pass along the opening left for that purpose.

Fig. 9 represents part of the arm L, half the real size; S the slider; *m* the pulley, over which the cord *xtyz* is returned towards the centre; *v* the other cord going to the pulley *n* of *fig*. 8; R the brass piece movable upon the pin *c*, to keep the lamp upright. At R is a wire riveted to the brass piece, upon which is held the lamp by a nut and screw.

"Every artist," says the ingenious inventor, "will soon perceive that the motions of this micrometer are

capable of great improvement by the application of wheels and pinions, and other well known mechanical resources; but as the principal object is only to be able to adjust the two lucid points to the required position and distance, and to keep them there for a few minutes, while the observer measures their distance, it will not be necessary to say more upon the subject.

"I am now to show the application of this instrument. It is well known to opticians, and others who have been in the habit of using optical instruments, that we can with one eye look into a microscope or telescope, and see an object much magnified, while the naked eye may see a scale upon which the magnified picture is thrown. In this manner I have generally determined the power of my telescopes; and any one who has acquired a facility of taking such observations will very seldom mistake so much as one in fifty in determining the power of an instrument, and that degree of exactness is fully sufficient for the purpose.

"The Newtonian form is admirably adapted to the use of this micrometer; for the observer stands always erect, and looks in a horizontal direction, notwithstanding the telescope should be elevated to the zenith. Besides, his face being turned away from the object to which his telescope is directed, this micrometer may be placed very conveniently without causing the least obstruction to the view: therefore, when I use this instrument, I put it at ten feet distance from the left eye, in a line perpendicular to the tube of the telescope, and raise the movable board to such a height that the lucid point of the central lamp may be upon a level with the eye. The handles, lifted up, are passed through two loops fastened to the tube, just by the observer, so as to be ready for his use. I should observe that the end of the tube is cut away, so as to leave the left eye entirely free to see the whole micrometer.

"Having now directed the telescope to a double star, I view it with the right eye, and at the same time with the left see it projected upon the micrometer: then, by the handle P, which commands the position of the arm, I raise or depress it so as to bring the two lucid points to a similar situation with the two stars; and, by the handle D, I approach or remove the movable lucid point to the same distance of the two stars, so that the two lucid points may be exactly covered by or coincide with the stars. A little practice in this business soon makes it easy, especially to one who has already been used to look with both eyes open.

"What remains to be done is very simple. With a proper rule, divided into inches and fortieth parts, I take the distance of the lucid points, which may be done to the greatest nicety, because, as I observed before, the little holes are made with the point of a very fine needle. The measure thus obtained is the tangent of the magnified angle under which the stars are seen to a radius of ten feet; therefore, the angle being found, and divided by the power of the telescope, gives the real angular distance of the centres of a double star."

Mr. Cavallo invented a micrometer which consists of a thin and narrow slip of mother of pearl finely divided, and situated in the focus of the eye-glass of a telescope, just where the image of the object is formed. It is immaterial whether the telescope be a refractor or a reflector, provided the eye-glass be a convex lens, and not a concave one, as in the Galilean construction.

The simplest way of fixing it is to stick it upon the diaphragm, which generally stands within the tube and in the focus of the eye-glass. When thus fixed, if you look through the eye-glass, the division of the micrometrical scale will appear very distinct, unless the diaphragm is not exactly in the focus; in which case, the micrometrical scale must be placed exactly in the focus of the eye-glass, either by pushing the diaphragm backwards or forwards, when this is practicable; or else the scale may be easily removed from one or the other surface of the diaphragm by the interposition of a circular piece of paper or card, or by a bit of wax. This construction is fully sufficient, when the telescope is always to be used by the same person; but, when different persons are to use it, then the diaphragm which supports the micrometer must be constructed so as to be easily moved backwards or forwards, though that motion need not be greater than about a tenth or an eighth of an inch. This is necessary, because the distance of the focus of the same lens appears different to the eyes of different persons; and, therefore, whoever is going to use the telescope for the mensuration of any angle must first of all unscrew the tube which contains the eye-glass and micrometer from the rest of the telescope, and, looking through the eye-glass, must place the micrometer where the divisions of it may appear quite distinct to his eye.

Fig. 10 exhibits this micrometer scale, but shows it twice the real size of one which Mr. Cavallo adapted to a three-feet achromatic telescope magnifying about eighty-four times. It is something less than the twenty-fourth part of an inch broad; its thickness is equal to that of common writing-paper; and the length of it is determined by the aperture of the diaphragm, which limits the field of the telescope. The divisions upon it are the 200ths of an inch, which reach from one edge of the scale to about the middle of it, excepting every fifth and tenth division, which are longer. The divided edge of it passes through the centre of the field of view, though this is not a necessary precaution in the construction of this micrometer.

In looking through a telescope furnished with such a micrometer, the field of view appears divided by the micrometer scale, the breadth of which occupies about one-seventh part of the aperture; and, as the scale is semi-transparent, that part of the object which happens to be behind it may be discerned sufficiently well to ascertain the division, and even the quarter of a division, with which its borders coincide.

At first view, the observer is apt to imagine that it is difficult to count the divisions which may happen to cover or to measure an object; but, upon trial, it will be found that this is readily performed; and even those persons who have never been used to observe with the telescope soon learn to measure very quickly and accurately with this micrometer; for, since every fifth and tenth division is longer than the rest, the astronomer soon acquires the habit of saying five, ten, fifteen; and then adding the other divisions less than five completes the reckoning. Even with a telescope which has no stand, if the object end of it be rested against a steady place, and the other end be held by the hand near the eye of the observer, an object may be measured with accuracy sufficient for several purposes, as

for the estimation of small distances, for determining the height of a house, &c. (See TELESCOPE.)

II. The micrometer has not only been applied to telescopes, and employed for astronomical purposes, but there have also been various contrivances for adapting it to *microscopical* observations. Mr. Leeuwenhoek's method of estimating the size of small objects was by comparing them with grains of sand, of which 100 in a line took up an inch. These grains he laid upon the same plate with his objects, and viewed them at the same time. Dr. Jurin's method was similar to this; for he found the diameter of a piece of fine silver wire, by wrapping it as close as he could about a pin, and observing how many rings made an inch; and he used this wire in the same manner as Leeuwenhoek used his sand. Dr. Hooke used to look upon the magnified object with one eye, while at the same time he viewed other objects placed at the same distance with the other eye. In this manner he was able, by the help of a ruler, divided into inches and small parts, and laid on the pedestal of the microscope, to cast as it were the magnified appearance of the object upon the ruler, and thus exactly to measure the diameter which it appeared to have through the glass, which being compared with the diameter as it appeared to the naked eye easily showed the degree in which it was magnified. "A little practice," says Mr. Baker, "will render this method exceedingly easy and pleasant."

"The mode of actual admeasurement," observes Mr. Adams in his *Microscopical Essays*, page 59, "is without doubt the most simple that can be used; as by it we comprehend, in a manner, at one glance, the different effects of combined glasses; and as it saves the trouble, and avoids the obscurity, of the usual modes of calculation."

The only other instrument which our space permits us to describe consists of a screw, which has fifty threads to an inch; this screw carries an index, which points to the divisions on a circular plate, which is fixed at right angles to the axis of the screw. The revolutions of the screw are counted on a scale, which is an inch divided into fifty parts; the index to these divisions is a fleur-de-lis marked upon the slider, which carries the needle-point across the field of the microscope. Every revolution of the micrometer screw measures one-fiftieth part of an inch, which is again subdivided by means of the divisions on the circular plate, as this is divided into twenty equal parts, over which the index passes at every revolution of the screw; by which means we obtain with ease the measure of 1000th part of an inch: for fifty, the number of threads on the screw, being multiplied by twenty, the divisions on the circular plate, are equal to 1000; so that each division on the circular plate shows that the needle has either advanced or receded 1000th part of an inch. (See MICROSCOPE.)

MICROSCOPE. The history of this instrument is veiled in considerable obscurity, and among the moderns the discovery of the microscope has been claimed by several individuals. The ancients appear to have been acquainted with it in one of its forms; for Seneca says, "Letters, though minute and obscure, appear larger and clearer through a glass bubble filled with water." In the middle ages this knowledge was lost. The invention of the modern instrument is attributed by the celebrated Dutch mathematician Huygens to a countryman of his, named Drebell, who constructed them about 1621, or thirty-one years after the invention of the telescope. Borelli attributes it to Jansen, the reputed contriver of the telescope; Viviani to Galileo. The first compound microscope consisting of two double convex lenses seems to have been made by F. Fontana, a Neapolitan, who dates his invention from 1618.

The numerous forms of microscopes may be included under the heads of single, compound refracting, and compound reflecting microscopes. The theory of the *single microscope* may be thus explaned. We all know that at a small distance we see more distinctly than at a large. If we look at two men, one 200 feet distant, the other 100 feet, the former will appear only one half the height of the latter, or the angle which the latter subtends to the eye of the observer will be twice that subtended by the former. Hence we must conclude that the nearer we can bring an object to the eye the larger it will appear. Now if, to render the parts of a minute object distinguishable, we bring it very near the eye (suppose within one or two inches), it will become very indistinct and confused, in consequence of the great divergence of the rays of light from the object, and the power of the crystalline lens of the eye not being sufficient to collect the rays whereby an image of the object may be formed on the retina at the proper distance on the back of the eye. Now if we employ a single microscope, which consists of a convex lens, usually made of glass (though any other transparent substance would have the same power in a greater or less degree), and mounted in a brass setting, and place it between the object and the eye, the former being in the focus of the glass, the diverging rays from the object will be refracted and rendered parallel by the lens, and thus we shall obtain a distinct and near view of the object. The increase of apparent magnitude obtained by the employment of lenses is proportioned to the difference of the distance of an object from the lens and the distance when seen without its assistance. This latter distance (the distance of distinct vision of minute objects with the naked eye) varies in different persons, and at different periods of life. Some measure therefore must be assumed as a standard, before we can express the amplifying power of a lens so as mutually to have the same idea of the magnitude of an object. Some authors adopt ten inches as the standard of the focus of the eye, under ordinary circumstances, and its decimal character makes it a convenient multiplier or divisor. With this decimal standard we can determine the magnifying power of lenses of any focal length, or formed of any substance (media). Thus if we have a lens which requires for distinct vision the object to be one inch from its centre (in a double convex), we must divide the standard ten by one, which will give ten as the magnifying power. If the lens require the object to be $\frac{1}{25}$th of an inch distant, its magnifying power will be 250. We have called the magnifying power in the first instance ten, because the length of the object is increased ten times; but, as its breadth is also increased ten times, the real magnifying power of the lens is ten times ten, or 100. The common form of the magnifiers employed for microscopes is double-convex, and they should be made as thin as possible; for the wandering or spreading out of the rays proceeding from an object when refracted by a lens with spherical surfaces, whereby an indistinctness is produced in its image, will be decreased, as the square of the thickness of the lens

employed, and the loss of light in passing through the lens is less in proportion as it is thin.

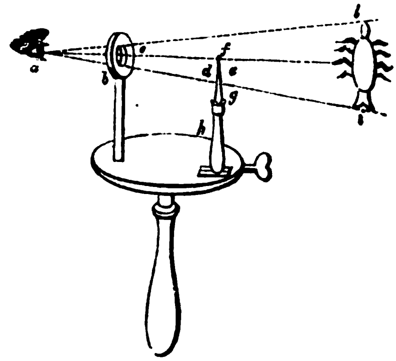
Within a few years, diamonds have been formed into lenses in consequence of their high refractive power, whereby we can obtain lenses of any degree of magnifying power with comparatively shallow curves; and, as the dispersion of colour in this substance is very low, the lens is nearly achromatic. Next to the diamond the sapphire possesses all the powers requisite for the formation of perfect magnifiers, and presents less difficulty in their construction; hence the expense of employing it is considerably less.

A *compound refracting microscope* is an instrument consisting of two or more convex lenses, by one of which an enlarged image of the object is formed, and then by means of the other, employed as an eye-glass, a magnified representation of the enlarged image is obtained. The distance at which the two lenses of a compound microscope are placed from each other must always exceed the sum of their focal lengths, in order that the image may be formed by the object-glass in the anterior focus of the eye-glass. Compound microscopes have been constructed of almost all possible dimensions, from a few inches in length to twenty feet; but from experience it appears that whenever their magnitude is augmented beyond a certain point the effect is diminished, though we suppose the amplifying power of both microscopes the same.

The *solar microscope* consists of a common microscrope connected with a reflector and condenser, the former being used to throw the sun's light on the latter, by which it is condensed to illuminate the object placed in its focus. This object is also in the focus of the microscopic lens on the other side of it, which transmits a magnified image of it to a wall or screen (sometimes a combination of two magnifying lenses is used). The magnifying power will be greater in proportion as the focal distance of the object-glass compared with the distance of the wall or screen from the object-glass is less. The principle of the *lucernal microscope* is the same, except that a lamp is used instead of the sun to illuminate the objects; this lamp is enclosed in a lantern, to screen the light from the observers.

Having thus given a general outline of the arrangement of the microscope in its various forms, it will now be advisable to furnish our readers with such graphic and descriptive particulars as will enable any ingenious workman, reading this article in conjunction with our treatise on OPTICS, to construct the instrument. To render this systematic and intelligible it may be advisable to commence with the most simple form.

A very convenient form of microscope is shown in the following engraving, where *b* is a circular piece of brass or ivory, in the middle of which is a small hole, one-twentieth of an inch diameter: in this hole is fixed, with a wire, a small lens, whose focal distance is *c d*. At that point is placed a pair of pliers, *g h*, which may be adjusted by means of the sliding screw, as in the figure, and opened by means of two little studs. The object may be viewed with the eye placed in the other focus of the lens at *a*; and, according to the focal length of the lens, the object *f* will appear more or less magnified, as represented at *i l*. If the focal length be half or one-fourth of an inch, the length, surface, and bulk of the object will be magnified in a similar proportion. This small instrument may be put into a case for the pocket. Those lenses whose focal lengths are three-tenths, four-tenths, and five-tenths of an inch, are the best for common use.



Since the nearer the eye can approach to an object the larger it appears, it is plain, a double and equally convex lens magnifies more than a plano-convex lens; because, if the sphere, or convexity, be the same, the focal length of the former is but half that of the latter; and, since the double convex consists of two segments of a sphere, the more an object is to be magnified the greater must the convexity be, and therefore the smaller the sphere; till at last the utmost degree of magnifying power will require that these segments become hemispheres, and, consequently, the lens will be reduced to a perfect spherule, or very small sphere.

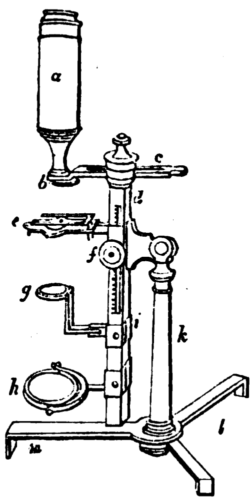
If the radius of the spherule be one-tenth of an inch, the eye will have distinct vision of an object by means thereof, at the distance of $1\frac{1}{2}$ radius (that is, three-twentieths of an inch), and, as this is but the fortieth part of six inches, the length of an object will be magnified forty times, the surface 1600 times, and the solidity 64,000 times, by such a small sphere.

If the radius of a spherule be but one-twentieth of an inch, then will the eye have distinct vision of an object at the distance of three-fortieths of an inch, and, as this is but the eightieth part of six inches, the length of objects will appear eighty times greater, the surface 6400 times, and the bulk 512,000 times greater, to the naked eye at six inches distance.

In using these spherule microscopes, the objects are to be placed in one focus and the eye in the other; and, since the focus is so exceedingly near the glass, it is impossible to view any but pellucid bodies; for, if any opaque object were to be applied, the eye being, as it were, just on the spherule, would entirely prevent any light falling on it, and it would be too obscure to be viewed.

To remedy this inconvenience, the focal length should be increased and a concave mirror substituted for the plate *b*. The object *f*, being placed in the focus of the mirror, is illuminated by reflected light, and the most opaque insect may thus be seen with advantage to the naturalist. If the instrument thus arranged be directed towards the sun, the effect will be very materially improved; and, when this cannot be accomplished, a sheet of white paper should be placed beneath the instrument.

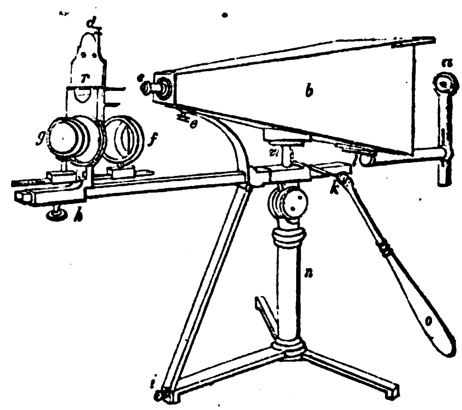
The *compound-microscope*, as made by Messrs. Jones, of Holborn, is shown in the engraving beneath. The body of the instrument *a* is screwed to the horizontal sliding arm *c*. At *b* is a circular plate, containing a series of glasses, varying in their magnifying power. The objects to be magnified are placed in the stage *e*, and the proper focus obtained by moving the rack at *f d*. The lens *g* is employed to concentrate the light of a lamp, or that of the sun, on the object to be examined. The reflector at *h* has two mirrors, the one concave, the other flat. The whole instrument is supported by the pillar *k* and the triangular stand *l m*.



The great facility with which objects can be represented on paper, or a rough glass, in the camera obscura, and copies drawn from them by any person, though unskilled in drawing, evidently suggested the application of the microscope to this instrument. The greatest number of experiments that appear to have been made with this view were by Mr. Martin and Mr. Adams, the former of whom frequently applied the microscope to the portable camera, and with much effect. But, these instruments being found to answer only with the assistance of the sun, Mr. Adams directed his experiments to the construction of an instrument of more extended utility, which could be equally employed in the day and by night. He accordingly succeeded so far as to produce, by candle-light, the images of objects refracted from a single magnifier, upon one or two large convex lenses (of about five inches, or upwards, in diameter), at the end of a pyramidal-shaped box, in a very pleasing manner, so as to give opaque objects, as well as transparent ones, the utmost distinctness of representation: but still the light of a candle, or lamp, was found generally insufficient to throw the requisite degree of illumination on the objects. The invention of the Argand lamp offered a complete remedy for this defect, by the intensity and steadiness of its light.

The advantages of this excellently-conceived instrument are numerous and important. "As the far greater part of the objects which surround us are opaque," says Mr. Adams, "and very few are sufficiently transparent to be examined by the common microscopes, an instrument that could be readily applied to the examination of opaque objects has always been a desideratum. Even in the examination of transparent objects, many of the fine and more curious portions are lost, and drowned, as it were, in the light which must be transmitted through them; while different parts of the same object appear only as dark lines or spots, because they are so opaque as not to permit any light to pass through them. These difficulties, as well as many more, are obviated in the lucernal microscopes, by which opaque objects of various sizes may be seen with ease and distinctness, the beautiful colours with which most of them are adorned are rendered more brilliant, without changing in the least the real tint of the colour, and the concave and convex parts retain also their proper form. The facility with which all opaque objects are applied to this instrument is another considerable advantage, and almost peculiar to itself: as the texture and configuration of the more tender parts are often hurt by previous preparation, every object may be examined by this instrument first as opaque, and afterwards (if the texture will admit of it) as transparent.—The lucernal microscope does not in the least fatigue the eye; the object appears like nature itself, giving ease to the sight and pleasure to the mind: there is also, in the use of this instrument, no occasion to shut the eye which is not directed to the object. A further advantage peculiar to this microscope is that by it the outlines of every object may be taken, even by those who are not accustomed to draw; while those who can draw well will receive great assistance, and execute their work with more accuracy and in less time than they would otherwise have been able to have performed it. Transparent objects as well as opaque may be copied in the same manner. The instrument may be used at any time of the day, but the best effect is by night; in which respect it has a superiority over the solar microscope, as that instrument can be used only when the sun shines.

"Transparent objects may be examined with the lucernal microscope in three or four different modes, from a blaze of light almost too great for the eye to bear to that which is perfectly easy to it; and, by the addition of a tin lantern to the apparatus, may be thrown on a screen, and exhibited at one view to a large company, as by the solar microscope."

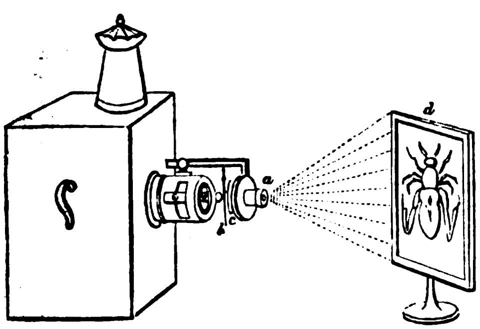


In the above engraving we give a view of this instrument mounted to examine opaque objects. *b* is a large mahogany pyramidal box, which forms the body of the microscope; it is supported firmly on the brass pillar *n*, by means of the socket *m* and the curved piece *e*. *a* is a guide for the eye, in order to direct it in the axis of the lenses; it consists of two brass tubes, *l*, one sliding within the other, and a vertical flat piece, at the top of which is the hole for the eye. The inner tube may be pulled out, or pushed in, to adjust it to the focus of the glasses. The vertical piece may be raised or depressed, that the hole

through which the object is to be viewed may coincide with the centre of the field of view: it is moved by a milled screw, which could not be shown in this figure. At *l* is a dove-tailed piece of brass, made to receive the dove-tail at the end of the tubes, by which it is attached to the wooden box. The tubes may be removed from this box occasionally, for the convenience of packing it up in a less compass. At the small end of the cone is placed a tube which carries the magnifiers, one of which is represented at *c*; the tube may be unscrewed occasionally from the wooden body. Beneath the cone is placed a long square bar, which passes through, and carries the stage or frame that holds the objects; this bar may be moved backward or forward, in order to adjust it to the focus, by means of the pinion *k*. A handle furnished with a universal joint, for more conveniently turning the pinion, is shown at *o*. When the handle is removed a nut may be used in its stead. The stage *h* for opaque objects fits upon the bar by means of a socket, and is brought nearer to or removed further from the magnifying lens by turning the pinion *k*: the objects are placed in the front side of the stage. The two upper pieces of brass, *r*, are movable; they are fixed to a plate, which is acted on by a spiral spring, that presses them down and confines the slider with the objects: this plate, and the two upper pieces of brass, are lifted up by the small nut *d*.

At the lower part of the stage, there is a semicircular lump of glass, *g*, which is designed to receive the light from the lamp, and to collect and throw it on the concave mirror *f*, whence it is reflected on the object. The upper part of the opaque stage takes out, that the stage for transparent objects may be inserted in its place.

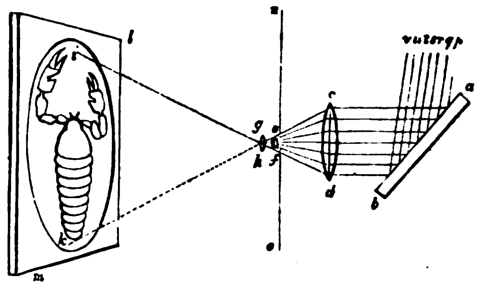
Another still more simple mode of effecting the same object is shown beneath:



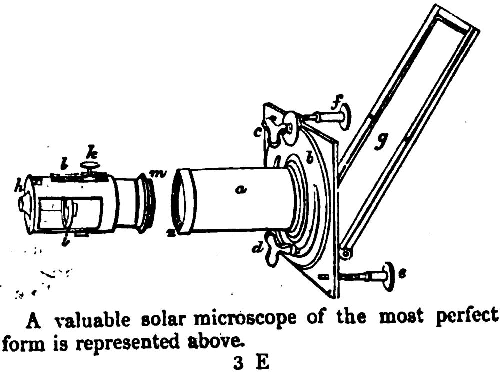
The lantern is provided with a sliding tube for the introduction of the objects to be magnified. The movable lenses are shown at *a*. Other objects differing in their character may be placed in the forceps *b*, attached to the sliding frame by the plate *c*. A plate of ground glass, shown at *d*, serves to receive the figure of the object.

The more recent application of a jet of oxy-hydrogen, acting on a ball or cylinder of lime, would not be understood by the reader without a previous acquaintance with both these gases. The editor, therefore, purposes describing a large and powerful apparatus of this description, which he has had constructed for his public lectures, under the article OXY-HYDROGEN.

The mode of constructing the *solar microscope* may now be illustrated.



It is shown in its simplest form in the above engraving, in which *a b* is the diagonal mirror for receiving the rays of light, *p q r s t u v*. They are reflected by the polished surface, and thrown on the lens *c d*. Within the focus at *e f* is placed any transparent object to be magnified, and the image thus illuminated passes through the lens *g h*. The size of the magnified figure, *i k*, will depend on the distance the instrument is placed from the wall *l m*. The room should be darkened, which is usually effected by employing a large shutter at *n o*. Mr. Baker, speaking of this instrument, says, "that it has conveniences attending it which no other microscope can have: for the weakest eyes may use it without the least straining or fatigue: numbers of people together may view any object at the same time; and, by pointing to the particular parts thereof, and discoursing on what lies before them, may be able better to understand one another, and more likely to find out the truth, than in other microscopes, where they must peep one after another, and perhaps see the object neither in the same light nor in the same position. Those, also, who have no skill in drawing, may by this contrivance easily sketch out the exact figure of any object they have a mind to preserve a picture of, since they need only fasten a paper on the screen, and trace it out thereon either with a pen or pencil, as it appears before them. It is worth the while of those who are desirous of taking many draughts in this way to get a frame, in which a sheet of paper may be placed or taken out at pleasure; for, if the paper be single, the image of an object will be seen almost as plainly on the back as on the fore-side; and, by standing behind the screen, the shade of the hand will not obstruct the light in drawing, as it must in some degree when one stands before it."



A valuable solar microscope of the most perfect form is represented above.

The square plate *b c d* is attached to the window-shutter by the screws *e f*. The glass plate *g* is mounted in a brass frame, and may be elevated or depressed by a screw at *d*. A rotatory motion is communicated by a pinion and handle at *c*, which acts on a large wheel, concealed by the square plate. The first lens is placed in the tube *a*, immediately adjoining the mirror. Another tube *m* is attached by a screw at *n*, and contains two small lenses, and the rack-work *k l* for adjusting the focus of the instrument. The objects are introduced at *i*; those best fitted for exhibition are the wings of insects, and the cuttings of wood. When glasses of high-power are employed at *h*, they are now constructed on the achromatic principle.

We may now proceed to furnish our readers with some necessary particulars respecting the method of using microscopes. On this, Mr. Adams, in his *Essay on the Microscope*, has been very copious; with a view, as he informs us, to remove the common complaint made by Mr. Baker, "that many of those who purchase microscopes are so little acquainted with their general and extensive usefulness, and so much at a loss for objects to examine by them, that after diverting their friends some few times with what they find in the sliders which generally accompany the instrument, or perhaps with two or three common objects, the microscope is laid aside as of little further value; whereas no instrument has yet appeared in the world capable of affording so constant, various, and satisfactory an entertainment to the mind."

In using the microscope, there are three things necessary to be considered. 1. The preparation and adjustment of the instrument itself. 2. The proper quantity of light, and the best method of adapting it to the object. 3. The method of preparing the objects, so that their texture may be properly understood.

With regard to the microscope itself, the first thing necessary to be examined is whether the glasses be clean or not: if they are not so, they must be wiped with a piece of soft leather, taking care not to soil them afterwards with the fingers; and, in replacing them, care must be taken not to place them in an oblique direction. We must likewise be careful not to let the breath fall upon the glasses, nor to hold that part of the body of the instrument where the glasses are placed with a warm hand; because the moisture thus expelled by the heat from the metal will condense upon the glass, and prevent the object from being distinctly seen. The object should be brought as near the centre of the field of view as possible; for there only will it be exhibited in the greatest perfection. The eye should be moved up and down from the eye-glass of a compound microscope, till the situation is found where the largest field and most distinct view of the object are to be had: but every person ought to adjust the microscope to his own eye, and not depend upon the situation it was placed in by another. A small magnifying power should always be begun with; by which means the observer will best obtain an exact idea of the situation and connexion of the whole, and will of consequence be less liable to form any erroneous opinion, when the parts are viewed separately by a lens of greater power. Objects should also be examined first in their most natural position; for, if this be not attended to, we shall be apt to form very erroneous ideas of the structure of the whole, as well as of the connexion and use of the parts. A living animal ought to be as little hurt or discomposed as possible. From viewing an object properly, we may acquire a knowledge of its nature: but this cannot be done without an extensive knowledge of the subject, much patience, and many experiments; as in a great number of cases the images will resemble each other, though derived from very different substances. Mr. Baker, therefore, advises us not to form an opinion too suddenly, after viewing a microscopical object; nor to draw our inferences till after repeated experiment and examinations of the objects in many different lights and positions; to pass no judgment upon things extended by force, or contracted by dryness, or in any manner out of a natural state, without making suitable allowances. The true colour of objects cannot be properly determined by very great magnifiers; for, as the pores and interstices of an object are enlarged according to the magnifying power of the glasses made use of, the component particles of its substance will appear separated many thousand times further asunder than they do to the naked eye: hence the reflection of the light from these particles will be very different, and exhibit different colours. It is likewise somewhat difficult to observe opaque objects; and, as the apertures of the larger magnifiers are but small, they are not proper for the purpose. If an object be so very opaque that no light will pass through it, as much as possible must be thrown upon the upper surface of it. Some consideration is likewise necessary in forming a judgment of the motion of living creatures, or even of fluids, when seen through the microscope; for, as the moving body, and the space wherein it moves, are magnified, the motion will also be increased.

On the management of the light depends, in a great measure, the distinctness of the vision: and as, in order to have this in the greatest perfection, we must adapt the quantity of light to the nature of the object and the focus of the magnifier, it is therefore necessary to view it in various degrees of light. In some objects, it is difficult to distinguish between a prominence and a depression, a shadow and a black stain; or between a reflection of light and whiteness, which is particularly observable in the eye of the libella and other flies, all of these appearing very different in one position from what they do in another. The brightness of an object likewise depends on the quantity of light, the distinctness of vision, and on regulating the quantity to the object; for one will be in a manner lost in a quantity of light scarcely sufficient to render another visible.

There are various ways in which a strong light may be thrown upon objects, as by means of the sun and a convex lens. For this purpose, the microscope is to be placed about three feet from a southern window; then take a deep convex lens, mounted on a semicircle and stand, so that its position may easily be varied: place this lens between the object and the window, so that it may collect a considerable number of rays, and refract them on the object or the mirror of the microscope. If the light thus collected from the sun be too powerful, it may be lessened by placing a piece of oiled paper, or a piece of glass slightly ground, between the object and lens. Thus a proper degree of light may be obtained, and diffused equally over the surface of an object, a circumstance which ought to be particularly attended to; for, if the light be thrown irregularly upon it, no distinct view can be obtained.

On account of the sun's motion, and the variable state of the atmosphere, solar observations are rendered both tedious and inconvenient, so that it may be advisable for the observer to be furnished with a large tin lantern, formed something like the common magic lantern, capable of containing an argand lamp. There ought to be an aperture in the front of the lantern, which may be moved up and down, and be capable of holding a lens, by which means a pleasant and uniform as well as strong light may easily be obtained. The lamp should likewise move on a rod, so that it may be easily raised or depressed. A weak light is best fitted for viewing many transparent objects, among which we may reckon the prepared eyes of flies, as well as the animalculæ in fluids. The quantity of light from a lamp or candle may be lessened by removing the microscope to a greater distance from them, or by diminishing the strength of the light which falls upon the objects. This may very conveniently be done by pieces of black paper with circular apertures of different sizes, and placing a larger or smaller one upon the reflecting mirror, as occasion may require. The light of a lamp or candle is generally better for viewing microscopic objects than day-light, it being more easy to modify the former than the latter, and to throw it upon the object with different degrees of intensity.

With regard to the preparation of objects, Swammerdam has, in that respect, excelled almost all other investigators who either preceded or have succeeded him. He was so assiduous and indefatigable that neither difficulty nor disappointment could make the least impression on him; and he never abandoned the pursuit of any object until he had obtained a satisfactory acquaintance with it. Unfortunately, however, the methods he made use of in preparing his objects for the microscope are now entirely unknown.

For dissecting *small insects*, Swammerdam had a brass table, to which were attached two brass arms, movable at pleasure. The upper part of each of these vertical arms was constructed in such a manner as to have a slow vertical motion, by which means the operator could readily alter their height. One of these arms was to hold the minute objects, and the other to apply the microscope.

The lenses for Swammerdam's microscopes were of various sizes as well as foci. His observations were always begun with the smallest magnifiers, from which he proceeded by progressive steps to the greatest.

The minute scales or feathers which cover the wings of moths or butterflies afford very beautiful objects for the microscope. Those from one part of the wing frequently differ in shape from such as are taken from other parts; and near the thorax, shoulder, and on the fringes of the wings, we generally meet with hair instead of scales. The whole may be brushed off the wing, upon a piece of paper, by means of a camel's hair pencil; after which the hairs can be separated, with the assistance of a common magnifying glass.

Great difficulty is experienced in dissecting properly the proboscis of insects, such as that of the gnat, and the experiment must be repeated a great number of times before the structure and situation of the parts can be thoroughly investigated, as the observer will frequently discover in one what he could not in another. The *collector of the bee*, which forms an exceedingly curious object, ought to be carefully washed in spirit of turpentine, by which means it will be freed from the unctuous matter adhering to it: when dry, it is again to be washed with a camel's hair pencil, to disengage and bring forward the small hairs which form part of its microscopic beauty. The best method of preparing the stings of insects, which are in danger of being broken from their hardness, is to soak the case and the rest of the apparatus for some time in spirit of wine, or turpentine; then lay them on a piece of paper, and with a blunt knife draw out the sting, holding the sheath with the nail of the finger, or any other blunt instrument; but great care is necessary to preserve the feelers, which, when cleaned, add much to the beauty of the object. The *beard* of the lepas antifera is to be soaked in clean soft water, frequently brushing it, while wet, with a camel's hair pencil: after it is dried, the brushing must be repeated, with a dry pencil, to disengage and separate the hairs, which are apt to adhere together.

The eyes of insects in general form very beautiful and curious objects. Those of the libellula and other flies, as well as of the lobster, &c., must be cleaned from the blood, &c., after which they should be soaked in water for some days: one or two skins are then to be separated from the eye, which would be otherwise too opaque and confused, but some care is requisite in this operation; for, if the skin be rendered too thin, it is impossible to form a proper idea of the organization of the part. In some substances, however, the organization is such that by altering the texture of the part we destroy the objects which we wish to observe. Of this sort are the nerves, tendons, and muscular fibres, many of which are viewed to most advantage when floating in some transparent fluid. Thus very few of the muscular fibres can be discovered when we attempt to view them in the open air, though great numbers may be seen if they be placed in water or oil. By viewing the thread of a ligament in this manner, we find it composed of a vast number of smooth round threads lying close together. Elastic objects should be pulled or stretched out while they are under the microscope, that the texture and nature of those parts the figure of which is altered by being thus extended may be more fully discovered.

To examine bones by the microscope, they should first be viewed as opaque objects; but afterwards, by procuring thin slices of them, they may be viewed as transparent. The sections should be cut in all directions, and well washed and cleaned; and, in some cases, maceration will be useful, or the bones may be heated to a high temperature, in a clear fire, which will render the bony cells more conspicuous.

MIDWIFERY is the art of aiding and facilitating childbirth, and of providing for the preservation of the health and life of the mother during and after her delivery. It is founded on physiological and pathological science. Midwifery, in some form, has been employed from the most ancient times, even among the rudest nations, although it was at first very defective, and consisted, probably, only in the most obvious and indispensable manual applications and aids. Even in the most cultivated nations of antiquity, this art was in a low state. The Israelites had their midwives. The first accounts of scientific male midwifery are to be found among the Greeks of the age of Hippocrates, who died 357 B. C. From the writings of that period, we learn that the obstetrical art had

then reached a higher degree of cultivation among the Greeks than in most parts of Europe during the last century. There was, notwithstanding, much that was wrong and injudicious in their system, and only a small part of the proper means of assistance was made use of. They often contented themselves with invoking Ilithyia, the goddess of childbirth. Among the Romans, midwifery was confined to a few simple aids, and sacrificing to Juno Lucina, and other deities who presided over childbirth. It was not till a later period that the Roman women commonly employed midwives; but, in difficult cases, the physicians were called in. These were either Greeks living in Rome, under the dominion of the Roman emperors, or they drew their knowledge chiefly from Greek authors. To this epoch belong particularly Soranus, and Moschion, who composed the first manual of midwifery which has come down to us.

In the middle ages, the science was very much neglected: it was confined to the cutting of the fœtus from the body of the mother, in case of her death before delivery. In consequence of the injudicious interference of the popes, who conferred the professorships in the newly-established schools on the monks, and gave them the privilege of practising physic, while they strictly prohibited the practice of surgery and anatomy both to the physicians and laity (1215), the obstetric art became confined to internal and superstitious applications, and, indeed, generally sunk into the hands of women, monks, peasants, and other ignorant persons. When they had exhausted their medical skill, the saints were invoked, images and relics were hung upon the woman in labour, &c. The art continued in this state till the sixteenth century. At this time, the improvements in printing and engraving gradually introduced a better era, since the surviving works of the Greeks, Romans, and Arabians were multiplied, the intellectual intercourse among men became more general, and the spirit of enquiry was awakened and found a wider field. At this period, the business of midwifery was so exclusively in the hands of women that it was disgraceful for a man to engage in it. Such an undertaking was considered as an abominable attempt on the virtue and honour of the female sex, and he who ventured upon it as little better than a monster. In Hamburg, in 1521, Veites was condemned for this offence to the flames. Several books, however, were published for the better instruction of midwives in their profession. The first was by Eucharius Roslein, at Worms, called the *Rose-Garden for Midwives and pregnant Women* (1513). The science of anatomy, which was now more freely studied and patronized, also contributed much to the improvement of midwifery, in which Vesalius, in Padua (1543), particularly distinguished himself. The physicians and surgeons turned their attention only to the theoretical part of the science, but the latter gradually proceeded to the practice of it, by performing the Cæsarean operation on women who had died in childbirth (which was now not only permitted but commanded by law), and gradually undertaking other operations on women pregnant and in labour.

Francis Rousset, a surgeon in Paris, published a treatise, in 1581, in which he brought several proofs of the possibility of safely performing the Cæsarean operation on the living mother, and it was he who first gave this operation its present name. After the publication of this treatise, the operation was frequently performed on the living subject, both in and out of France, and sometimes even when it was not unavoidably necessary. Pineau, a surgeon in Paris, first suggested, in 1589, the section of the pubes, by the observations which he communicated on the separation which takes place between the bones of the pelvis, for the purpose of facilitating birth, when made difficult by the extreme narrowness of the pelvis.

In Germany, midwifery long remained in an imperfect state: the midwives were generally ignorant, and men were seldom employed; while in France and Italy it was already a common thing to call in the aid of physicians and surgeons. A surgeon named Clement, distinguished in the practice of midwifery, and who had attended La Valiere, the mistress of Louis XIV., in her delivery, first received the name of *accoucheur* as a title of honour. The surgeons were so well pleased with the name that they gradually adopted it as a general appellation. Henry of Deventer, a surgeon of Holland, was the first who, in 1701, endeavoured to establish midwifery on scientific principles. In France, where the art had risen to higher perfection than in other countries, a school for midwives was established in the *Hôtel Dieu*, in 1745.

The history of the origin and invention of the forceps, that highly useful instrument in midwifery, is involved in some obscurity. Between 1660 and 1670, Chamberlin, a London surgeon, professed to have invented an instrument with which he was able to terminate the most difficult labours without injuring either the mother or child: but he kept this discovery to himself, and in 1688 went to Amsterdam, where he sold it to certain practitioners, who turned it to their profit. It was thus kept secret among certain persons for a long time. At last, Palfyn, a famous anatomist and surgeon, of Ghent, in Flanders, acquired some knowledge of the instrument, and caused one to be made in 1723. Some species of forceps appear to have been known even in the time of Hippocrates; but the merit of Chamberlin's invention consisted in making the blades separable, and capable of being locked together after having been introduced into the vagina, and placed one on each side of the head of the child. It was afterwards very much improved, especially by Levret, in 1747; Plevier, in Amsterdam, 1750; and Smellie, in London, 1752. The art of midwifery was also perfected by the writings and instructions of these men. Germany, too, produced several men of eminence in this department of the medical art, who were not only famous for their operative skill, but contributed much to the advancement of midwifery by their observations, and to the diffusion of correct principles on the subject by their lectures and writings. The establishment of several schools of midwifery also facilitated the study of the art, and brought it to the degree of perfection which it now boasts. The course now adopted seems to be the true one, viz. by the cultivation of all the branches of knowledge connected with this department, to determine the cases in which art may and ought to be passive and leave the work to nature, and those in which nature is insufficient to accomplish the delivery alone, or, at least, without injury to the mother or child.

Military Schools and Academies; schools in which soldiers receive instruction, or in which youths are educated for the army. Among the former are the *soldier-schools*, in which, as is the case in many

armies, particularly in the Prussian, the private soldiers learn reading, writing, and arithmetic; they are also, in the last-named country at least, often instructed in singing; so that it is common, in the Prussian army, for a battalion to have its choir, which sings during divine service, and on other occasions. Instruction has become so general in the Prussian army, by means of regimental and battalion schools, that during the last years of peace the army was considered an institution for the instruction of the whole country, as every Prussian is obliged to serve for a short time in the standing army. In some armies *conversazioni* have been introduced, in which the officers hold discourse with the sergeants and privates on subjects connected with the service. When the officers in the armies of the European continent were taken from the nobility only, academies were established by government to educate young noblemen. They were called in Germany *Ritterakademien*, and sometimes were of a high character. These establishments must be distinguished from the *cadet-houses*, so called, where, generally speaking, the children of officers only are educated for the army. In many countries noblemen only are admitted into these also. In several French cities companies of *cadets* existed when Louis XV., in 1751, first established an *école royale militaire* for 500 young noblemen, from eight to eleven years old. The principal features of its organization have been retained in most similar institutions.—See *Recueil d'Edits Déclarations, Reglemens et Ordonnances du Roi, concernant l'Hôtel de l'Ecole roy. militaire* (Paris, 1762). The (so called) *Ritterakademien* originated later. Frederic the Great established the *école militaire* at Berlin for the further accomplishment of young officers. Even before the seven years' war, every French city in which a regiment of artillery was garrisoned had its artillery school. Saxony followed in 1766, Austria and Prussia later. At present, the two latter have excellent artillery schools, as well as others in the department of engineering. Since 1815, the standard of scientific education of officers has been much raised in several armies; in none, however, so high as in the Prussian, in which no person can be promoted without a severe examination. Besides the regimental schools in this army, mentioned above, every division has its school, to which young sergeants, &c., are admitted (if they appear, on examination, to possess the necessary elementary knowledge), in order to prepare themselves for examination for a lieutenancy. Mathematics, history, geography, statistics, the applied mathematics, modern languages (particularly French), and the military sciences, are here the chief subjects of study. The artillery corps and engineer corps have their separate schools for young officers to prepare themselves for examination for the rank of captain. The captain must continue his studies by himself, to stand an examination for the rank of major. Of the troops of the line, every regiment is allowed to send a few of its young officers, who must have shown great diligence, talent, and considerable acquirements, to the general military school in Berlin—an institution of a very high character. Here the highest branches of mathematics, geology and mineralogy, chemistry and natural philosophy, history, politics, the military sciences, languages, &c., are taught in a course which occupies three years. The officers also attend such lectures in the university as they choose. It is evident how much such establishments must raise the standard of learning in the whole army; and, indeed, the corps of officers contains some of the most accomplished men in Prussia. In France, the former cadet-houses have been called, since the revolution, *military schools*. (For the system of military education pursued in this country, see WOOLWICH ACADEMY.)

MILITARY SCIENCES have, by some of the latest writers, been divided into the following heads:—

1. *Tactics*, or the science of the drilling of an army, as well as of disposing and directing it in battle, requiring, of course, an acquaintance with the different kinds of arms. The artillerist devotes himself particularly to the ordnance, and the various branches of science requisite for its proper management. The lower, or elementary tactics, treats of the drilling and formation of soldiers, and accustoming them to the movements of small and large divisions, and varies in character with the different regulations of different armies. Tactics proper treats of the mode of disposing troops in the actual combat, and of the peculiar use of each species of force, cavalry, infantry both heavy and light, and artillery. With them is nearly connected the choice of camps, or castrametation, though, since the introduction of the system of requisition, this branch of military science has gone almost entirely out of use. The knowledge of the employment of pontons seems also to fall within this department.

2. *Strategy*, the science of forming the plans of operation, and of directing armies accordingly. It has been but lately treated as an independent branch, since Von Bulow wrote on the subject. Many military writers will not as yet admit such a division; but little doubt can exist that it will be universally adopted.

3. The branch which treats of the just understanding and proper use of the surface of the earth for military purposes. The tactics of our time can overcome a number of obstacles, arising from the character of the ground, which were formerly considered insurmountable; still, however, this department of military science, embracing, as it does, a knowledge of the usual character of the ground under given circumstances, the course of rivers, of mountains, valleys, geological formations, &c., remains indispensable for a useful officer. To this branch belongs, or, at least, with it is intimately connected, reconnoitring, surveying, drawing of topographical maps, &c.

4. *Military Architecture*, or *Fortification*, which teaches how to fortify any given point by artificial means, so that a few persons may be able to defend themselves against the attacks of many. It embraces the construction of proper fortresses, the attack and defence of fortified places, and the knowledge of field fortification, which treats of the construction, attack, and defence of redoubts in the field, raised for transitory purposes, and not so solid as in standing fortifications.

5. *Military History and Biography*, which embraces a knowledge of all important wars, and also of the various organizations of armies, the principles upon which war has been carried on, the different arms used, and the consequences attending their use, &c.; also the lives of the greatest generals, and the resources which they found in situations where many leaders would have despaired. The history of military literature, to a certain extent, is indispensable for a young officer, that he may be directed to

the best works of the different nations. Of the auxiliary sciences, the most important is mathematics, which is indispensable for a scientific soldier; military geography, embracing a knowledge of roads, rivers, valleys, &c., the law of nations, modern languages, and gymnastics. The branches of study now enumerated are more or less essential to the well-educated soldier; but they cannot make a general, any more than the study of the thorough base can make a Mozart, or the knowledge of perspective, anatomy, and colours, a Raphael. Although it would be a useless waste of time to set about proving that scientific study is essential to a commander, yet the greatest general must find the most important resources in his own genius; and this must act with unfailing promptness. An artist, if unsuccessful, may renew his efforts; but in war the issue of a battle may depend upon an instant decision, and a failure is ruin.

Militia, in the modern adaptation of the word, a body of armed citizens regularly trained, though not in constant service in time of peace, and thereby contradistinguished from *standing armies*. It includes all classes of the citizens, with certain exceptions, who are drilled at particular periods in peace, and liable, according to certain laws, to march in cases of emergency against the enemy, in some countries, however, not beyond the frontier. The regular organization of the militia distinguishes it from the *levée-en-masse*.

The militia exists in different countries under different names; in some countries, they are denominated *burgher-guards;* in Austria and Prussia, *landwehr* (defence of the country); while the *levée-en-masse* is called in these two countries *landsturm*. When the feudal system had rendered almost every nobleman on the European continent an independent monarch in miniature, he kept his own warriors in his castle or territory, and the difficulty of assembling a large general army, even for a good purpose, was immense. In the cities, where a more republican spirit prevailed, all the citizens were obliged, at least, to take part in the defence of their city,—a duty which they were not seldom called upon to perform. The introduction of standing armies, chiefly in consequence of the endeavour of monarchs to render their governments more and more independent of the nation at large, caused the citizens to take less and less share in the military service, and in many cases excluded them from it entirely; yet while in some countries the services of the citizen soldiers were becoming every day of less importance, so that burgher-militia even became a term of contempt in many places, other governments began to foster the national militia. The Swedish army was, at an early period, a kind of general militia. The army consisted of twenty-one regiments, of which each owner of landed property was bound to maintain one man. They assembled every year for three weeks, and during this time, as well as in war, received full pay (as is now the case in Prussia). The Danish army was formed on a somewhat similar plan, about a third of each regiment consisting of enlisted foreigners, while two-thirds were Danish subjects, who, like those in Sweden, were supported by the owners of landed property, but, in return, were obliged to assist the latter in the cultivation of their estates. In Germany, similar plans were adopted. The privates and non-commissioned officers of the militia followed their agricultural or mechanical pursuits, and were generally under the command of officers out of active service. They were obliged to serve only within the country. Frederic the Great used them to garrison the fortresses: the same was the case with the Austrian militia during the war of succession. The bad organization and unmilitary spirit of these troops rendered them the butt of the troops of the line. In some cases, it was even considered allowable, by the laws of war, not to give them any quarter, when they were employed out of the limits of their country, and were taken prisoners.

The militia of this country is somewhat differently organized. The origin of this national force is generally traced back to Alfred. The feudal military tenures succeeded; and although the personal service which this system required degenerated by degrees into pecuniary commutations, or aids, the defence of the kingdom was provided for by laws requiring the general arming of the citizens. Under Edward III., it was provided that no man should be compelled to go out of the kingdom at any rate, nor out of his shire except in cases of urgent necessity, nor should provide soldiers unless by consent of parliament. We first find lord-lieutenants of counties, whose duty was to keep the counties in military order, mentioned as known officers in the fifth year of Philip and Mary. When Charles I. had, during his northern expeditions, issued commissions of lieutenancy, and exerted certain military powers, which, having been long exercised, were thought by one party to belong to the crown, it became a question in the long parliament how far the power over the militia did inherently reside in the king, which, after long agitation, ended by the two houses denying the crown this prerogative, and taking into their own hands the entire power over the militia. After the restoration, when the military tenures were abolished, the sole right of the crown to govern and command the militia was recognized.

The most characteristic features of our militia at present are, that a number of persons in each county are drawn by lot, and officered by the lord-lieutenants and other principal land-owners, under a commission from the crown. When drawn out, they are subject to military law. In all cases of actual invasion, or imminent danger thereof, and in all cases of rebellion or insurrection, the king may embody the militia, and direct them to be led into any part of the kingdom, having communicated the occasion to parliament, if sitting, or, if not sitting, having declared it in council, and notified it by proclamation.

In Tyrol, a general arming against the French was effected in 1799. When, in 1808, the arch-duke Charles was placed at the head of military affairs, a general *landwehr* was organized throughout the Austrian provinces. In 1809 these troops fought well. They amounted at that time to 300,000 men; after 1811 to only 71,500; but after 1813 the *landwehr* was again placed on its old footing, and part of it have since been called out to increase the army intended to overawe the Italian States. In Hungary, the common law obliges every nobleman to serve himself, and to bring his vassals into the field, if called upon. This *levée* is called an "insurrection of the nobility." In 1809 this insurrection consisted of 17,000 horse and 21,000 foot.

In 1807 a general militia was organized in Russia,

which in 1812 was of considerable service against the French. Prussia has carried the *landwehr* to greater perfection than any other country; in that country the militia forms the main body of the army. In 1813 every male person under forty-eight years of age was obliged to serve against the French in the militia. The national militia, at that time, included both infantry and cavalry. The lower commissioned officers were elected by the militia-men, and the higher by the estates of each circle. When Napoleon returned from Elba, Prussia had 150,000 infantry and 20,000 cavalry of the militia under arms. After the peace of 1815, the *landwehr* was established on its present footing. Every Prussian, with the single exception of mediatized princes, is obliged to serve for three years in the standing army, between his seventeenth and twenty-third year. Part of this time, however, he is generally on furlough. If a person equips himself and undergoes an examination, by which he proves that he has received a certain education, he has to serve one year only in the standing army. After this time, every Prussian belongs, until his thirtieth year, to the first class of the *landwehr*, attends frequent drills on Sunday afternoons, and has to serve for three weeks every year, when the *landwehr* is called together foı great manœuvres. Every man is in the *landwehr* what he was in the standing army—foot-soldier, horseman, or artillerist. Government hires horses for the time of manœuvring, and, as they are well fed and ridden by experienced men, the owners generally like to let out their horses for the occasion. Every Prussian, from his thirtieth year until his fortieth, belongs to the second class of militia. This is not called together in time of peace, and, in war, only in time of the greatest emergency, and then only for local or provincial service. Thus Prussia is enabled to assemble a very large army in proportion to its population, whether to the injury of the nation is a question not to be discussed here.

In regard to the militia of the United States of America, it was provided, by act of congress of 1792, that "all able-bodied white male citizens, between the age of eighteen and forty-five, with certain exceptions (officers of government, members of congress, mariners in service, &c.), shall be enrolled in the militia. The persons so enrolled are to provide themselves with the common arms of infantry, and with ball cartridges, &c., at their own expense. These are arranged into brigades, regiments, companies, &c., as the legislatures of the several states may direct. Each battalion is to have at least one company of grenadiers, light-infantry, or riflemen, and each division at least one company of artillery and one troop of horse. Proper ordnance and field artillery are to be provided by the government of the American states. The cavalry and artillery troops are to consist of volunteers from the militia at large, not exceeding one company to each regiment, and are to equip themselves, with the exception of the ordnance above mentioned. Whenever the United States of America are in danger of actual invasion from any foreign nation or Indian tribe, the president is authorized to call forth such number of the militia of the state or states most convenient to the scene of action as he may judge necessary. In case of an insurrection in any state against the state government, he may, on application from the legislature of such state (or from the executive, when the legislature cannot be convened), call forth such number of the militia of any other state or states as may be applied for, or as he may judge necessary to suppress the insurrection."

MILK; a secretion peculiar to the females of the class *mammalia*, or those animals which feed their young from their teats, and which takes place, in some of them, only during and after the time of gestation. It differs as procured from different animals, but its general properties are the same in all. When this fluid is allowed to stand for some time, it undergoes spontaneous changes, and is resolved into its component parts: a thick yellowish substance collects on the surface, which is *cream*, while the milk beneath becomes thinner than before, and is of a pale bluish colour. When cream is kept for some days without being disturbed, it gradually becomes thicker, till at last it acquires the consistence of cheese; so that one method of making cream-cheese is merely by putting cream into a linen bag, and leaving it there till it becomes solid. When cream is shaken, it is resolved into its component parts. The process by which this is accomplished is called *churning*, by which two substances are obtained, *butter* and *butter-milk*. In the making of butter, cream is allowed to stand for some time, during which an acid is generated. It is then put into a churn and shaken, by which the butter is gradually separated. What is left (the butter-milk) has a sour taste, but by no means so much so as that of the cream before the churning. Butter is sometimes also made from cream which has not become sour, but the process is much more tedious, the acid formed in the other case favouring its separation. Butter is merely an animal oil, solid at a natural heat, but held in solution in milk by some of the other substances. As thus procured, it is not pure, but may in a great measure be freed from its impurities by washing it with cold water; and, though apt to become rancid, yet, when mixed with salt, may be kept any length of time. Milk from which butter has been taken undergoes spontaneous changes. It becomes much sourer, and congeals into a mass of the consistence of jelly. When heated, the fermentation of this coagulum is hastened, and by the addition of certain substances it very soon takes place; thus acids and spirit of wine curdle it, which is owing to the albumen it contains being acted on by them, in the same way as blood or white of eggs. By far the most powerful coagulator, however, is the substance called *rennet*, which is the decoction of the stomach of animals, as a calf. When the milk is previously heated, and rennet added, it is almost instantly coagulated. If after this it is cut, a thinnish fluid oozes from it, and, if it is put into a bag and squeezed, the whole of this is forced out, and a whitish tough matter is left; the former is *whey*, the latter *curd*. On this depends the process of making cheese, which varies in richness according to the mode followed in preparing it. When milk is heated gradually, and merely to the temperature at which it curdles, and the curd freed gently from the whey, it retains almost the whole of the cream, which adds to its richness and flavour. But when it is curdled quickly, and the whey is speedily removed by cutting the curd, a great deal or nearly the whole of the cream is carried off, and the cheese is poor, and has not the rich flavour of that made in the other way. The latter is the method generally followed in Scotland, where both cheese and butter are obtained from milk, the

whey procured in the process yielding a considerable quantity of the latter; and hence the comparative poorness of Scottish cheese. In making cheese, having obtained the curd, and freed it from its whey, the remaining part of the process is merely to subject it to pressure, by which the whole of the whey is forced out, the colour being communicated by the addition of colouring matter: that generally used is annotta, which is mixed with the milk. Whey has a pleasant taste, and contains a considerable quantity of a sweetish substance, called *sugar of milk;* hence it is frequently used as drink, and, from its nutritious quality, it is administered to delicate people; hence also the use of asses' milk, which contains a large quantity of it. It is from its containing this saccharine matter that it is sometimes, as in some of the northern parts of Europe, made to undergo fermentation, by which a very weak spirituous fluid is obtained. By evaporation it affords a minute quantity of saline matter, and a considerable portion of sugar of milk. When whey or milk is exposed to a temperature between 60° and 80° it undergoes a spontaneous change, attended by the production of an acid, which was originally examined by Scheele, and has been termed *lactic acid.*

Mill-stone; the stone by which corn is ground. The mill-stones which we find preserved from ancient times are all small, and very different from those in use at present. Thoresby mentions two or three such found in England, among other Roman antiquities, which were about twenty inches broad; and there is good reason to believe that the Romans, as well as the Egyptians and Jews, did not employ horses, or wind, or water, as we do, to turn their mills, but made their slaves and captives do this laborious work.

In a very picturesque part of Germany, on the banks of the Rhine, and at about five leagues lower down than Coblentz, are situated the very extensive mill-stone quarries of Nieder Mending. They were discovered and opened by the Romans, who long extracted from them stones for the hand-mills, which formed an indispensable part of the equipment of a Roman army. Since then they have been constantly worked more or less; for even the wild hordes of our Saxon ancestors, who also spread over this part of Germany, destroying the dominions of the Romans and avenging their slaughtered and conquered countrymen, were acquainted with the means of grinding corn and bruising malt, and contrived to extract mill-stones from the Roman quarries. At present they are worked to a great extent, and not only supply all the neighbourhood, but are sent down the Rhine into Holland, in great numbers, whence they are again further exported to England, and to the West and East Indies. The sending them down the river forms one great branch of the commerce which is carried on by all the little towns and villages situated on the Rhine in this vicinity, though the little town of Andernach is its principal seat. The mode of conveyance is not expensive, the stones being merely laid on some of the immense rafts of timber which are annually floated down the Rhine, from the upper part of Germany, to supply the industrious Dutchmen with boats, ships, and houses. Numerous small rafts, which come down the little rivers that are lost in the course of the Rhine, are united at Andernach into one great floating forest, and thence, carrying along with it many travellers, as well as a great number of people necessary to manage it, and various heavy substances, the produce of Germany, this forest descends into Holland, to be again broken up and distributed, and, when converted into ships, destined to bear the produce of one quarter of the globe to the other.

The principal quarries are situated in a plain called *Hacher*, about half a mile from the village of Nieder Mending. They are seven in number, about fifty feet deep each, and employ a great many hands: while some are raising the ponderous stones to the surface by means of cranes and wheels, others are cutting them, a third class are piling them up, and a fourth are loading the vehicles which are to carry them away. An opening is made into all these quarries in the same manner, which is curious, not only in itself, but from the long time it has been practised. The strata from which the mill-stones are cut lies fifty feet below the surface, and it is difficult to imagine how it was first discovered. To arrive at it a shaft is sunk of the shape of an inverted cone, or of a funnel, being twenty-five feet in diameter at the top, eleven or twelve feet diameter at the bottom, and fifty feet deep. Around the sides a very narrow spiral path is made, by which the workmen descend, and even children run down and up for their amusement. It is customary for five or six families to unite their labours to sink such a shaft, and with time and much hard work they are thus enabled to reach the stones, which are the means of supplying them with both meat and clothing. The earth through which they have to dig is formed partly of gravel and partly of large masses of a compact lava, which, however, it requires no very extraordinary force to break through. Arrived at the depth of fifty feet, a hard, blackish, heavy stone is met with, full of small, but regular pores, which gives a few sparks when struck with steel, but is not at the same time so hard but that the workmen can fashion it to their will, with strong and well-tempered tools. Mineralogists describe this stone as a sort of lava, or like the melted mass which flows down burning mountains, and suppose it to have been produced by those subterraneous fires which once perhaps were the means of effecting a great change over all the surface of the globe, and which still exist in various places. They suppose that it extends at least all over the plain already mentioned; but, never having as yet been dug through, its thickness has not been ascertained. Were this stone solid throughout its whole extent, it would have been nearly impossible to work it; but, on cooling, it had separated into numerous masses of a prismatic form, which enable the labourers to interpose wedges or levers, and break off pieces large enough to make mill-stones of five or six feet in diameter. So many of these have now been taken away that immense galleries have been cleared out, which, separated from each other by the prismatic columns left standing to support the roof, like stalactites in an artificial cavern, have a resemblance to the most ancient of our Gothic cathedrals. Every thing in them seems vast and grand, except the beings so insignificant in appearance at the side of these enormous pillars, by whose labours, however, they have been brought to light, and can be crumbled to dust.

Mill-stones have been made so large in this country that the centrifugal force which results from their rotatory motion has been known to tear them asunder. The ancient mill-stones, on the contrary, where so small that they could readily be carried by a single individual.

The mill-stones employed in Tuscany differ from those used in this country: indeed, on account of their great superiority of form, it may be advisable to describe them somewhat in detail. The size of the mill-stone used for the most powerful mills, as well as for those of inferior strength, is a circle of four feet; the size of the eye is about seven inches. The face of the upper stone is hollowed to a conical surface, the depth or height being about one-inch and a half. The face of the lower stone is convex; the surface is nearly a portion of a sphere, having a radius of thirty feet, so that a distance of about an inch is left between the centre of the two faces. A deep socket is let into the upper stone, or runner, for the reception of the iron nut, placed on the square of the spindle. The runner is balanced, and rendered parallel to the convex or bed stone, by means of four small wooden wedges, two on each side, between the nut and the socket.

They profess to cut the teeth in the form of the hyperbolic spiral; but, being cut without any great regard to mathematical precision, they are usually portions of circles, the place of whose centres are in the circumference of a circle of fourteen inches radius, described from the centre of the stone. In general, the teeth are as close as possible to each other; but near the eye they are fewer, deeper, and coarser.

The tool employed to cut the teeth is a double edge hammer, four inches wide, very sharp, and weighing about 12lbs. When the stones are new from the quarry, a few days are sufficient for this operation: and, when they have been already in use, any able miller's man will complete it in twenty minutes. The real grinding surface is the six or eight inches next the circumference of the stone.

The flour produced varies in colour, according to the nature of the stones employed.

When the upper stone, or runner, is made of diallage rock, consisting of crystals of diallage imbedded in nearly compact felspar (both of which are so soft as to yield without much difficulty to the knife, and yet always preserve a sufficient degree of roughness, even after long-continued friction), the face of the stone being made perpendicular to the plane of the bed of the rock, and the bed, or lower stone, made of a compact porcellanous limestone, of a pale flesh colour, softer than the diallage rock, the stones are applied to the grinding of the finer wheat, the combination of the hard and soft stone being well adapted to grind the central parts of the grain into fine flour, leaving the bran broad and clean; and it is difficult, even by coarse sifting, to give a brown tinge to bread made of this flour.

When both stones are made of a granular talcase quartz, with garnet imbedded in it, the mill is used for grinding the coarser and harder kinds of corn. These stones grind almost the whole of the grain exposed to their action; so that the quantity of bran that remains after sifting is extremely small; hence this mode of grinding is essentially economical. However carefully the flour produced by these mills may be sifted, the bread it produces, although very wholesome and agreeable, is always dark-coloured, and sometimes almost a black.

This system of grinding used in Italy differs greatly from that of the English millers, and possesses considerable advantages over our method.

In England the hardest French buhrs are used for both stones; the grinding surfaces are flat and parallel to each other, and the teeth in right lines: hence the grinding is partly performed by rubbing, and partly by cutting, so that the bran is more or less torn, and part of it, being ground as fine as the flour itself, is not separable by dressing or bolting, and injures the colour. The friction of the stones also excites considerable heat, so that the meal comes out warm to the touch, and is sometimes so much heated as to be incapable of making light bread.

In Italy, for fine flour, hard and soft stones being combined, the difficulty is overcome much more readily, since white flour is produced by means of the same dressing which, when applied to two hard stones, produces brown flour. The upper stone is far from hard, and the lower is still softer; the teeth are very shallow, but their form is such as to impel the grain towards the circumference, where the distance between the stones is continually lessening, so that the grain appears to be ground by friction, without any cutting of the bran, especially as the corn is soft, from its dampness; hence the flour is not liable to be overheated, and, the bran being separated almost wholly by the first sieve, the flour is pure.

Mill-Work. Under this head we purpose noticing the simplest combinations of wheel work which are employed in the construction of mills, and, under the articles Wind and Water Mills, complete views, both graphic and descriptive, will be given of their construction.

The business of a millwright is usually combined with the practical part of engineering, and much of the wind and water power formerly employed in giving motion to machinery is now superseded by the introduction of the steam-engine. Indeed, without the agency of steam-power, this country could in no shape compete with other manufacturing nations; so that, on account of the great importance of the steam-engine as a prime mover, it will be advisable to devote a commensurate space to its illustration.

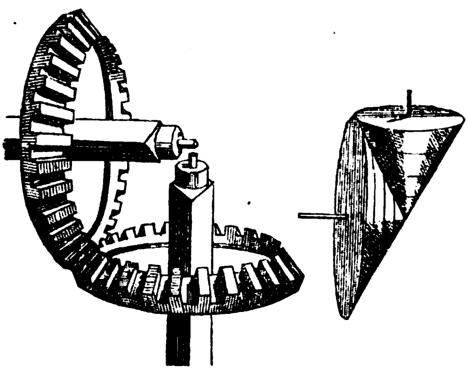
Various are the methods by which motion may be communicated from one part of a machine to another; and much of the skill of the millwright consists in his adapting certain methods to his particular purposes. Sometimes a simple cord, or a cord with pulleys, may be used. Levers, either simple or combined, are employed to communicate and also change the direction of the motion. Rods also are employed, which may be carried to a great distance by being connected together. But, of all the methods of communicating motion, that by means of wheels is the most frequent. Wheels may be made to turn each other even by the simple contact of their surfaces when pressed together; or their circumferences may be formed into brushes with short thick hair, which enable them to turn each other with considerable force; or they may have cords, or straps of leather, or chains, passing from one to another; and at other times there are points or protuberances on the rims of the wheels. The most usual method, however, of making wheels drive each other is by means of teeth. These are either cut into the substance of which the wheel is composed, when it is of metal; or formed at the same time as the rest of the wheel, when it is cast.

The proper method of shaping the teeth of wheels, so as to communicate the motion equally, and with as little friction as possible, is a matter of very great nicety, and has given rise to much study among mechanics. The ends of the teeth should be curves,

but not parts of complete circles. They may be formed of the curve called the epicycloid; or of the involutes of circles, which are curves described by a point of a thread which has been wound round the wheel while it is uncoiled.

A wheel which has teeth cut upon the circumferences, so as to project out in the plane of its face, is called a spur wheel; and, when the projection of the teeth is at right angles to the face of the wheel and parallel to the axis, the wheel is called a crown or contrate wheel. Sometimes the faces of the two wheels are in the same plane, and consequently the axes parallel; and at other times the axes are at right angles to each other, one being a spur and the other a contrate wheel.

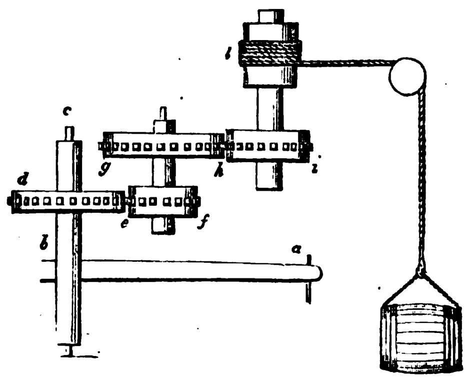
There is a mode of placing the teeth frequently resorted to, which consists in levelling the edge of the wheel, and cutting the teeth on the bevel, by which they may turn in each other, though variously inclined, and the teeth have also great strength. Their principle consists in two cones rolling on the surface of each other, as in the accompanying small engraving; if their bases are equal, they will perform their revolutions in one and the same time.



If the cones are fluted, or have teeth cut in them diverging from the centre, they are then called *bevel geer*. The teeth may be made of any dimension, according to the strength required; and it is of great use to communicate a motion in any direction, or to any part of a building. The bevel geer represented in the left-hand figure must be supported by a frame at the point where the pivots intersect each other. The frame is usually formed of iron or wood, and when the latter is employed the pivot-hole is of brass. The perpendicular shaft should always be made to revolve on a sharp point in the centre.

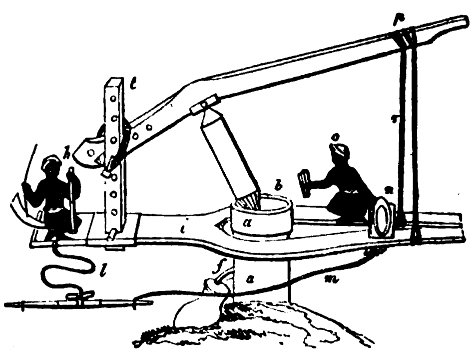
Hook's universal Joint, described under that article, may be applied to communicate motion instead of bevel geer, where the speed is to be continued the same, and where the angle does not exceed thirty or forty degrees and the equality of motion is not regarded; for, as it recedes from a right line, its motion becomes very irregular. This joint may be constructed by a cross, or with four pins fastened at right angles upon the circumference of a hoop, or solid ball. It is of great use in cotton mills, where the tumbling shafts are continued to a distance from the moving power.

The employment of animal power in the simplest species of mill-work may be well illustrated by the accompanying sketch, in which a horse may be attached to a long lever, and thus made to raise a weight by a train of wheels and pinions.



The weight to be raised is suspended by a rope or chain which winds round the drum *l*. On the same axis is placed a wheel, *i*, actuated by another wheel, *g h*. The wheel *d e* gives motion to the whole by the intervention of the small wheel at *f*. A horse at *a* may be considered as the prime mover, as the lever *a b* is on the axis *c*. Now, in this apparatus, there is a loss of power, but a gain in velocity.

The various modes of constructing mills for domestic as well as manufacturing processes will be explained hereafter, and we now purpose confining ourselves to a single example of the mode of employing animal power in a way which, from its simplicity, might be adopted to a great extent in this country. There is a mill of a cheap and effective kind used in many parts of the East, which appears to have suggested the use of the ordinary snuff-mill. Indeed, it is, in some respects, superior to it. This mill, which is employed in the preparation of sugar, consists of a mortar, beam, lever, pestle, and regulator, as represented in the engraving beneath:—



The mortar, *a a*, is a tree about ten feet long, and fourteen inches over, which is sunk in the earth, so as to leave about two feet above ground. At the top is formed a conical cavity like a funnel, which ends in a hollow cylinder, with a hemispherical projection at the bottom, in order to allow the juice to run freely to the small opening that conveys it to a spout, *f*,

from which it runs into an earthen pot. Round the upper mouth of the mortar is a circular cavity, *b*, which serves to collect any of the juice that may run over from the upper end of the pieces of cane. A channel is cut to convey this juice down the outside of the mortar to the spout, *f*.

The beam, *i*, is about 16 feet long, and six inches thick, and is cut from any large tree that is divided by a fork into two arms A hollow circle is made in the fork for the mortar, round which the beam turns horizontally: the surface of this excavation is secured by a semicircle of some strong wood; the other end of the fork is left quite open, in order that the beam may be changed without any trouble. The bullock driver sits on the undivided end, to which the cattle are yoked by a rope, *l*, from his end of the beam; and they are kept in the circular tread by another rope, *m*, which passes from the yoke to the forked end of the beam. A basket, *n*, is placed upon the forks to hold the cuttings of the cane, and the man, *o*, who feeds the mill, sits between this basket and the mortar. He takes care to place the pieces of cane sloping down the cavity of the mortar, just at the time that the pestle comes round; and, after the pestle has passed, he removes those which have been squeezed.

The lever, *p*, is a piece of timber nearly as long as the beam. The thickest end, which is also the lowest, is connected with the undivided end of the beam by means of a regulator, *t*. A little way from the place where it is joined to the regulator, a piece of very hard wood is morticed into the lower side of the lever, and a smooth conical hollow is made in this piece, to receive the head of the pestle. The end of the lever furthest from the regulator is fastened by two ropes to the two arms of the beam.

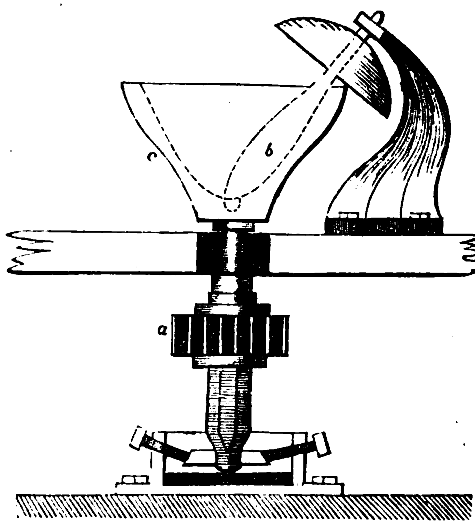
The pestle is a strong cylindrical piece of timber, cut to a point at each end. The upper end is a smooth cone, the lower end a piramid of twelve to fifteen sides, at the point of which is a short cylinder. As the pestle is placed obliquely, it rubs strongly against the sides of the mortar as it passes round; and its cylindrical point rubs also on the top of the hemispherical projection, *d*, which is in the bottom of the cavity of the mortar.

The regulator, *t*, is a strong square of timber, which passes through the undivided end of the beam, and is secured below it by part of its circumference being left for cheeks. It is pierced by eight holes, and a pin is placed in the lowest hole, to prevent the regulator from falling when the strain is removed.

The canes with which the mill is supplied are cut into pieces, six inches long. The mill goes night and day during crop time, and presses about fifty-six pots or 218 gallons of juice in that time. Two bullocks are used at a time, and, as they are driven very fast, they are changed every time three pots of juice are expressed, and work no more that day.

In the manufacture of snuff in this country, the grinding is performed by a loaded pestle, made to turn round as it rubs against the sides of a cast-iron mortar, the pointed lower end of the pestle being retained in its place by a hole at the bottom of the mortar. In large manufactories, a number of these mortars are placed in a circle, having a large toothed wheel in the centre, surrounded by as many upright spindles with pinions to work in the wheel.

Mr. Gill has proposed an improvement on this plan, which is represented beneath.



The mortar, *c*, is in this arrangement made to revolve, and the pestle, *b*, is supported by a bracket firmly attached to the beam beneath. The pinion, *a*, rests on a conical axis, and communicates, as in the old arrangement, with the principal driving wheel.

Water-mills are of three kinds:—*breast-mills*, *undershot-mills*, and *overshot-mills*, according to the manner in which the water is applied to the great wheel. In the first, the water falls down upon the wheel at right angles to the *float-boards*, or bucket, placed to receive it. In the second, which is used where there is no fall of water, the stream strikes the float-boards at the lower part of the wheel. In the third, the water is poured over the top, and is received in buckets arranged round the wheel.

A less quantity of water will turn an overshot-mill (in which the wheel has buckets instead of float-boards) than a breast-mill, where the fall of water seldom exceeds half the height of the wheel; so that, when there is but a small quantity of water, and a fall great enough for the wheel to lie under it, the bucket, or overshot-wheel, is always used: but, where there is a large body of water with a small fall, the breast or float-board must be used. Where the water runs only upon a small declivity, it can act but slowly upon the under part of the wheel, in which case the motion of the wheel will be slow; and therefore the floats ought to be very long, that a large surface of water may act upon them, so that what is wanting in velocity may be made up in power; and then the cog-wheel may have a greater number of cogs in proportion to the rounds in the trundle, in order to give the mill-stone a sufficient degree of velocity.

It was the opinion of Smeaton that the powers necessary to produce the same effect on an undershot-wheel, a breast-wheel, and an overshot-wheel, must be to each other as the numbers 2.4, 1.75, and 1.

Wind, which we may consider as the next substitute for animal power, appears to have been first employed to give motion to machinery in the beginning of the sixth century. The use of this species of

mechanical force is however principally limited to the grinding of corn, the pressing of seed, and other simple manipulations, the great irregularity of this element precluding its application to those processes which require a continued motion.

A windmill with four sails, measuring seventy feet from the extremity of one sail to that of the opposite one, each being six feet and a half in width, is capable of raising 926 lbs. 232 feet in a minute, and of working on an average eight hours per day. This is equivalent to the work of thirty-four men, twenty-five square feet of canvass performing the average work of a day labourer. A mill of this magnitude seldom requires the attention of more than two men; and it will thus be seen that, making allowance for its irregularity, wind possesses a decided superiority over every species of animal labour.

The following very important errors have frequently been made by mathematicians and practical mechanics, in the estimation of the force of the wind or the water on oblique surfaces; they have generally arisen from inattention to the distinction between pressure and mechanical power. It may be demonstrated that the greatest possible pressure of the wind or water, on a given oblique surface at rest, tending to turn it in a direction perpendicular to that of the wind, is obtained when the surface forms an angle of about 55° with the wind; but that the mechanical power of such a pressure, which is to be estimated from a combination of its intensity with the velocity of the surface, may be increased without limit by increasing the angle of inclination, and consequently the velocity. The utmost effect that could be thus obtained would be equal to that of the same wind or stream acting on the float-boards of an undershot-wheel: but, since in all practical cases the velocity is limited, the effect will be somewhat smaller than this: for example, if the mere velocity of the sails or float-boards be supposed equal to that of the wind, the mechanical power will be more than four-fifths as great as that of an undershot-wheel; that is, in the case of a windmill, more than four-fifths of the utmost effect that can be obtained from the wind. In such a case Maclaurin has shown that the sails ought to make an angle of 74° with the direction of the wind: but in practice it is found most advantageous to make the angle somewhat greater than this, the velocity of the extremities of the sails being usually, according to Mr. Smeaton, more than twice as great as that of the wind. It appears, therefore, that the oblique sails of the common windmill are in their nature almost as well calculated to make the best use of any hydraulic force as an undershot-wheel; and, since they act without intermission throughout their whole revolution, they have a decided advantage over such machines as require the sails or fans to be exposed to a more limited stream of the wind during one half only of their motion, which is necessary in the horizontal windmill, where a screen is employed for covering them while they are moving in a direction contrary to that of the wind: and such machines, according to Smeaton, are found to perform little more than one-tenth of the work of those which are more usually employed. The sails of a common windmill are frequently made to change their situation according to the direction of the wind, by means of a small wheel with sails of the same kind, which turns round whenever the wind strikes on either side of it, and drives a pinion turning the whole machinery; the sails are sometimes made to furl or unfurl themselves according to the velocity of the wind, by means of a revolving pendulum, which rises to a greater or less height, in order to prevent the injury which the flour would suffer from too great a rapidity in the motion, or any other accidents which might happen in a mill of a different nature. The inclination of the axis of a windmill to the horizon is principally intended to allow room for the action of the wind at the lower part, where it would be weakened if the sails came too nearly in contact with the building, as they must do if they were perfectly upright. When it is necessary to stop the motion of a windmill, a break is applied to the surface of a large wheel, so that its friction operates with a considerable mechanical advantage.—*Partington's Scientific Gazette.*

MINA, among the Greeks; a weight of a hundred drachmæ: also a piece of money valued at a hundred drachmæ; sixty of them were equivalent to a talent.

MINARET; a round tower, generally surrounded with balconies, and erected near the mosques in Mohammedan countries, from which the *muezzin* summons the people to prayer, and announces the hours, bells, as is well known, not being in use among the Mohammedans. (See MOSQUE.)

MINE, in *military language;* a subterraneous passage dug under the wall or rampart of a fortification, or under any building or other object, for the purpose of blowing it up with gunpowder. The gunpowder is in a box, and the place where the powder is lodged is called the *chamber* (in French, *forneau*). The passage leading to the powder is termed the *gallery;* the line drawn from the centre of the chamber perpendicularly to the nearest surface of the ground is called the *line of least resistance.* It has been found, by experience, that the figure produced by the explosion is a paraboloid, and that the centre of the powder, or charge, occupies the *focus.* The pit or hole made by springing the mine is called the *excavation.* The fire is communicated to the mines by a pipe, or hose, made of coarse cloth, whose diameter is about 1½ inch, called a *saucisson* (for the filling of which nearly half a pound of powder is allowed to every foot), extending from the chamber to the entrance of the gallery, to the end of which is fixed a match, that the miner who sets fire to it may have time to retire before it reaches the chamber. The saucisson is laid in a small trough, called an *augut,* to prevent it from contracting any dampness. This is made of boards. The mine of a fortress is called a *countermine,* the gallery of which runs under the covered way along the outer margin of the fosse. From this, ramifications, called *rameaux,* extend under the glacis, from which again little passages are made on both sides, to afford means for listening to and finding out the enemy's subterraneous movements. If the powder is lodged so deep under ground that its explosion is not perceptible on the surface, it yet shakes the ground all around, and destroys the hostile mines in the neighbourhood. This is the *globe de compression,* invented by Belidor.

The miners are often armed with short weapons, as pistols and cutlasses, in order to defend themselves, if they meet a hostile mine. The mines are often so long that it is necessary to convey fresh air by artificial means to the most advanced workmen,

and those who are faint are passed back from one to the other; the same is done with the dead, if a combat ensues below. Frequently, also, balls, made of all kinds of substances which produce an offensive smoke, are lighted, in order to stop the enemy, provided the mine permits the party who leave the ball an easy retreat. Sometimes mines are dug in the field, with a view of blowing up such of the enemy as can be allured to the spot. In such case, a small body of men must generally be placed there, in order to induce the enemy to attack them; these are sometimes sacrificed with the enemy.

Mining; the process for obtaining minerals from the bowels of the earth. Mines are vast underground works, furnished with galleries which frequently extend for miles from the entrance of the shaft or well. Light is constantly procured from artificial sources, and in some mines the dull glimmer of the "Davy lamp" is the only substitute for the cheerful rays of the sun. Vegetation assumes a new character, so that plants lose their colour, and in most cases their ordinary flavour. The miner is at one time exposed to an atmosphere which forbids any thing like healthful respiration, and at another the destructive fire blast comes on the wings of the wind ready charged for his destruction. The best means of averting these dangers will be found under our articles Ventilation and Safety Lamp. The minerals are found in veins, strata, or lumps, and contain gold, silver, platina, quicksilver, lead, iron, copper, tin, zinc, calamine, bismuth, cobalt, arsenic, manganese, antimony, molybdena, and other metallic substances; also sulphur, brown-coal, pit-coal, bitumen, alum, and all combinations of sulphuric acid with metallic bases. The mines are generally denominated from the substances obtained from them; for instance, gold, silver, iron, lead, coal, alum, salt mines, &c. We must distinguish, 1. the mines in primitive mountains: 2. those in flœtz mountains; 3. those in alluvions. Of the first sort the most important are the following:—

1. The mines in the Cordilleras in Spanish America. There are few regions so remarkable for their richness in minerals as this chain of mountains. The most important mines are those of silver; yet there are also several gold, quicksilver, copper, and lead mines. In Chili, especially in the province of Coquimbo, are several silver and some important copper mines. The richness of the silver mines of Potosi (Buenos Ayres) may be judged of from the fact that more than 1300,000,000 of dollars have been coined there since the year 1545; but the ores are now poor. Copper, lead, and tin are also found in Buenos Ayres, the last, however, in beds of sand or clay, from which it is obtained by washing. On the opposite side of the chain, in a low plain, are the silver mines of Guantajaya, famous for the large lumps of solid silver which they formerly furnished, and of which one weighed 800 lbs. In Peru, there are forty districts particularly celebrated for their gold and silver mines. Gold is found especially in the provinces of Guailas and Pataz, and silver in the districts of Guantajaya, Pasco, and Chota. The mines of Pasco, which twenty years ago produced more than two millions of dollars yearly, had been, like most of those of South America, very negligently managed, till, in 1816, miners from Cornwall began to work them by means of steam-engines.

The mines of the province of Chota now furnish about 42,000 lbs. troy of silver every year. The quicksilver mine of Guancavelica, in Peru, is the only one of this kind in the new world. In the province of Guantajaya, rock-salt mines are also found. North of the province of Chota, the Cordilleras are not so rich in metals.

In New Grenada there are several silver mines; at Aroa, in Caraccas, a copper mine exists, which yields 1600 cwt. of metal yearly; and at Santa Fe rock-salt and pit-coal are found. Although Mexico contains various metals, very little except silver has been obtained from that country. Almost all the mines are situated in the Cordilleras, and consist of 3000 pits, which comprise from 4000 to 5000 beds or layers.

The only mine in Mexico in which pumps of any kind had been tried prior to the late introduction of machinery from England is that of Moran, in the district of Rëal del Monte; of which M. Humboldt gives the following account:—

The mountains of the district of mines of Rëal del Monte contain beds of porphyry, which, with respect to their relative antiquity, differ a good deal from one another. The rock which forms the roof and the wall of the argentiferous veins is a decomposed porphyry, of which the base sometimes appears clayey, and sometimes analogous to splintery hornstone. The presence of hornblende is frequently announced merely by greenish stains, intermingled with common and vitreous feldspar. At very great elevations (for example, in the beautiful forests of oak and pine of Oyamel), we find porphyries with a base of pearl-stone containing lobsidian in layers and nodules.

What relation exists between these last beds, which several distinguished mineralogists consider as volcanic productions, and the porphyries of Pachuca, Rëal del Monte, and Moran, in which nature has deposited enormous masses of sulphuret of silver and argentiferous pyrites. This problem, which is one of the most difficult in geology, will be resolved only when a great number of zealous and intelligent travellers shall have gone over the Mexican Cordilleras, and carefully studied the immense variety of porphyries which are destitute of quartz, and which abound both in hornblende and vitreous feldspar.

The district of mines of Rëal del Monte does not display (as at Friberg in Saxony, Derbyshire in England, or the mountains of Zimapan and Tasco in New Spain) a great number of rich veins of small size, on a small tract of ground. It rather resembles the Hartz and Scheminitz mountains, in Europe, or those of Guanaxuato and Potosi, in America, of which the riches are contained in a few mineral depositions of very considerable dimensions. The four veins of Biscaina, Rosario, Cabrera, and Encino, run through the districts of Rëal del Monte, from Moran, and Pachuca, at extraordinary distances, without changing their direction, and almost without coming in contact with other veins which traverse or derange them.

The Veta de la Biscaina, of less considerable dimensions, but perhaps still richer than the vein of Guanaxuato, was successfully wrought from the beginning of the sixteenth to the eighteenth century. In 1726, and 1727, the two mines of Biscaina and Xacal still produced together 333,969 ounces of silver. The great quantity of water which filtrated through the

crevices of the porphyritic rock, joined to the imperfection of the means of drawing it off, compelled the miners to abandon the works when they were yet only sixty-five fathoms in depth. A very enterprising individual, Don Joseph Alexandro Bustamente, was courageous enough to undertake a level near Moran; but he died before completing this great work, which is 7715 feet in length from its mouth to the point where it crosses the vein de la Biscaina. The level of Moran traverses the vein de la Biscaina, in the San Ramon shaft, at a depth of 115 fathoms below the level of the surface on which the whims are placed. The profit of the proprietors has been annually diminishing since 1774. In place of driving levels for trial, to discover the vein on a great extent, they continued their sinking to a depth of nearly fifty-three fathoms below the level. At that depth the vein preserved its great wealth in sulphuret of silver mixed with native silver; but the abundance of water increased to such a degree that twenty-eight whims, each of which required more than forty horses, were not sufficient to draw it off. In 1783, the weekly expenses amounted to 1875*l.* After the death of the old Count de Regla, the works were suspended till 1791, when the proprietors ventured to re-establish all the whims. The expense of these machines, which drew up the water, not by means of pumps, but by bags suspended by ropes, then amounted to more than 31,252*l.* per annum. At length they reached the deepest point of the mine, which, according to accurate measurement, is only 1064 feet above the level of the lake of Zumpango; but the ore which they extracted did not compensate the expense of the process, and the mine was again abandoned in 1801.

It is surprising that they never thought of substituting foı this wretched plan of drawing off the water by bags proper pump apparatus, put in motion by horse whims, by hydraulic wheels, or by machines moved by a column of water (colonne d'eau). A level begun at Pachuca, or lower down towards Gazare in the valley of Mexico, would have exhausted the mine of Biscaina at the pit of San Ramon, for a depth of 202 fathoms. The same object could be obtained at less expense by following the project of M. D'Elluyar, in placing the mouth of a new level near Omitlan, in the road which leads from Moran to the place of amalgamation at Regla. This last level, before reaching 12,466 feet in length, would cut the vein of Biscaina.

The plan which is at present followed is to leave off the clearing of the old works, and to investigate the mineral repository in points where it has never yet been worked, and this is effected by boring. In studying at Reäl del Monte the surface and undulations of the ground, we observe that the vein of Biscaina has furnished for three centuries its greatest riches from a single spot; that is to say, from a natural hollow contained between the shafts of Delores, Joya, Santa Cayetano, San Teresa, and Guadaloupe.

The mines of Moran, formerly of great celebrity, were abandoned for forty years on account of the abundance of water, which could not be drawn off. In this district of mines, which is near the mouth of the great level of Biscaina, there was placed in 1801 a machine *à collonne d'eau,* of which the cylinder is ten feet three inches in height, and six feet nine inches in diameter. This machine, the first of the kind ever constructed in America, is much superior to those of the mines of Hungary. It was executed agreeably to the calculations and plans of M. del Rio, professor of mineralogy in Mexico, who has visited the most celebrated mines of Europe, and who possesses at once the most solid and most various acquirements. The merit of the execution is due to M. Lachansee, a Brabant artist of great talents, who has also fitted up for the school of mines of Mexico a very remarkable collection of models, for the use of students in mechanics and hydrodynamics. It is to be regretted that this fine machine, in which the regulator of the suckers is put in motion by a particular mechanism, was placed in a situation where there is great difficulty in procuring a sufficiency of water to keep it going. M. Humboldt says that, when he was at Moran, the pumps could work only three hours a day. The construction of the machine and the aqueducts cost 10,937*l.* sterling: they did not at first calculate on more than half the expense, and they imagined the mass of water to be very considerable; but, the year in which the water was measured being exceedingly rainy, it was believed to be much more abundant than it actually was.

The benefits described as being conferred on the mining districts by putting their industry in motion were thus justly anticipated in the report of Don Lucas Alaman, minister for foreign affairs, dated November 1, 1828.

"It is a principle admitted by all writers on political economy that the most direct encouragement which can be given to agriculture and to industry is to facilitate the consumption of the produce of the one and the sale of the manufactures of the other. If the mines be considered amongst us under this point of view, it will be found that nothing contributes so much as they do to the prosperity of those essential branches of the public riches. The great number of people that are occupied in them, the animals that are employed in the working of the machinery and in transporting the ores, the consumption that arises therefrom of grain, as well as of soap, paper, iron, &c., give a powerful impulse to agriculture, the arts, and to commerce. If practical illustration be necessary to prove those facts which are doubted only by men whose minds are pre-occupied by the paradoxical assertions of systematic economists, they may be found on a comparison of the state of our mining provinces, such as Guanaxuato and Zacatecas, previous to the year 1810 and at the present period. Abundance and prosperity then reigned throughout both of them. The agriculturist found in those famous reales (districts) a ready and certain market for his produce; the smith, the carpenter, the mason, a constant employment for his industry; the merchant an extensive consumption for the goods which he introduced; and the treasures drawn from the bowels of the earth were distributed throughout, and revivified the most distant provinces, in payment for the soap, wood, salt, magistral, horses, and mules, that were brought from all parts. The nature of our ores is also a powerful cause of these happy results: they are generally poor in metal, and most abundant in quantity, and require for their manufacture a great quantity of machinery and ingredients; and it may therefore be said that the miner merely draws forth funds to distribute them freely among the labourers, merchants, and artisans; and we must naturally conclude that the prosperity of these classes depends principally upon the impulse given to them by the

mines, which in our notion are thus the acting principle of all the other branches of industry."

In America gold is principally obtained by washing. The principal gold-washings are on the western side of the Cordilleras; in New Grenada, from the province of Barbacoa to the isthmus of Panama; in Chili and on the shores of the Gulf of California; or on the eastern side in the upper valleys of the Amazon. The washings of New Grenada also furnish platina.

2. The mines of Hungary, including those of Transylvania, and of the Bannat of Temeswar, compose four great districts:—*a*. the north-western, which includes the mines of Schemnitz, Kremnitz, Kœnigsberg, Neusohl, Schmœlnitz, Bethler, Rosenau, &c., which chiefly furnish gold, silver, copper, lead, &c.;—*b*. the north-eastern, containing the mines of Nagybanya, Kapnick, Felsœbanya, Wizbanya, Olaposbanya, and Olapos, which all yield gold, besides the mines of Marmarosch, which furnish great quantities of iron;—*c*. the eastern district, in which the mines of Nagyag, Korosbanya, Vœrœspatak, Boitza, Csertesch, Fatzsbay, Almas, Porkura, Botschum, and Stonischa, deserve notice, which chiefly furnish gold and copper; near Vayda-Huniad and Gyalar are important iron-mines;—*d*. the south-western district, or the mines of the Bannat of Temeswar, yield silver and copper in Oravitza, Moldawa, Szaska, and Dognaczka; while in Dombrawa, and Ruchersberg, iron, quicksilver, and cobalt, are obtained. Hungary contains also mines of pit-coal and rock-salt, the latter especially on the banks of the Danube, the Marmarosch, and the Nera. The whole produce of Hungary amounts to 3250 lbs. troy of gold, 53,125 lbs. troy of silver, from 36,000 to 40,000 cwt. of copper, 8000 cwt. of lead, and about 60,000 cwt. of iron.

The interior of an Hungarian mine, of which a view is given in the above engraving, differs very much from that of the mines in this country. Vast chasms provided with inclined planes take the place of the shafts and galleries in our underground works.

Dr. Clarke thus describes his descent of the Presburg mine, his visit to which was made after he had personally inspected many of the principal works of the same nature in other countries, and especially in his own:—

"As we drew near to the wide and open abyss, a vast and sudden prospect of yawning caverns, and of prodigious machinery, prepared us for the descent. We approached the edge of the dreadful gulf whence the ore is raised, and ventured to look down, standing upon the verge of a sort of platform, constructed over it in such a manner as to command a view into the great opening, as far as the eye could reach amidst its gloomy depths; for to the sight it is bottomless. Immense buckets, suspended by rattling chains, were passing up and down; and we could perceive ladders scaling all the inward precipices, upon which the work-people, reduced by their distance to pigmies in size, were ascending and descending. Far below the utmost of these figures, a deep and gaping gulf, the mouth of the lowermost pit, was, by its darkness, rendered impervious to view. From the spot where we stood, down to the place where the buckets are filled, the distance might be about seventy-five fathoms; and, as soon as any of these buckets emerged from the gloomy cavity we have mentioned, or until they entered it in their descent, they were visible, but beyond this point they were hid in darkness.

"The clanking of chains, the groaning of the pumps, the hallooing of the miners, the creaking of the blocks and wheels, the trampling of horses, the beating of the hammers, and the loud and frequent subterraneous thunder from the blasting of the rocks by gunpowder in the midst of all this scene of excavation and uproar, produced an effect which no stranger could behold unmoved: we descended, with two miners and our interpreter, into this abyss. The ladders, instead of being placed like those in our Cornish mines upon a series of platforms, as so many landing-places, are lashed together in one unbroken line, extending many fathoms, and warped so as to suit the inclination or curvature of the sides of the precipices: they are not always perpendicular, but hang over in such a manner that, even if a person held fast by his hands, if his feet should happen to slip, they would fly off from the rock and leave him suspended over the gulf; yet such ladders are the only means of access to the works below,—and, as the labourers are not accustomed to receive strangers, they neither use the precautions, nor offer the assistance, usually afforded in more frequented mines. In the principal *tin* mines of Cornwall, the staves of the ladders are alternate bars of wood and iron: here they were of wood only, and in some parts rotten and broken, making us often wish, during our descent, that we had never undertaken an exploit so hazardous. In addition to the danger to be apprehended from the damaged state of the ladders, the staves were covered with ice or mud, and thus rendered so cold and slippery that we could have no dependence upon our benumbed fingers, if our feet failed us. Then, to complete our apprehensions, as we mentioned this to the miners, they said, —'Have a care! It was just so,' talking about the staves, 'that one of our women fell, about four years ago, as she was descending to her work.' 'Fell!' said our Swedish interpreter, rather simply, 'and

pray what became of her?' 'Became of her!' continued the foremost of our guides, disengaging one of his hands from the ladder, and slapping it against his thigh, as if to illustrate the manner of the catastrophe,—'*she became* (pantaker) a pancake.'

"As we descended further from the surface, large masses of ice appeared, covering the sides of the precipices. Ice is raised in the buckets with the ore and rubble of the mine: it was also accumulated in such quantity in some of the lower chambers that there are places where it is fifteen fathoms thick, and no change of temperature above prevents its increase."

This seems to militate against a notion now prevailing, that the temperature of the air in mines increases directly as the depth from the surface, owing to the increasing temperature of the earth under the same circumstances and in the same ratio; but it is explained by the width of the aperture at the mouth of the mine, which admits a free passage of atmospheric air. In our *Cornish* mines, ice would not be preserved in a solid state at any considerable depth from the surface.

"After much fatigue, and no small share or apprehension, we at length reached the bottom of the mine. Here we had no sooner arrived than our conductors, taking each of us by an arm, hurried us along, through regions of 'thick-ribbed ice' and darkness, into a vaulted level, through which we were to pass into the principal chamber of the mine. The noise of the countless hammers, all in vehement action, increased as we crept along this level; until, at length, subduing every other sound, we could no longer hear each other speak, notwithstanding our utmost efforts. At this moment we were ushered into a prodigious cavern, whence the sound proceeded; and here, amidst falling waters, tumbling rocks, steam, ice, and gunpowder, about fifty miners were in the very height of their employment. The magnitude of the cavern, over all parts of which their labours were going on, was alone sufficient to prove that iron ore is not deposited in veins, but in beds. Above, below, on every side, and in every nook of this fearful dungeon, glimmering tapers disclosed the grim and anxious countenances of the miners. They were now driving bolts of iron into the rocks, to bore cavities for the gunpowder, for blasting. Scarcely had we recovered from the stupefaction occasioned by our first introduction into this *Pandemonium*, when we beheld, close to us, hags more horrible than perhaps it is possible for any other female figures to exhibit, holding their dim quivering tapers to our faces, and bellowing in our ears. One of the same sisterhood, snatching a lighted splinter of deal, darted to the spot where we stood, with eyes inflamed and distilling rheum,—her hair clotted with mud; and such a face, and such hideous yells, as it is impossible to describe,"

> "Black it stood as night—fierce as ten furies—
> Terrible as hell!"

This description, though poetical, is of the greatest value, as coming from the pen of one of the most acute observers who have yet written on the subject.

3. The mines of the Altai mountains are very important; they constitute the districts of Kolyvan, Zmeof, Tcherepanofsky, Smenofsky, Nikolaisky, Philipofsky, &c., with a yearly produce of upwards of 1875 lbs. troy of gold, 37,500 lbs. troy of silver, and a considerable quantity of copper, iron, and lead.

4. The mines of the Ural are dispersed, at different distances, around Ekaterinburg; those of Tourinsky produce about 20,000, and those of Goumechefsky 40,000 cwt. of copper yearly. The iron, which is obtained in the regions of Balgodat and Keskanar, amounts to more than 1,000,000 cwt. yearly. Near Berezov 312 lbs. troy of gold were formerly produced; but the quantity is now far more considerable.

5. The mines of the Vosges and the Schwarzwald (Black Forest). In the former, nothing but iron is found; in the latter, silver, at Badenweiler, Hochberg, and Wolfach, amounting to 1125 lbs. troy; at the first of these places, moreover, 800 cwt. of lead are obtained yearly, and at Wittichen, cobalt; besides iron in different places.

6. The mines of the Hartz: *a.* the silver, lead, and copper mines, &c., of the Upper Hartz, in the environs of the mining towns of Clausthal, Zellerfeld, Lautenthal, Wildemann, Grund, and Andreasberg; *b.* gold, silver, and copper mines, near Goslar; *c.* copper mines in the neighbourhood of Lauterberg; *d.* iron mines at Lauterberg, Walkenried, Elbingeroda, and Blankenburg; *e.* silver, lead, and iron mines, in the vicinity of Magdesprung: annual produce about 6¼ lbs. troy of gold, 18,750 lbs. troy of silver, 2000 cwt. of copper, 50,000 cwt. of lead, 30,000 cwt. of litharge, 200,000 cwt. of iron.

7. Mines in the eastern part of Germany:—*a.* in the Saxon Erzgebirge, at the towns of Freiberg, Marienberg, Annaberg, Ehrenfriedersdorf, Johanngeorgenstadt, Schneeberg, annually yielding about 32,500 lbs. troy of silver; at Altenberg, Geyer, Ehrenfriedersdorf, Zinnwald, annually from 3000 to 4000 cwt. of tin; at Schneeberg, annually 8000 cwt. of cobalt, 600 cwt. of copper, 80,000 of iron;—*b.* in Bohemia: silver, at Joachimsthal, Mies, Przibram, &c., 13,800 marcs (8625 lbs. troy); tin, at Schakenwald, &c., 2000 cwt.; cobalt, 4000 cwt.; lead, 1800 cwt.; iron, 190,000 cwt.;—*c.* in the Fichtelgebirge, principally iron, annually about 50,000 cwt.;—*d.* in Moravia, at Iglau, &c., 3125 lbs. troy of silver; *e.* in the Riesengebirge, at Jauer, Kupferberg, Reichenstein, 330 cwt. of copper, 560 cwt. of smalt; 1900 cwt. of arsenic, 1200 cwt. of sulphur, 20,000 cwt. of vitriol.

8. Mines in the middle and north-western parts of France. Those at Villefort, in the department of the Lozère, yield 2000 cwt. of lead and 1000 lbs. troy of silver; at Poullaouen and Huelgoat, in Bretagne, 10,000 cwt. of lead, 1250 lbs. troy of silver.

9. Mines of Scandinavia. Norway produces 1600 marcs (1000 lbs. troy) of silver; at Kongsberg, in 1768, 25,000 lbs. troy, 7200 cwt. of copper, 140,000 cwt. of iron, 4000 cwt. of smalt, 10,000 cwt. of alum; Sweden, 1875 lbs. troy of silver, from 18,000 to 20,000 cwt. of copper, 1,500,000 cwt. of iron.

10. Mines of the Pyrenees: these are insignificant, and iron only need be mentioned.

11. Mines of the Alps: they are not, by any means, proportioned to the immense masses of those mountains; the silver mines of Allemont, in Dauphiné, annually produce 2000 marcs (1250 lbs. troy); the iron mines of Allevard, in the department of the Isere, and the lead and silver mines of Pesey, in Savoy, formerly produced 4000 cwt. of lead, and 1562 lbs. troy of silver annually; the iron mines of Cogna and Traverselle, in Piedmont, annually yield upwards of 200,000 cwt. of iron; the copper mines at Falkenstein and Schwarz, in the Tyrol, formerly

were of importance; the gold mines at Gastein and Muerwinkel, in Saltzburg, annually yield 118 marcs (74 lbs. troy) of gold; the iron mines in Saltzburg and the Tyrol annually produce from 60,000 to 70,000 cwt.; the iron mines in Styria 450,000 cwt.; those in Carinthia 260,000 cwt., and those in Carniola 100,000 cwt.; the copper mines at Schladming in Styria, at Kirschdorf in Carinthia, at Agardo in the territory of Venice, and at Zamabor in Croatia, furnish copper containing silver; the zinc mines at Raibel, in Carinthia, annually produce 3400 cwt.; the lead mines at Villach and Bleiberg, &c., about 50,000 cwt.; the quicksilver mines at Idria, about 1500 cwt.; the rock-salt mines, at Hallein, Berchtesgaden, Aussee, Ischel, Hallstadt, &c., upwards of 3,000,000 cwt. of salt.

12. Mines of the countries bordering on the Rhine, and of the Ardennes. Copper is obtained from the mines of Rheinbreitenbach and Dillenburg, about 1200 cwt. yearly; lead and silver, from the mines of Holzapfel, Pfingstwiese, Læwenburg, Augstbach, Ehrenthal; of the former, 12,000 cwt.; of the latter, 2187 lbs. troy; iron of an excellent quality, and in great quantity, is procured in the Stahlberg, in the environs of the town of Siegen, on the banks of the Lahn and Sayn, at Hohenkirchen in Hesse, on the Hundsrück, in the Eifel, in the territories of Luxemburg, &c., calamine in the vicinity of Limburg, in the Netherlands, 15,000 cwt. yearly; in the neighbourhood of Aix-la-Chapelle, from 30,000 to 40,000 cwt.; in the county of Mark, 2600 cwt.; lead, at Vedrin, not far from Namur, 4000 cwt., together with 437 lbs. troy of silver.

The mines of other countries may be thus briefly noticed:—The environs of Nertschinskoi, in Siberia, are very rich in useful minerals, and yield from 18,750 to 21,750 lbs. troy of silver.

The mineral wealth of Spain and Portugal is now almost exhausted; the quicksilver mines of Almaden formerly furnished 20,000 cwt. yearly; the lead and copper mines are still productive, yielding annually more than 100,000 cwt. There are copper mines in Japan, China, Persia, Arabia, in Tartary, in the islands of the Indian Sea, in Barbary, Morocco, Abyssinia, &c.; tin is produced in China, Pegu, the peninsula of Malacca, Sumatra, Banca, &c., in the latter country alone, 70,000 cwt.: zinc is said to be abundant in India; quicksilver in China and Japan; Brazil furnishes 17,500 lbs. troy of gold yearly, which is more than is obtained from any other country; Africa at least 4375 lbs. troy, and Southern Asia at least 1250 lbs. troy yearly. The island of Elba contains a great deal of iron.—

The mines in Flœtz mountains are highly important: above all, the coal mines—this country alone furnishing 400,000,000 cwt.; France, 20,000,000; the Netherlands and the countries along the Rhine, 62,000,000; Silesia, 6,000,000; Saxony, 1,200,000; Austria, 680,000; Bavaria, 320,000; Hanover, with the rest of Germany, 6,000,000. The lead mines in the vicinity of Aix-la-Chapelle, which annually furnish from 14,000 to 16,000 cwt. of lead and upwards of 20,000 cwt. of lead ore, called *alquifou*, used for glazing earthenware, are in Flœtz mountains; also the copper mines in the territories of Mansfeld, at Frankenberg, Bieber, and Riegelsdorf, in Hesse, the former yielding 10,000 cwt. of copper and 5000 lbs. troy of silver; the important iron mines on the Stahlberg, in the Hessian seignory of Schmalkalden; the lead mines at Tarnowitz, in Upper Silesia, annually yielding 5300 cwt. of lead and 937 lbs. troy of silver; the calamine and zinc mines, in upper Silesia and Poland, which annually afford 80,000 cwt. of calamine and 25,000 cwt. of zinc.

We may now turn more particularly to the progress of mining in our own island, more especially as regards Devonshire, Cornwall, and North Wales. Our mines, though of such great national importance, have as yet attracted but little attention from any but those immediately concerned in them, and near the places in which they are situated; it is the more to be wished that men of science would address themselves to the consideration of their management as those engaged in them are not often men of sufficient ability, or science, to strike out any material improvements. To be a good miner requires an active mind, with industry and strict observation; these should be accompanied by some general knowledge, at least, of practical mineralogy, chemistry, mechanics, hydraulics, &c., and such a knowledge of principles as might lead to improvements in the mechanical parts of his business. It would be unreasonable to expect to find these qualifications general, but the attention of men of science would not fail to point out to the practical miner the improvements of which his operations are susceptible.

On the continent, many of the most eminent men have not thought it beneath them to undertake the management of mines; and to this it is fair to ascribe the success with which many of them have been conducted. In our own country, the superintendence of men of science during the last few years has been attended with very considerable advantage, and has given to this species of property a new, important, and improved stimulus.

The tin of Britain was known in distant parts of the world at a very remote period. It is generally believed that the Phœnicians were the nation principally engaged in trading with Britain for this article. Tin works were carried on, long before iron was known in this country: many tools of oak are now found, which tradition, among the miners, make to have belonged to the Saxons and Danes.

It is asserted that the greatest quantity of tin was formerly found in the forest of Dartmoor, in the county of Devon; and works to a vast extent must have been carried on there, if it be true, as we are told, that 30,000 men found employment upon this tract. It is, however, to be considered that by the ancient mode of working, without the aid of machinery, many more hands must have been found necessary than at present, probably in the proportion of three to one. All these works at Dartmoor were only on or near the surface: now, however, the lodes or veins of tin found in this district are not valuable enough, or do not continue to a sufficient depth to make them profitable to work.

Almost all the tin procured in former ages was probably from stream works, in bottoms or low grounds, where fagments of the ore, washed from the lodes in the neighbouring hills, subside, and are separated from the earth in a granular form by washing. This, of course, is obtained without any subterranean work. In such situations as these, it is probable that metals were first discovered, mixed merely with the upper soil, or lodging in clefts of rocks.

The tracing and following lodes of ores into the earth is a more difficult task than coming to the me-

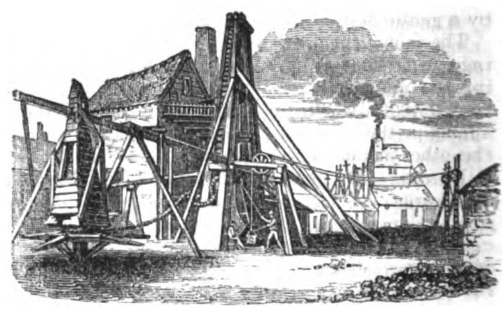
tal in the way of stream works; it requires more energy of mind, and a more advanced state of the arts. The difficulty that must attend keeping a mine, sunk to some depth, free from water, by manual labour only, could not but prevent miners, before the application of machinery, from sinking low into the bowels of the earth. We have, however, some instances in Cornwall, where old workings are met with at so great a depth as to be even now with difficulty kept dry by means of machinery; but these, though they may be accounted ancient, were probably opened long subsequent to the origin of mining in this country.

There are many mines which could not possibly be worked without the aid of gunpowder, and, until the discovery of this powerful agent, under-ground operations must have been both uncertain and difficult. The hammer and wedges for metals were probably the first materials for splitting rocks (and they still continue, in the ground that will yield to them, to be used both in Cornwall and Wales), and the pick, or instrument for clearing the ground, having a head for driving the wedges, called by the miners *gads*, from the Cornish word *gedn*, a wedge. The form of these instruments, found in old works, afford evidences of their antiquity. Wedges of dry wood were also very ingeniously made use of, by driving them in the clefts, and then wetting them, so as to cause them to swell, and cleave the rocks asunder. Fire was an agent long since employed in splitting the rocks; but the effects of gunpowder so far exceeded every thing before made use of, for such purposes, that its discovery and application to works of this kind form a grand epoch in the history of mining. This, it appears, took place in Hungary, or Germany, about the year 1620, and was first introduced into England at the copper mine at Ecton, in Staffordshire, about the year 1670, by German miners, brought over by Prince Rupert; but it was not in use in Somersetshire till 1684, after which, probably, the Cornish miners became acquainted with this powerful assistant to their operations.

Tin was the first object of enquiry by the miners of Cornwall. It was probably first found on the surface of the ground; almost all the low grounds in Cornwall bear the marks of having been *streamed*. The Romans probably interested themselves in the working of the mines; indeed, one principal inducement to that people's turning their attention to this island seems to have been the metals that were reputed to be found here. The Saxons neglected these hidden treasures, but the Normans worked them to great advantage. From that time to the end of the reign of John, the mines were not profitable, and mostly in the hands of the Jews. They revived in the time of Richard; but in the reign of Edward II. the Jews were banished the kingdom, and the mines were neglected. Edmund, the eldest son of the king, and Earl of Cornwall, however, made some important alterations in the regulations of the tin works, by a charter, which was confirmed by Edward I., in the latter part of his reign. Indeed, it is from this time that the peculiar laws and privileges relating to the Stannaries are to be dated. Mining infringed in some instances upon property, and caused disputes, besides requiring indulgences, not general; and thus cases arose, not cognizable by the common law. In this way a peculiar code, springing from custom, took its rise; and, though it in some measure existed before, yet it was not till this period that it was confirmed by royal charter, and enforced by subsequent acts of Parliament. It was by this charter that the bounding of land for the purpose of tinners working on it, the duties to the earl of Cornwall, and the coinages of tin, or stamping with the earl's seal, were established. Before the reign of Edward I. tinners worked on the earl's land only, paying him a fifteenth part of what they obtained; they were not permitted to dig in sanctuary ground, churches, mills, houses, gardens, and so on; and if, in working under, they chanced to damage any house or highway, they were obliged to make it good. When it became an object to search throughout any place or person's land, a court also to determine cases belonging to the tin works was necessary; and this, adjudging under the authority of, and according to the code of laws before-mentioned, was first established by Edward, and is called the "Stannary Court."

The ores are found in veins, or, as they are provincially called, *lodes;* the most important of which generally run in an east and west direction. These lodes vary considerably in breadth; the average may be taken at from one foot to four feet: for in some cases they are only a barley-corn in width, while in Nangiles mine the lode is in some places thirty feet wide, and in Relistion mine it is even thirty-six feet wide. The width of a lode is by no means regular; for it will vary from six inches to two feet in the space of a few fathoms.

The deepest mine in this country now at work is Dolcoath, so named from an old woman, Dorothy Koath, who lived on the spot when the working of the mine commenced. The appearance of the shaft of the Dolcoath mine, with the connecting machinery, is well given in the accompanying engraving.



The mines of that neighbourhood alone give employment to more than 2000 men. The east and west lodes are cut by others, called *cross courses*, which run north and south, and not only cause an interruption to the lodes, but alter their position, so that the miners must search, generally to the right hand, to find them again; it is very rare that left-handed heaves occur. These heaves occasion much trouble to the miners; in H… Pever it took a search of forty years to recover … lode.

When adventurers determine to work a mine, t… have agreed with the proprietor of the soil respec… his share, *or dish,* three points are to be consider… 1. The discharge of the water that may be met w… 2. The removal of the *deads,* that is, the barren r… and rubbish. 3. The raising of the ore. The f… object, therefore, is to cut an adit, or undergro… passage, about six feet high and two feet and a l…

wide, from the bottom of some neighbouring valley, up to the vein. This is a considerable expense; but still, in the end, it is the most economical mode of getting rid of the water, which must otherwise be raised by pumping, an operation which must still be resorted to in regard to that part of the mine which is below the upper part of the adit. Some of these adits are of great length; the one into which the steam-engine of Chacewater mine pumps its water is not less than twenty-four miles long: it is the deepest adit in Cornwall, and flows into one of the creeks of Falmouth Haven.

As soon as the vertical opening or shaft is sunk some depth, a whim is erected, to bring up the deads and ore in baskets, called *kibbuls*, one of which goes down empty while another comes up full. The whims are turned by horses, steam, or other power. As the lode never runs down perpendicularly, it is necessary to cut galleries, called levels, generally about two feet wide and six feet high, in a horizontal direction. Other shafts are also sunk, which traverse the several levels; or a special communication is made between only two galleries by a particular shaft called *wins*. When several levels run parallel to each other through the rock, or country, as it is called, they are made to communicate by other levels, called cross cuts.

For keeping the galleries from being inundated, each mine is furnished with a chain of pumps, descending from the adit level to the bottom of the mine, or *sump*, as it is called: all these pumps are worked by a single pump-rod, moved by steam-engines, whose aggregate power is frequently equivalent to the labour of more than 1000 men. The water is raised by these pumps, each of which receives the water brought up by the one immediately below it, until it reaches the adit, through which it flows by a gentle descent to the surface.

The subterranean excavations are effected by breaking down the looser parts with a pick-axe, or by blasting the more solid parts by gunpowder. No less than 30,000*l.* worth of this article is annually consumed in the mines of this country. (See IRON, and the other metals in their alphabetical order.)

MINERAL WATERS. Fluids generally take up a vast variety of ingredients, many of which are of great value in a medicinal point of view. Our own country has many mineral springs in which medicinal properties are found to reside: and, if this vast natural laboratory beneath the earth's surface were better known, there is no doubt but what it would be more generally resorted to. We purpose, in the first instance, giving a list of these springs, and then showing the mode of analysing their contents.

The following is an alphabetical table of the most celebrated medicinal waters in Europe, showing their peculiar medicinal properties.

[illegible]mes of Springs.	*Places in which they are found.*	*Medicinal Virtues.*
[illegible]ourt	Near St. Germains, France	Diuretic and purgative.
[illegible]n	Middlesex	Strongly purgative.
[illegible]aloo	Tyrone, Ireland	Alterative. Useful in scrofulous and cutaneous diseases.
[illegible] la-Chapelle	Juliers, Germany	Diaphoretic, purgative, & diuretic. Used as baths, as well as taken internally. Useful in rheumatisms, & all diseases proceeding from a debility of the system.
Alford, or Awford	Somersetshire	Strongly purgative.
Arbroath	County of Forfar, Scotland	Diuretic. Used in indigestions, nervous disorders, &c.
Askeron	Yorkshire	Diuretic.
Antrim	Ireland	Similar to Borrowdale water, but weaker
Baden	Suabia, Germany	See *Aix-la-Chapelle*, which it resembles in medicinal properties.
Bagnigge wells	Middlesex	Strongly purgative.
Ball, or Baudwell	Lincolnshire	Astringent. Drank to the quantity of two pints, or two and a half.
Balaruc	Languedoc, France	Drank as a purgative, and used for hot-baths.
Ballynahinch	Down, Ireland	Useful in scorbutic disorders, and diseases of indigestion.
Bagniers	Biggore, France	The waters used for baths, like those of Aix-la-Chapelle. Some of the springs are purgative, and others diuretic.
Bareges	Biggore, France	Diuretic and diaphoretic. Useful in nervous and cutaneous disorders.
Barnet, and Northhall	Hertfordshire	Purgative.
Bath	Somersetshire	Highly useful in cases of gout, rheumatism, indigestion, palsy, and biliary obstructions. The temperature varies from 93° to 117° Fah.
Bandola	Italy	Gently laxative, diuretic, and diaphoretic.
Beulah	Surrey	Highly purgative. This has now become a place of fashionable resort, and the botanical lectures delivered by Dr. Dickson in the grounds were well attended during the last season (1833).
Borrowdale	Cumberland	Emetic and Cathartic.
Brentwood	Essex	Purgative.
Bristol	Somersetshire	Used as a bath. Useful in consumptions.
Bromley	Kent	Diuretic and corroborative.
Broughton	Yorkshire	Similar to Harrowgate.
Buxton	Derbyshire	Useful in gout and rheumatism. Used as baths, and drank to the quantity of five or six pints per day.
Caroline baths	Bohemia	Purgative, and used as baths. Of service in disorders of the stomach & bowels, scrofula, &c.
Carlton	Nottinghamshire	Diuretic and corroborative.
Carrickfergus	Antrim, Ireland	Weakly purgative.
Carrickmore	Cavan, Ireland	Purgative and diuretic.
Cashmore	Waterford, Ireland	Purgative, diuretic, and sometimes emetic.
Castle-Leod	Ross-shire, Scotland	Diuretic and diaphoretic. Useful in cutaneous diseases.
Castlemain	Kerry, Ireland	Diuretic.
Cawley	Derbyshire	Gently purgative.
Cawthorp	Lincolnshire	Purgative.
Chadlington	Oxfordshire	Purgative.
Chaude Fontaine	Liege, Germany	Resembles those of Aix-la-Chapelle and Buxton.
Cheltenham	Gloucestershire	Purgative and corroborant. Is useful in cases of indigestion and scorbutic disorders; also in the gravel.
Chippenham	Wiltshire	Diuretic.
Cleves	Germany	Diuretic.
Clifton	Oxfordshire	Gently laxative, and used as a bath for cutaneous disorders.
Cobham	Surrey	Purgative and diuretic.
Colchester	Essex	Strongly purgative.
Comner, or Cumner	Berkshire	Purgative, in the quantity of one, two, or three quarts.
Coolauran	Fermanagh, Ireland	Diuretic.
Corstorphin	Mid-Lothian, Scotland	Diuretic and laxative.

Names of Springs.	*Places in which they are found.*	*Medicinal Virtues.*
Coventry	Warwickshire	Purgative and diuretic.
Crickle-Spa	Lancashire	Purgative, and resembling Harrowgate water.
Croft	Yorkshire	Purgative.
Cross-town	Waterford, Ireland	Diuretic, purgative, and sometimes emetic.
Cunley-house	Lancashire	Purgative and diuretic.
D'Aix en Foix	Thoulouse, France	Used as a bath, and also drank like the Aix-la-Chapelle waters.
Deddington	Oxford	Alterative and purgative.
Derryhinch	Fermanagh, Ireland	Diuretic and diaphoretic.
Derrindaff	Cavan, Ireland	Diuretic.
Derrylester	Cavan, Ireland	
Drig-well	Cumberland	
Dropping-well	Yorkshire	Astringent.
Drumas-nave	Leitrim, Ireland	Powerfully diuretic and anthelmintic, and of use in cutaneous and scrofulous disorders.
Drumgoon	Fermanagh, Ireland	
Dublin salt springs	Ireland	Purgative.
Dulwich	Kent	Purgative and diuretic. Useful in nervous cases and diseases proceeding from debility.
Dunnard	Near Dublin	Diuretic.
Dunse	Berwickshire, Scotland	Strongly chalybeate.
Durham	Durham	Similar to the Harrowgate water.
Egra	Bohemia	
Epsom	Surrey	Purgative.
Fairburn	Ross-shire, Scotland	Alterative, and useful in cutaneous diseases.
Felstead	Essex	
Filah	Yorkshire	Powerfully diuretic and purgative.
Frankfort	Germany	Similar to Harrowgate.
Gainsborough	Lincolnshire	Diuretic and laxative.
Galway	Ireland	
Glenmile	Ireland	
Glastonbury	Somersetshire	
Glendy	Merns county, Scotland	
Granshaw	Down, Ireland	
Haigh	Lancashire	Emetic and cathartic.
Hampstead	Middlesex	Alterative and diuretic.
Hanbridge	Lancashire	Purgative.
Hanlys	Shropshire	Purgative.
Harrowgate	Yorkshire	Alterative and purgative. Useful in scurvy, scrofula, and cutaneous diseases.
Hartfell	Annandale, Scotland	Astringent.
Hartlepool	Durham	Diuretic and laxative.
Holt	Wiltshire	Mildly purgative.
Joseph's-well	Stock Common, near Cobham, Surrey	Alterative, purgative, and diuretic.
Ilmington	Warwickshire	Diuretic and laxative.
Inglewhite	Lancashire	Alterative. Useful in scorbutic and cutaneous diseases.
Kanturk	Cork, Ireland	
Kedleston	Derbyshire	Similar to Harrowgate; but intolerably fetid.
Kilbrew	Meath, Ireland	Emetic and cathartic.
Kilburn	Near London	Purgative.
Killasher	Fermanagh, Ireland	Similar to Swadlingbar water.
Killingshanvally	Fermanagh, Ireland	Diuretic.
Kilroot	Antrim, Ireland	
Kinalton	Nottinghamshire	Purgative.
Kincardine	Merns, Scotland	
Kingscliff	Northamptonshire	
Kirby	Westmoreland	Laxative, and useful in correcting acidities.
Knaresborough	See *Dropping-well*	
Knowsley	Lancashire	
Kuka	Bohema	Operates by insensible perspiration.
Latham	Lancashire	
Llandrindod	Radnor, South Wales	Useful in the scurvy, and cutaneous disorders.
Llangybi	Caernarvonshire, North Wales	Useful in disorders of the eyes, scrofula, &c.
Leamington	Warwickshire	Emetic and cathartic.
Lees	Essex	
Lincomb	Somersetshire	

Names of Springs.	*Places in which they are found.*	*Medicinal Virtues.*
Lisbeak	Fermanagh, Ireland	Similar to Swadlingbar water.
Lis-done-Vurna	Clare, Ireland	Emetic, cathartic, and diuretic.
Mahereberg	Kerry, Ireland	Similar to Borrowdale water.
Mallow	Cork, Ireland	Useful in consumptions.
Malton	Yorkshire	Similar to Scarborough water.
Malvern	Gloucestershire	Diuretic and cathartic.
Markshall	Essex	
Matlock	Derbyshire	
Maudsley	Lancashire	Purgative.
Mechan	Fermanagh, Ireland	Purgative.
Miller's Spa	Lancashire	
Moffat	Annandale, Scotland	Diuretic, and sometimes purgative.
Moss-house	Lancashire	Strongly purgative.
Moreton	Shropshire	
Mont d'Or	France	Diuretic, purgative, and diaphoretic.
Nevel Holt	Leicestershire	Purgative, diuretic, and diaphoretic. — Powerfully antiseptic in putrid diseases, and excellent in diarrhœa, dysenteries, &c.
New Cartmall	Lancashire	Purgative.
Newnham Regis	Warwickshire	
Newtondale	Yorkshire	Astringent.
Newton-Steward	Tyrone, Ireland	
Nezdenice	Germany	Diuretic, diaphoretic, and tonic.
Nobber	Meath, Ireland	Similar to Hartfell.
Normanby	Yorkshire	Similar to Askeron water.
Nottington	Dorsetshire	Useful in cutaneous diseases.
Orston	Nottingham	Purgative.
Oulton	Norfolk	
Owen Breun	Cavan, Ireland	Diuretic.
Passy	Near Paris	
Pettigoe	Donnegal, Ireland	Diuretic.
Pitkeathly	Perthshire, Scotland	Gently purgative.
Pontgibault	Auvergne, France	Diuretic and laxative.
Pougues	Nivernois, France	Diuretic and laxative.
Pyrmont	Westphalia, Germany	Diuretic, diaphoretic, and laxative. Recommended in cases where the constitution is relaxed.
Queen Camel	Somersetshire	Used in scrofulous and cutaneous disorders.
Richmond	Surrey	
Rippon	Yorkshire	Diaphoretic.
Road	Wiltshire	Useful in scrofula, scurvy, and cutaneous disorders.
St. Bernard's well	Near Edinburgh	A very valuable spring, much used in scorbutic diseases. It is diuretic and purgative.
St. Erasmus's well	Staffordshire	Similar to Borrowdale water.
Scarborough	Yorkshire	Diuretic and purgative.
Sedlitz	Bohemia	Strongly purgative.
Seltzer	Germany	Diuretic. Useful in the gravel, rheumatism, scurvy, scrofula, &c.
Sene, or Send	Wiltshire	
Seydschutz	Germany	
Shapmoor	Westmoreland	Diuretic.
Shettlewood	Derbyshire	Purgative.
Shipton	Yorkshire	Similar to Harrowgate.
Somersham	Huntingdonshire	Corroborant & alterative.
Spa	Liege, Germany	Diuretic and purgative.
Stanger	Cumberland	Emetic and cathartic.
Suchaloza	Hungary	Diuretic and tonic.
Sutton Bog	Oxfordshire	Alterative and laxative.
Swadlingbar	Cavan, Ireland	Alterative and diaphoretic.
Sydenham	Kent	Purgative.
Tarleton	Lancashire	Diuretic and purgative.
Tewksbury	Gloucestershire	Strongly purgative.
Thetford	Norfolk	Purgative and diuretic.
Thursk	Yorkshire	Diuretic and purgative.
Tibshelf	Derbyshire	Similar to Spa water.
Tilbury	Essex	Diuretic and diaphoretic.
Tober Bony	Near Dublin, Ireland	Similar to Tilbury.
Tonstein	Cologne, Germany	Similar to Seltzer, but more purgative.
Tralee	Kerry, Ireland	

Names of Springs.	*Places in which they are found.*	*Medicinal Virtues.*
Tunbridge	Kent	An excellent chalybeate, useful in all diseases for which the Spa is recommended.
Upminster	Essex	Purgative and diuretic.
Vahls	Dauphiny, France	Diuretic and laxative.
Wardrew	Northumberland	Similar to Harrowgate water.
Weatherstack	Westmoreland	Purgative.
Whiteacre	Lancashire	Astringent.
Wigglesworth	Yorkshire	Emetic.
Wildungan	Waldeck, Germany	Useful in scorbutic and gouty diseases.
Witham	Essex	Diuretic and alterative.
Wirksworth	Derbyshire	Useful in scrofulous and cutaneous diseases.
Zahorovice	Germany	Much esteemed in scrofulous cases.

The first step in the *analysis* of a *mineral water* is to ascertain the gaseous substances it contains, as these frequently contribute to hold the solid substances dissolved.

Carbonic acid uncombined, or in excess, may be discovered by the pungent acidulous taste of the water, and its sparkling appearance when poured into a glass. Waters impregnated with it become vapid from exposure to the air, or to a moderate heat, from the escape of the gas.

The chemical tests to discover it are infusion of litmus and lime-water, the former receiving from the mineral water an evanescent redness, the latter producing a milkiness or precipitation, which disappears when an excess of the mineral water is added, the carbonic acid rendering soluble the carbonate of lime, to which the turbid appearance is owing. The transparency is equally restored by dropping into the liquid a little muriatic or nitric acid. By the evanescent redness given to litmus, carbonic acid is distinguished from any other free acid that might be present; and, by the transparency being restored by these re-agents, the fallacy that might arise from the precipitation of the lime by any sulphate in the water is guarded against. The quantity may be ascertained by exposing the water to heat in a retort, collecting the gas disengaged in a jar over mercury, and introducing a solution of potash, by which the carbonic gas is absorbed.

Sulphurous acid gas is very seldom to be looked for; when present, it is discovered by its smell, by giving a permanent red colour to a solution of litmus, and by rendering colourless an infusion of roses. Its quantity is estimated by expelling it; exposing the gas to a solution of potash, and obtaining the sulphite of potash; or by adding to it sulphuretted hydrogen gas as long as any diminution of volume is produced, these two gases, by their mutual action, being converted into water and sulphuric acid, and being therefore entirely condensed.

Nitrogen gas is discovered by remaining unabsorbed when the elastic fluid, expelled from a mineral water by heat, has been exposed to a solution of potash.

Sulphuretted hydrogen existing in a water is discovered by its smell, by the deposition of sulphur from it on exposure to the air, or, on the addition of nitrous acid, by blackening silver or mercury immersed in it, and affording a dark-coloured precipitate with acetate of lead. The quantity has been estimated by expelling it from the water by heat, but the whole of it cannot thus be expelled; nor can it easily be collected to be measured with accuracy, as it is absorbed by water, and acts on quicksilver. It may be decomposed by the addition of fuming nitrous acid, or, according to Kirwan's method, a quantity of the water, so as to combine with the oxygen of the atmosphere; nitrous acid is formed, and this, being absorbed by the water, decomposes the sulphuretted hydrogen; the quantity may be inferred from the quantity of sulphur precipitated, and collected on a filter, thirty-four grains of sulphur being held equivalent to 100 cubic inches of sulphuretted hydrogen gas. When sulphuretted hydrogen and carbonic acid gases exist together in mineral water, the elastic fluid obtained from the water by heat is exposed in a tube to nitrous acid, by which the sulphuretted hydrogen is immediately absorbed and decomposed.

After the gaseous substances in mineral waters have been ascertained, the solid contents are to be examined.

The mineral acids, when combined with any base, or in excess, are discovered by the water giving a permanent red colour to vegetable infusions; but in this state they are very rarely present.

The neutral and earthy salts are the chief ingredients of mineral water. We have to ascertain the acids they contain, and the bases with which these are united; and for this purpose it is in general necessary to reduce the volume of the water by evaporation, to render more sensible the operation of the re-agents by which they are detected; only taking care, when the evaporation is executed with this view, not to carry it so far as to give rise to the separation of any of the solid ingredients.

Sulphuric acid, in combination with the alkalies or earths, is detected by muriate of barytes, acetate of lead, and nitrate of mercury, all of these causing an immediate precipitation. The first is at once the most delicate and most accurate, and the others therefore may be regarded as superfluous. Its delicacy is such that it discovers the most minute quantity of sulphuric acid. The only fallacy to which it is liable is that of affording a precipitate from the presence of an alkaline or earthy carbonate; this is obviated by adding, previously to the water, a small quantity of pure nitric or muriatic acid, or by the turbid appearance, after it has been produced, disappearing, if it has arisen from this, on the addition of a few drops of either of these acids.

Muriatic acid is detected by nitrate of silver, the muriate of silver which is formed being, from its insolubility, instantly precipitated, and giving rise to a bluish turbid appearance. The delicacy of this as a re-agent is great, the most minute quantity of muriatic acid in any state of combination being detected. It is liable to fallacy, however, from a precipitate being likewise produced by it from the presence either of any carbonate or any sulphate. The operation of the former is obviated by the previous addition of a few drops of pure nitric acid, which decompose the carbonate and expel the carbonic acid; to avoid the latter it is necessary to decompose any sulphate by the addition of nitrate of barytes.

Carbonic acid, in combination with the alkalies or earths, may be discovered by the effervescence produced by the addition of sulphuric acid when concentration has been produced by evaporation, and by muriate of barytes forming a precipitate soluble with effervescence in nitric or muriatic acid. The alkaline carbonates are distinguished by their power of changing the vegetable colours; the earthy and

metallic carbonates, by being precipitated when the water is partly evaporated.

These are the acids usually met with in mineral waters; they are commonly combined with the fixed alkalies, lime, magnesia, or alumina, or with oxide of iron.

Lime is *immediately* precipitated by oxalic acid. Some of the mineral acids, however, either decompose this acid, or hold dissolved the precipitate it forms with the lime, and hence, if disengaged by the decomposition, they might have this effect. This fallacy is guarded against by using, not the pure acid, but oxalate of potash or ammonia, the alkali neutralizing the acid disengaged from the lime. Oxalic acid produces a precipitate likewise with magnesia, but this takes place very slowly, even when the magnesian salt is in large quantity, while with lime it is immediate. Sulphuric acid is also a test to discover lime, but it is one of much less delicacy.

Ammonia and lime-water are the tests of magnesia; the former precipitating it partially, the latter entirely. In order that the lime may be an accurate test, it is necessary to remove any carbonic acid which may exist in the water, by previously adding nitric acid; and any sulphuric acid, by muriate of barytes. Another source of fallacy more important arises from alumina being precipitated by the re-agents as well as magnesia. The nature of the precipitate may be discovered by dissolving it in nitric or muriatic acid, and again precipitating the solution by carbonate of potash. If this dried precipitate be subjected to the action of diluted sulphuric or muriatic acid it will be immediately dissolved if the earth be magnesia; while, if it be alumina, it will dissolve slowly; or the precipitate may be boiled in a solution of potash; if it be alumina it will be dissolved, while magnesia will remain undissolved. Succinate of ammonia too precipitates alumina, but not magnesia. But the best mode of discovering magnesia is by the formation of its triple phosphate with ammonia. This may be effected by the method of Dr. Wollaston, by adding carbonate of ammonia to a solution containing any magnesian salt; no effect appears, but on adding phosphate of soda precipitation takes place; or the same result may at once be obtained by adding sub-phosphate of ammonia.

The alkalies, when in a state of combination, cannot be discovered by any striking tests, but their presence is inferred when acids are discovered in a mineral water which are not free, and which, at the same time, from the application of tests, do not appear to be combined with earthy or metallic bases.

Soda is the alkali generally present. The peculiar salts which it and potash form with the different acids serve to distinguish them. With oxalic acid, soda forms a salt sparingly soluble; while potash forms, with the same acid, a salt easily dissolved. With tartaric acid, on the contrary, soda forms a soluble salt; while with potash an acidulous tartrate is formed, of comparatively sparing solubility. Muriate of platina affords a test still more delicate, giving a precipitate with the salts of potash, but not with those of soda.

Silicious earth is contained in some waters, not combined, however, with any acid. A portion of alkali, likewise, generally exists in such water; but this is either in the state of a carbonate, or in such small quantity that it can scarcely be considered as the solvent of the silex. This earth may be discovered by evaporating the water, and adding nitric or muriatic acid to the solid residuum; the silex will remain undissolved; and its nature may be still more clearly proved by fusing it with the blow-pipe, with either of the fixed alkalies.

Of the metals existing in mineral waters, iron is the principal; any other, indeed, is of very rare occurrence. It is combined sometimes with sulphuric acid, but more generally with carbonic acid.

Chalybeate waters, as those impregnated with iron are named, deposit an ochrey sediment, on exposure to the air. The iron is discovered by very delicate tests, principally infusion of galls and prussiate of potash, the former striking a purple colour, the other giving rise to a blue precipitate. The latter is liable to fallacy, principally from the iron which exists in its composition, and which is liable to be evolved by an acid, so as to give rise to the blue precipitate. The former is not liable to this or any other important fallacy, and is much more delicate, a deep colour being struck when the iron is present in very small proportion. The colour is liable to be varied by the action of various salts, alkaline and earthy carbonates rendering it violet, neutral alkaline salts deepening the purple tint, and sulphate of lime rendering the precipitate at first whitish and afterwards black. Carbonate of lime has a singular effect. If the iron is in small quantity, and at a high state of oxidation, the colour does not appear; while, if it is in a low state of oxidation, the purple tint is even heightened. By applying this test before and after ebullition of the mineral water, we discover whether the oxide of iron has been dissolved by carbonic acid or sulphuric acid: if the former has been the solvent, being expelled during the boiling, the oxide is precipitated, so that either the liquor, after filtration, when cold, does not suffer the change of colour, or the tint is much less deep. The quantity of oxide may be in some measure determined by its precipitation from exposure to the air and ebullition; or it may be precipitated by succinate of soda, and the precipitate, calcined at a red heat with a little carbonaceous matter, gives the quantity of oxide of iron. Benzoate of soda may be substituted as more economical.

Besides the method of discovering the saline ingredients in mineral waters by re-agents which indicate their principles, they may, by certain methods, be obtained in their entire state, and their quantities determined.

Evaporation is employed with this view, different substances being obtained as the evaporation is carried to a greater or less extent. Thus the carbonates of lime and magnesia are usually first precipitated, afterwards sulphate of lime falls down: if after these precipitations the liquor be drawn off and allowed to cool, the alkaline neutral salts and the sulphate of magnesia will crystallize, while muriate of magnesia and muriate of lime, if present, will remain, forming an uncrystallizable residue.

Alcohol facilitates the analysis by a similar operation. When added to the water brought to a certain state of concentration, it throws down first sulphate of lime, afterwards carbonate of lime and carbonate of magnesia; and if added in larger quantity, or after a renewed evaporation, it either precipitates or causes to crystallize sulphate of magnesia and sulphate of soda, while any muriates remain dissolved. Advantage, too, is taken of its solvent power, the solid sub-

stances being obtained by evaporation to dryness, and their separation being facilitated by the addition of alcohol in successive portions.

It is by these methods of evaporation and precipitation that the ingredients of mineral waters have been determined. By the use of re-agents, their principles are discovered, and even the quantity of these may be estimated. The quantity, for example, of sulphuric acid may be ascertained from the weight of the precipitate formed by adding muriate of barytes, the proportion of sulphuric acid which a given weight of this brought to a certain state of desiccation contains being known: the quantity of muriatic acid may be inferred from the weight of the precipitate formed by adding nitrate of silver; that of carbonic acid from the weight of the precipitate formed by water of barytes or lime; that of lime from the weight of the oxalate of lime precipitated by oxalate of potash; and, in a similar manner, the weights of other substances that can be precipitated by re-agents in new states of combination may be determined. But it is always from the substances actually obtained that the composition is previously inferred, these being supposed to be the ingredients which exist in solution. (See Water, Analysis of.)

Mite; a small coin, formerly current, equal to about one-third of a farthing; it also denotes a small weight used by the moneyers. It is equal to the 20th part of a grain, and divided into 24 doits.

Mitre, in *architecture*, is the workman's term for an angle of forty-five degrees, or half a right one. If the angle be a quarter of a right angle, they call it a *half-mitre*. To describe such angles, they have an instrument called the *mitre-square*; with this they strike the mitre-lines on their quarters or battens; and, for despatch, they have a *mitre-box*, as they call it, which is made of two pieces of wood, each about an inch thick, one nailed upright on the edge of the other; the upper piece has the mitre-lines struck upon it on both sides, and a kerf to direct the saw in cutting the mitre-joints readily, by only applying the piece into this box.

Mnemonics, the art of assisting the memory. One species of mnemonics, and perhaps the earliest, is to attach the idea to be remembered to some impression of the senses, such as those external objects which are most familiar to our eyes. Some persons make use of a picture, arbitrarily drawn, to which they attach the subjects to be remembered, in a certain order; others make use of numbers. There are certain natural aids to the memory, which we all employ: for instance, if we put a piece of paper in a conspicuous part of a room, or make a knot in a handkerchief, in order to be reminded of certain things at particular times. An orator who intends to deliver a long speech without notes may derive assistance from previously entering the room where he is to speak, and attaching in his mind to certain prominent objects in the room the chief heads of his speech. To remember dates, several methods have been advised. The one proposed in Gray's *Memoria Technica* is to make certain changes in the names of persons, places, &c., in such a way that the words shall signify also certain numbers, according to a plan previously adopted. A table must be drawn up, similar to the following:—

a	*e*	*i*	*o*	*u*	*au*	*oi*	*ei*	*ou*	*y*
1	2	3	4	5	6	7	8	9	0

If we now wish to impress in our memory that Julius Cæsar arrived at the supreme power 46 B. C., we may change the *Julius* into *Julios*, which will be easily remembered whenever we think of *Julius*, and *os* signifies, according to the above plan, 46. If we wish to remember that Alexander the Great founded his empire 331 B. C., we change *Alexander* into *Alexita*, *ita* signifying 331 according to the above. In the same way *Cyrus*, changed into *Cyruts*, gives the year of the foundation of his great empire. This method may much facilitate the retaining of facts to a certain extent; but it would seem as if the changes themselves might become too numerous to be easily remembered.

Systems of mnemonics of a more *general* character have been proposed; few, however, or none, have remained in vogue for any length of time. Generally speaking, mnemonics ought to be individual: each person should find out that method of assisting his memory which is most convenient to himself; and this will vary, of course, with his habitual associations. The only true basis of a philosophic memory, however, is just classification.

Considerable aid to the memory may be derived from the use of rhymes, or a rhythmical arrangement of words. Before the invention of writing, rhythm was employed to preserve the memory of historical facts. The ancients were well acquainted with mnemonics; according to some, the science came from the East to the Greeks; others consider the poet Simonides as the inventor of them; but such inventions cannot be properly assigned to any particular individual. In the time of Cicero it was known among the Romans. After Quintilian's time, mnemonics again declined. In considering the use of mnemonics by the ancient orators, we should remember that they delivered long orations indeed, but had nothing like our debates, in which a member of a deliberative body sometimes rises, and speaks for hours in succession, recapitulating all which has been said before him on the question, and therefore, to a considerable degree, without premeditation. Most of the systems of mnemonics devised for the ancients would be useless for a parliamentary orator of the present day. In the place of the ancient mnemonics, the schoolmen used the tabulary method. Conrad de Celtes, in the fifteenth century, and Schenkel, in the sixteenth, re-established the ancient system. In modern times, several scholars have given much attention to this subject. The degree to which the power of memory has been sometimes carried is almost incredible. Thus Seneca states that, by the mere effort of his natural memory, he was able to repeat 2000 words upon once hearing them, each in its order, though they had no dependence or connexion on each other. He also mentions Cyneas, ambassador to the Romans from king Pyrrhus, who in one day so well learnt the names of the people whom he saw that the next day he saluted all the senators, and all the populace assembled, each by his proper name. Pliny says that Cyrus knew every soldier in his army by name, and L. Scipio all the people of Rome. Charmipas, or rather Carneades, it is said, would repeat the contents of any volume found in the libraries, as readily as if he were reading. Dr. Wallis tells us that, without the assistance of pen and ink, or any thing equivalent, he was able, in the dark, by the mere force of memory, to perform arithmetical operations, as multiplication, division, extraction of roots

&c., to forty places. It is said of Magliabecchi that a gentleman having lent him a manuscript, which he was going to print, came to him soon after it was returned, and, pretending that he had lost it, desired him to repeat as much of it as he could; on which Magliabecchi wrote down the whole, without missing a word or varying the spelling.

Moat, or Ditch, in *fortification;* a deep trench dug round a rampart of a fortified place. The brink of the moat next the rampart is called the *scarp;* and the opposite one the *counter-scarp.* A dry moat round a large place, with a strong garrison, is preferable to one full of water, because the passage may be disputed inch by inch, and the besiegers, when lodged in it, are continually exposed to the bombs, grenades, and other fire-works, which are thrown incessantly from the rampart into their works. In the middle of dry moats, there is sometimes another small one called a *lunette,* which is generally dug till the water fills it. The deepest and broadest moats are accounted the best; but a deep one is preferable to a broad one: the ordinary breadth is about twenty fathoms, and the depth about sixteen. To drain a moat that is full of water, a trench is dug deeper than the level of the water, to let it run off, and then hurdles are thrown upon the mud and slime, covered with earth or bundles of rushes, to make a sure and firm passage.

Mobility; a contingent property of bodies, but most essential to their constitution. Every body at rest can be put in motion, and, if no impediment intervene, this change may be effected by the slightest external impression. Thus the largest cannon ball, suspended freely by a rod or chain from a lofty ceiling, is visibly agitated by the horizontal stroke of a swan shot which has gained some velocity in its descent through the arc of a pendulum. In like manner, a ship of any burden is, in calm weather and smooth water, gradually pulled along even by the exertions of a boy. A certain measure of force, indeed, is often required to commence or to maintain the motion; but this consideration is wholly extrinsic, and depends on the obstacles at first to be overcome, and on the resistance which is afterwards encountered. If the adhesion and intervention of other bodies were absolutely precluded, motion would be generated by the smallest pressure, and would continue with undiminished energy.

Mode, in *music;* a particular system or constitution of sounds, by which the octave is divided into certain intervals, according to the genus. The theories respecting the ancient modes are rendered somewhat obscure, by the difference among their authors as to the definitions, divisions, and names of their modes. While the ancient music was confined within the narrow bounds of the tetrachord, the heptachord, and octachord, there were only three modes admitted, whose fundamentals were one tone distant from each other. The gravest of these was called the Dorian; the Phrygian was in the middle, and the acutest was the Lydian. In dividing each of these tones into two intervals, place was given to two other modes, the Ionian and the Æolian, the first of which was inserted between the Dorian and Phrygian, and the second between the Phrygian and Lydian. The system being at length extended both upward and downward, new modes were established, taking their denomination from the first five, by joining the preposition *hyper* (over or above) for those added at the acute extremity, and the preposition *hypo* (under) for those below. Thus the Lydian mode was followed by the Hyper-Dorian, the Hyper-Ionian, the Hyper-Phrygian, the Hyper-Æolian, and the Hyper-Lydian, in ascending; and the Dorian mode was succeeded by the Hypo-Lydian, Hypo-Æolian, Hypo-Phrygian, Hypo-Ionian, and the Hypo-Dorian in descending. The moderns, however, reckon only two modes, the major and the minor. The major mode is that division of the octave by which the intervals between the third and fourth, and seventh and eighth, become half tones, and all the other intervals whole tones. The minor mode is that division by which the intervals between the second and third, and fifth and sixth, become half tones, and all the others whole tones. Another distinction also exists between the major and minor modes: the major mode is the same both ascending and descending; but the minor mode in ascending sharpens the sixth and seventh, thereby removing the half tone from between the fifth and sixth to the seventh and eighth.

Model; an original of any kind proposed for copy or imitation. It is used, in building, for an artificial pattern formed of stone or wood. In painting, this is the name given to a man or woman who is procured to exhibit him or herself, in a state of nudity, for the advantage of the students. These models are provided in all academies and schools for painting, and the students who have acquired a tolerable use of the pencil are introduced to this kind of study. By this means, the details and proportions of the human shape, the play of the muscles, the varieties of expression, &c., are displayed and inculcated far better than by any course of lectures or any study of former works. It is desirable that the living models used in an academy, or even in a private painting room, should be changed as frequently as possible, or the student is in danger of falling into mannerism. Millin speaks of a model, of the name of Deschamps, who did duty in this way upwards of forty years in the academy at Paris, and comments on the facility with which this person's form and features might be recognized, in every variety of subject or of expression in the paintings of the students of that period.

In sculpture a model implies a figure made of wax or terra cotta, or any other plastic substance, which the artist moulds to guide him in fashioning his work, as the painter first makes a sketch, or the architect a design. When a model of any existing object is to be taken, the original is first to be greased, in order to prevent the plaster from adhering to it, and then to be placed on a smooth table, previously greased, or covered with a cloth, to guard against the same accident; then surround the original with a frame or ridge of glazier's putty, at such a distance as will admit of the plaster resting upon the table, on every side of the subject, for about an inch, or as much as may be thought sufficient to give the proper degree of strength to the mould. An adequate quantity of plaster is then to be poured as uniformly as possible over the whole, until it is every where covered to such a thickness as to give a proper substance to the mould, which may vary in proportion to the size. The whole must then be allowed to continue in this way till the plaster shall have attained its firmness; when, the frame being removed, the mould may be inverted, and the subject taken from it.

Besides the models which are taken from inanimate bodies, it has been frequently attempted to take the exact resemblance of people while living, by using their face as an original for a model from which to take a mould; it may in this case be proper to mix the plaster with warm instead of cold water; and, to prevent any danger from the stoppage of respiration, the following method is to be practised:—Having laid the person horizontally on his back, the head must first be raised by means of a pillow to the exact position in which it is naturally carried when the body is erect; then the parts to be represented must be very thinly brushed over with oil of almonds: the face is then to be first covered with fine fluid plaster, beginning at the upper part of the forehead, and spreading it over the eyes, which are to be kept close, that the plaster may not come in contact with the globe, yet not closed so strongly as to cause any unnatural wrinkles. Then cover the nose and ears, first plugging up the *meatus auditorius* with cotton, and the nostrils with a small quantity of tow rolled up, of a proper size to exclude the plaster. During the time that the nose is thus stopped, the person is to breathe through the mouth: in this state the fluid plaster is to be brought down low enough to cover the upper lip, observing to leave the rolls of tow projecting out of the plaster. When the operation is thus far carried on, the plaster must be suffered to harden; after which the tow may be withdrawn, and the nostrils left free and open for breathing. The mouth is then to be closed in its natural position, and the plaster brought down to the extremity of the face. When the mask is dry, it forms a mould for a perfect cast.

MODILLION; an ornament resembling a bracket, in the Ionic, Corinthian, and Composite cornices. In Grecian architecture, however, the Ionic order is without modillions in the cornice, as are also the Roman examples of the same order, with the exception of the temple of Concord, at Rome, which has both modillions and dentils.

MODULATION, in *music*, is, in its most extensive meaning, the diversified and proper change of tones in conducting the melody, or the progression of tones in general, and the sequences of concords. In its narrower sense, *modulation* signifies that succession of tones by which a musical passage proceeds from one key into another. In quite short pieces, also in those compositions in which the theme remains for some time in the principal tone before it passes to another, good modulation consists only in continuing for some time melody and harmony in the assumed tone, with proper changes and variety, and at last concluding in that tone. For this it is requisite that, at the very beginning, the concord should become distinctly perceptible by the sound of its essential tones, the octave, fifth, and third; and further that the melody, as well as harmony, should be carried through the tones of the assumed scale, and that no tones foreign to it should be heard either in the melody or in the harmony. A variety of concords is however necessary, that the ear may enjoy the necessary change. The rule to let only those tones be heard which belong to the assumed scale is to be understood thus,—that a tone foreign to the scale ought to be used merely in passing, and to be left again immediately; thus, for instance, in the scale *C* sharp, one would certainly go through *G* sharp into *A* flat, and through *F* sharp to the dominant, and from this back again to the principal tone, without violating, by these two tones foreign to the fundamental tone, *C* sharp, the effect of the scale, or destroying it. It is only necessary to avoid tones totally foreign to the scale of *C* sharp; such, for instance, as *D* sharp.

The second kind of modulation, or that which is so called in a more restricted sense, requires more knowledge of harmony, and is subject to greater difficulty. It consists in giving to longer pieces the necessary variety, by more frequent change of tones, and requires a knowledge of the relation among the various keys, and of the tones connecting them. As it is indispensable in longer pieces to carry melody and harmony through several keys, and to return at last to the fundamental, it is necessary, in respect to such modulation, duly to consider the character of the composition, and, in general, whether the modulation has merely in view a pleasing variety or whether it is intended to serve as the support of a grand and bold expression. Considerations of this kind give to the composer the rules for particular cases, and show where he may depart widely from the principal tone and where he should remain near it, where he may thus depart suddenly, and perhaps with some harshness, and where his departures ought to be slow and gradual, because such departures are the most important means of musical expression.

In pieces of a mild and quiet character, it is not permitted to modulate so often as in those which have to express violent and great passions. Where every thing relating to expression is considered, modulation also must be so determined by the expression that each single idea in the melody shall appear in the tone which is most proper for it. Tender and plaintive melodies ought to dwell only on the flat tones; while the lighter sharp tones, which must be touched in the modulation, on account of the connexion, ought to be left immediately afterwards. It is one of the most difficult parts of the art to remain steadily without fault in a modulation. It is therefore to be regretted that those who write on the theory of the art dwell so little on this important subject, and believe that they have done enough if they have shown how the composer may gracefully leave the principal tone, pass through the circle of the ascending and descending scale, and return at last to the first tone.

Piccini had the best views of modulation. "Modulating," he says, "is to pursue a certain path. The ear will follow you; nay, it wishes to be led by you, yet upon condition that, after you have led it to a certain point, it shall find something to reward it for its journey, and to occupy it for some time. If you do not consider its claims, it suffers you to go on, at last, without regard, and every endeavour to attract it again is but lost labour." To conduct a melody according to a given modulation, never to deviate from it except for good reason, and in the right time to return to it in the proper way and without harshness, to make use of changes in the modulation only as means of expression, and perhaps for the necessary variety,—such are the real difficulties of the art; while to leave immediately a key which has hardly been perceived, to ramble about without reason or object, to leap about because the composer does not know how to sustain himself—in one word, to modulate in order to mo-

dulate, is to miss the true aim of the art, and to affect a richness of invention in order to hide the want of it.

MODULE; an architectural measure; the lower diameter of a column being divided into two parts, one is a module, and each module is divided into thirty minutes; thus neither is a determinate, but a proportionate measure. The term is also sometimes used with reference to the different sizes of medals.

MOLE, in *architecture;* a massive work formed of large stones laid in the sea by means of coffer-dams, extended either in a right line or an arc of a circle, before a port, which it serves to close, to defend the vessels in it from the impetuosity of the waves, and to prevent the passage of ships without leave. Thus we say, The mole of the harbour of Messina, &c.

MOLLE, in *music* (soft, or sweet); a relative term, signifying a *flat sound*, that is, a sound which is half a tone lower than the sound with which it is compared,—B flat, or B *molle*, is a semi-tone beneath B natural. This term, as its sense intimates, is applied to the flat sounds on account of their supposed softness or sweetness, in comparison with the effect of the natural and sharp tones.

MOLLITES OSSIUM; a morbid softness of the bones, which become preternaturally flexible, in consequence either of the inordinate absorption of the phosphate of lime, from which their natural solidity is derived, or else of this matter not being duly secreted and deposited in their fabric.

MOLTO, in *music;* a word used in conjunction with some other, by way of augmentation, as *molto allegro*, very quick; *molto adagio*, very slow.

MOLYBDENUM; a metal which has not yet been reduced in masses of any considerable magnitude, but is generally obtained in small, separate globules, of a blackish, brilliant colour. It is extremely infusible. By heat, it is converted into a white oxide, which rises in brilliant, needle-formed flowers. Nitric acid readily oxidizes and acidifies the metal; nitre detonates with it, and the remaining alkali combines with its oxide. Molybdenum unites with several of the metals, and forms with them brittle compounds. The specific gravity of the pure metal is 8.611: it has three degrees of oxidation, forming two oxides and one acid. The *molybdic acid* is composed of forty-eight parts of molybdenum and twenty-four of oxygen; it has a sharp, metallic taste, reddens litmus paper, and forms salts with alkaline bases; specific gravity, 3.4. It is very sparingly soluble in water; but the molybdates of potash, soda, and ammonia, dissolve in that fluid, and the molybdic acid is precipitated from the solutions by any of the strong acids. The *protoxide* of molybdenum is black, and consists of one equivalent of oxygen and one equivalent of molybdenum. The *deutoxide* is brown, and contains twice as much oxygen as the protoxide. Berzelius has formed three chlorides of this metal, the composition of which is analogous to the compounds of this metal with oxygen.

The native *sulphuret* of molybdenum occurs in most primitive countries, disseminated in granite or gneiss rocks, in thin plates of a foliated structure, soft, flexible, slightly soiling the fingers, and greasy to the feeling; colour pure lead-gray; lustre metallic; specific gravity 4.591. It does not melt before the blow-pipe, but emits sulphureous fumes. It is nowhere found in large quantities, although known to exist in numerous places. Its principal European localities are Altenberg, in Saxony, and Schlaggenwald and Zinnwald, in Bohemia. In the United States of America, the largest and best pieces have been found in the gneiss quarries of Haddam, Connecticut, where plates half an inch thick, and four inches over, have been met with. At this place it often exhibits the low six-sided prism. It also occurs at Brunswick, in Maine, in the same rock, and at Chesterfield, Massachusetts, in granite.

MOMENTUM, in *mechanics*, is the same with *impetus*, or quantity of motion, and is generally estimated by the product of the velocity and mass of the body. This is a subject, however, which has led to various controversies between philosophers, some estimating it by the mass into the velocity, as stated above, while others maintain that it varies as the mass into the square of the velocity; but this difference seems to have arisen rather from a misconception of the term than from any other cause, those who maintain the former doctrine understanding *momentum* to signify the momentary impact, and those who hold the latter considering it as the sum of all the impulses, till the motion of the body is destroyed.

MONEY; the common medium of exchange among civilized nations. Money must consist of a material, 1. which has a value of its own; 2. which every man is willing to accept in exchange for his property; 3. whose value is readily ascertained. If this material is moulded into a particular form, and stamped with a mark denoting its value, so that it is appropriated expressly to the exchanging of articles having value, it is called *money*, in distinction from other articles which have value, but which are not used as a medium of exchange. The materials of which money is made, as well as the coin, are merchandise, like other articles that are bought and sold. Different nations have chosen for money different materials, all having more or fewer of the above-mentioned peculiarities. All nations advanced in trade and the arts give preference to metals, especially the precious metals; for, 1. They derive value from the smallness of their quantities, compared with the demand for them in the ornamental and useful arts. 2. They are very little subject to corrosion and destruction by use. 3. They are susceptible of minute division, and may be used in small quantities or masses. 4. They are easily transported, as their transportation to any distance will cost but a small part of their value. 5. The quantity is increased by labour. The advantage of using the precious metals for a universal currency is still greater when persons are appointed under the authority of the law to decide what pieces shall be circulated as money, to stamp them so as to fix their weight and fineness, and to furnish them with the superscription of the authority by which they are authorised. Such pieces are called *coins*, and form the ordinary medium of exchange.

Instead of money, the merchant often receives a promissory note or bill: this substitute is sometimes improperly termed *money*. It is manifest that promissory notes or bills of exchange are of the same value with the real money only while they can be readily exchanged for coin, and that they must lose their value in proportion as the credit of those who issue them sinks. This is true of all paper money, all metallic money whose current value is higher than its real value, and all notes or bonds taken instead of money. That any sort of money may be received

for its real value, or that which it represents, and trade be carried on by means of it, it is necessary that its value should be acknowledged wherever it is used. A distinction, however, is made between money which is received in only one trading-place or small circle, issued in time of peculiar necessity, denominated *tokens*, &c., also coins current in only one country, and money which is every where acknowledged and received, such as bars of gold and silver, of a certain weight and fineness. The exchangeable value of gold and silver, like that of all other commodities, depends, in the first place, on their abundance or scarcity, or, in other words, the quantity supplied in comparison with the quantity wanted, or for which there is a demand; and, in the second place, upon the labour necessary in extracting the ore from the mines, and refining it.

The comparative value of gold and silver is necessarily very nearly the same all over the world, since each metal costs but a trifle for transportation, and both are articles of value every where. The quantities of gold in its various forms of coin and bullion of all descriptions, including bars, plate, &c., have been estimated at 10,000,000lbs. troy weight. A scarcity of money can occur only when, 1. the material of which it is manufactured is deficient; or, 2. when those who are in want of it have nothing to give in exchange to its possessors. In the latter case, there is no real deficiency of money, for there are individuals who, by the terms of the supposition, possess the money: there is only a deficient demand for goods on hand, and those only are in want of money who are unable to dispose of these goods. All mechanics, artisans, and manufacturers, want money enough to purchase the raw materials which they consume, and to pay the wages of their labourers. Merchants need money to pay manufacturers and producers for their goods, and to transport them where they are wanted; and the last consumer needs it to give in exchange for what he eats, drinks, wears, &c., to the dealer of whom he procures the requisite articles. Now, if any one of these classes has not the money required for any of those purposes, there is a scarcity of money for that class of individuals. In these and similar cases, the scarcity of money does not suppose a real scarcity of gold and silver, or a deficiency of coined metals. The scarcity arises from the want of industry, or means, in any class of citizens, to procure the money in circulation, or from their industry being directed to the production of such articles as there is no present demand for among the actual possessors of money; as when, for instance, in grain-growing countries, there is a deficiency of purchasers of the grain produced, there not being consumers enough of the grain, who can obtain or produce desirable articles in exchange for it. In such a case, the producers of grain can obtain money only by exportation of the article to foreign ports. And if it happen that the foreign lands to which it is exported are already provided with grain from some other quarter, it will remain unsold—not because there is no money, but because there is no motive to induce its possessors to part with it for grain.

In places where manufactures of any kind prosper, a certain quantity of money is required to provide the materials. This sum is easily ascertained, according to a certain average, and there is no scarcity of money for these purposes as long as this sum is on hand. But when the manufacture is increased, by the operation of particular circumstances, and the place produces more goods than common upon this account, a scarcity of money may easily occur among those devoted to this branch of business. If now these persons possess goods or credit, they make use of both to obtain the money required from other parts, which will depend, again, upon their being able to pay the expenses of transporting their goods, or to give to the holders of money a higher interest than they can elsewhere obtain. Money, in such cases, becomes of more value in these places than in those where it is not so much in demand; and it follows, from this, that money will leave the places where it is abundant to seek those where, from the want of it, more will be paid for its use; and, in this manner, a scarcity of money will work its own cure.

Money is profitable to any country only by means of its circulation; for circulation makes money the continually repeated cause of the production of new portions of property: and, on this account, a very small sum of money which is in constant circulation is of far more benefit to a country than the possession of the largest sums which remain locked up, and do not change owners. A great quantity of money, therefore, is of no service to a country, unless there are desirable things in that country, for the purchase of which it is to be paid, and thus transferred from one to another. When, therefore, more money flows into any country than will pay for what the country actually produces, money becomes of less value, and the money price of merchandise greater. In this case, it is better to procure the goods from countries where their money price is less. The money will thus be exported again, and procure a return of cheap goods in its place. But, by this process, the industrious part of the population is injured, and those only receive profit who make these exchanges of money for foreign goods. The labouring classes therefore experience a scarcity of money, because the articles which they produce do not command a ready sale. In this manner, all the gold and silver obtained by Spain and Portugal from South America passed into foreign countries in exchange for foreign necessaries. The only true means, then, to remove and to prevent permanently a scarcity of money is to improve the state of domestic and internal industry; and their opinion is wholly destitute of foundation who believe that a mere plenty of money is sufficient to develope a healthy state of domestic industry; for the money does not produce the goods, but follows their production. And money will not stay in a country that does not contain goods upon which it may be expended, but it seeks those countries which produce the objects of desire.

The money now used in this country is formed principally of the precious metals, with which our commercial transactions abundantly supply us; but the gold and silver money at present in circulation is principally of modern coinage, a fact sufficiently proved by the following tables:—

Gold Money.

Year.	Double Sovereigns.	Sovereigns.	Half Sovereigns.
1817	—	3,235,239	1,040,098
1818	—	2,347,230	515,143
1819	—	3,574	—
1820	—	931,994	17,521
1821	—	9,405,114	115,644

Year.	Double Sovereigns.	Sovereigns.	Half Sovereigns.
1822	—	5,356,787	—
1823	30,838	616,770	112,140
1824	1,402	3,767,904	295,769
1825	—	4,200,343	380,575
1826	—	5,724,046	172,415
1827	—	2,266,629	246,007
	32,240	37,855,633	2,895,314

Silver Money.

Year.	Crowns.	Half Crowns.	Shillings.	Sixpences.
1816	—	114,048	1,306,998	384,120
1817	—	1,011,582	1,151,568	273,042
1818	38,808	363,132	67,122	107,118
1819	170,874	598,752	379,764	117,810
1820	112,068	299,574	398,772	37,224
1821	109,494	179,388	123,156	21,582

	462,476	3,432,528	4,148,694	990,594

The following document, copied from a paper laid before the House of Commons, gives the quantity of pounds weight of standard gold received into His Majesty's mint from the 6th August, 1831, to the 9th February, 1832, and of the value of gold monies coined, specifying the proportion of each denomination of coin, and stating the amount retained for assaying, loss, and coinage, and how the same has been applied:—

Quantity of gold received in the Mint. Standard weight.	Value of monies coined.	Charges incurred for coinage.	How the charge for coinage has been applied.			
			To the moneyers, by agreement, bearing all waste and expenses in the coinage.	To the melter, by agreement, bearing all waste and expenses.	For the master's regulated fees, applied under act of Parliament.	For contingent expenses in the different offices of the Mint.
lbs. oz. dwt. gr.	*£. s. d.*	*£. s. d.*	*£. s. d.*	*£. s. d.*	*£. s. d.*	*£. s. d.*
12,365 11 14 15	438,046 10 0	3,134 15 3	1,640 12 6	390 12 6	859 7 6	244 2 9

The following is an accurate account of the bank notes or paper money in circulation for four successive years:—In 1829, 20,953,000; 1830, 19,631,000; 1831, 20,575,000; and in 1832, 18,542,000.

The value of the metallic currency, as a medium of circulation, differs considerably in different countries, even in coins of the same name. The following table furnishes a comparative view of their value with reference to our own money: it may, however, be proper to add that commercial changes will make some difference in this amount at different periods.

The copper coinage is almost entirely confined to the *cent*, which is worth rather more than the English halfpenny.

The following are the weights of the English coinage:

	oz.	dwt.	gr.
Sovereign	0	5	3.274
Half Sovereign	0	2	13.637
Double Sovereign	0	10	6.549
Five Sovereign	1	5	16.370
Sixpence	0	1	19.7-11ths
Shilling	0	3	15.3-11ths
Half-Crown	0	9	2.2-11ths
Crown	0	18	4.4-11ths

MONOCHORD, an ancient instrument, or machine, so called because it is furnished with only one string. Its use is to measure and adjust the ratios of the intervals, which it effects by the means of movable bridges, calculated to divide the chord at the pleasure of the experimentalist. The *monochord* appears to have been in constant use with the ancients, as the only means of forming the ear to the accurate perception, and the voice to the true intonation, of those minute and difficult intervals which were then practised in melody.

MONOCHROME, in *ancient painting;* a painting with one single colour. This description of art is very ancient, and was known to the Etruscans. The first specimens of the art of painting were of one tint only, which was most commonly red, made either with cinnabar or minium. Instead of red, white paint was sometimes used. Quintilian says of Polygnotus, and Pliny of Zeuxis, that their performances of this kind were of the latter description. The antique tombs of the Tarquins, in the neighbourhood of Corneto, offer several figures painted in white upon a dark ground. The first four plates in the first volume of the paintings of Herculaneum contain several monochromes upon marble. The most numerous monuments existing of this kind of painting are on terra cotta.

MONOLITHIC; consisting of a single stone. According to Herodotus, there was a monolithic sanctuary attached to a temple at Sais, dedicated to Minerva, twenty-one cubits long, fourteen wide, and eight high, which was brought from Elephantine. The carriage of it employed 2000 men three years. Some striking specimens of monolithic temples are still found in Egypt, and, like the monolithic obelisks, bear testimony to the wonderful application of mechanical power among the ancient Egyptians.

MONOPOLY is an exclusive right, secured to one or more persons, to carry on some branch of trade or manufacture, in contradistinction to a freedom of trade or manufacture enjoyed by all the world, or by all the subjects of a particular country. The most frequent monopolies formerly granted in Europe were the right of trading to certain foreign countries, the right of importing or exporting certain articles, and that of exercising particular arts or trades in certain towns or boroughs. These species of monopoly are now generally understood to be injurious. They still subsist, however, to a very considerable extent in Europe, but they have never been introduced into the United States of America. There is, however, one species of monopoly sanctioned by the laws, not only of that country, but of all countries that have made any advances in the arts, namely, the exclusive right of an invention or improvement for a limited number of years. The exclusive right of an author to the publication of his own work is hardly a monopoly, but rather a right of property, resting upon the same principle as the right to lands or chattels. The law, therefore, by giving an author the exclusive right to the publication of his own work, for a limited number of years, makes no grant; it is only allowing him what is his own, for a limited time. But the exclusive right to the use of an invention or improvement is a monopoly, since it deprives others, for that period, of the chance of the advantage of making the same improvement, discovery, or invention themselves. It is taking away a right which they before had.

MONSOONS; periodical trade-winds, which blow six months in one direction and the rest of the year in an opposite one. They prevail in the Indian Ocean, north of the tenth degree of south latitude. From April to October, a violent south-west wind blows, accompanied with rain; and from October to April a gentle, dry, north-east breeze prevails. The change of the winds, or the *breaking up* of the monsoons, as it is called, is accompanied by storms and hurricanes. These periodical currents of winds do not reach very high, as their progress is arrested by mountains of a moderate altitude. (See WINDS.)

MONSTERS, in *physiology;* creatures whose formation deviates in some remarkable way from the usual formation of their kind. The deviation consists sometimes in an unusual number of one or several organs; sometimes, on the contrary, in a deficiency of parts; sometimes in a malformation of the whole or some portion of the system, and sometimes in the presence of organs or parts not ordinarily belonging to the sex or species. In most cases, these unusual formations are not incompatible with the regular performance of the natural functions, although they sometimes impede them, and in some cases are entirely inconsistent with the continuance of the vital action. It is not surprising that we should be ignorant of the manner in which monsters, or irregular births, are generated or produced; though it is probable that the laws by which these are governed are as regular, both as to cause and effect, as in common or natural productions.

Formerly, it was a general opinion that monsters were not primordial or aboriginal, but that they were caused subsequently, by the power of the imagination of the mother transferring the imperfection of some external object, or the mark of something for which she longed and with which she was not indulged, to the child of which she was pregnant, or by some accident which happened to her during her pregnancy. But this has been disproved by common observation, and by philosophy: not perhaps by positive proofs, but by many strong negative facts; as the improbability of any child being born perfect, had such a power existed; the freedom of children from any blemish, though their mothers had been in situations most exposed to objects likely to produce them; the ignorance of the mother of any thing being wrong in the child, till, from information of the fact, she begins to recollect every accident which happened during her pregnancy, and assigns the worst or the most plausible as the cause; the organization and colour of these adventitious substances; the frequent occurrence of monsters in the brute creation, in which the power of the imagination cannot be great; and the analogous appearances in the vegetable system. Judging, however, from appearances, accidents may perhaps be allowed to have considerable influence in the production of monsters of some kinds, either by actual injury upon parts, or by suppressing or deranging the principle of growth, because, when an arm for instance is wanting, the rudiments of the deficient part may generally be discovered.

MONTGOLFIER BALLOON. This ingenious species of aëronautic machine appears better fitted for the purpose of navigating the air than the balloon usually employed, as it is less costly and more manageable than the hydrogen gas balloon. Under the article AERONAUTICS we have the history of its inven-

tion, and it only remains to point out its peculiar advantages.

The montgolfier or fire balloon, of which we give a graphic representation, owes its property offloating in the atmosphere to the rarefying power of heat applied to the air contained within. There is a vulgar error that the "smoke renders the balloon buoyant·" that, however, is not the fact, as the carbon of which the smoke is really composed is specifically heavier than the atmosphere. From this will be seen the impolicy of employing those combustible bodies which make much smoke. With common care on the part of the aëronaut, there is no real danger of the balloon igniting, as the air contained within, being deprived of its oxygen, might extinguish combustion, but would never produce it.

In a common hydrogen gas balloon the aërostat is made to ascend by discharging ballast, and descend by allowing the gas to escape. Now these processes will cease to operate for want of the necessary materials after one or two ascents; but with the montgolfier balloon a traveller may ascend by a slight addition to his fuel, or descend by lowering the fire, any number of times. With this control over the balloon, advantage may be taken of currents at different heights in the air, and the whole apparatus thus rendered much more manageable than it is usually found. The cloth should of course be rendered incombustible by some saline solution.

Month; the twelfth part of the year, and so called from the moon, by whose motions it was formerly regulated, being properly the time in which the moon runs through the zodiac. The lunar month is either illuminative, periodical, or synodical.

The *illuminative month* is the interval between the first appearance of one new moon and that of the next following. As the moon appears sometimes sooner after one change than after another, the quantity of the illuminative month is not always the same. The Turks and Arabs reckon by this month. A *lunar periodical month* is the time in which the moon runs through the zodiac, or returns to the same point again, the quantity of which is 27 d. 7 h. 43′ 8″. A *lunar synodical month*, called also a *lunation*, is the time between two conjunctions of the moon with the sun, or between two new moons, the quantity of which is 29 d. 12 h. 44′3″11‴. The ancient Romans used lunar months, and made them alternately of twenty-nine and thirty days. They marked the days of each month by three terms, *calends*, *nones*, and *ides*.

The *Solar month* is the time in which the sun runs though one entire sign of the ecliptic, the mean quantity of which is 30 d. 10 h. 29′ 5″, being the twelfth part of 365 d. 5 h. 49′, the mean solar year. The *astronomical* or *natural month* is that measured by some exact interval, corresponding to the motion of the sun or moon; such are the lunar and solar months above mentioned. The *civil* or *common month* is an interval of a certain number of whole days, approaching nearly to the quantity of some astronomical month. These may be either lunar or solar. The *civil lunar month* consists alternately of twenty-nine and thirty days. Thus will two civil months be equal to two astronomical ones, abating for the odd minutes; and so the new moon will be kept to the first day of such civil months, for a long time together. This was the month in civil or common use among the Jews, Greeks, and Romans, till the time of Julius Cæsar. The *civil solar month* consisted alternately of thirty and thirty-one days, excepting one month of the twelve, which consisted only of twenty-nine days, but every fourth year of thirty days. The form of civil months was introduced by Julius Cæsar. Under Augustus, the sixth month (till then, from its place, called *Sextilis*) received the name *Augustus* (now *August*), in honour of that prince; and, to make the compliment still greater, a day was added to it, which made it consist of thirty-one days, though till then it had only contained thirty days, to compensate for which a day was taken from February, making it consist of twenty-eight days, and twenty-nine every fourth year. Such are the civil or calendar months now used throughout Europe.

Monument. The productions of sculpture and architecture, intended to transmit to posterity the memory of remarkable individuals or events, are most generally understood by the term monuments of antiquity. Such as ornament public places, gardens, &c., are chiefly in commemoration of great events. Among the monuments in honour of individuals are tombs and sepulchral edifices or columns. In all ages, and with every nation, we find this description of monument, from the first rude attempts of art to its greatest perfection. The most ancient known to us are the obelisks and pyramids of Egypt, and, perhaps contemporary with these, the tombs of the Persian kings, which are still beheld with admiration in the ruins of Persepolis. These monuments command our awe by their grandeur and simplicity, in which they are perhaps superior to similar works of Grecian art, though the latter excel them in beauty. Hardly any country offered so great a number of monuments as Greece, where they were erected in honour of the victors in battle, and in the solemn games, and of other distinguished men, but were often also thrown away on the undeserving. The warrior had statues and trophies; the victor in the games had statues

and pillars. On the isthmus of Corinth, near the temple of Neptune, were statues of the victors in the Isthmian games; in the holy grove of Altis, near Olympia, were those of the victors in the Olympic games. There were also many trophies. Buildings were frequently erected in commemoration of distinguished persons or events, which differed greatly in form and splendour. Thus, in Athens, the choragic monuments were erected in honour of those who had received the prizes as *choragi* in the theatrical and musical games. In these games it was customary for each of the ten guilds of Athens to select one *choragus*, who, at his own expense, undertook the regulation and superintendence of the games. Each endeavoured to surpass the other; the conqueror received a tripod of brass as the prize, which was usually the work of a great artist, and was regarded as an honour to his family. This prize was publicly placed on a small edifice or a single pillar, on which the name of the *choragus* and the date of the games were inscribed. A particular street in Athens, called the street of *tripods*, was appropriated to these monuments. Some of these have been preserved to our time. The most splendid of all, and the most ornamented, is the choragic monument of Lysicrates, usually called the *lantern of Demosthenes;* next to this are the monuments of Thrasyllus and Thrasycles, and some pillars. The Romans, who contended with the Greeks in the arts, were equally successful in monuments, of which one species (the triumphal arch) is entirely theirs. (See TRIUMPHAL ARCH.)

The earliest tombs in Greece and Rome were erected either on the spot where the ashes of the deceased were deposited or in some other place chosen at pleasure. These latter were termed *cenotaphs.* Both kinds were found in the cities or their vicinity, and scattered along the roads, which they ornamented. The rude stone was by degrees transformed into a noble pillar; subsequently, on a foundation of stone, two small pillars were erected, covered with a pediment, and the intermediate space was destined for the image of the deceased, inscriptions, and bass-reliefs. Small buildings in the form of temples followed, and these, in time, increased in magnificence. (SEE TOMB.)

MOON is the name given to the satellites which revolve round the primary planets and illuminate them with light reflected from the sun. In common language, we mean by *moon* the particular satellite of our earth. Like the other heavenly bodies, it daily alters its apparent position among the fixed stars, and in the course of a month appears to make a complete revolution round the heavens, from west to east, while, at the same time, it has, like the fixed stars, an apparent daily motion from east to west. Among all the heavenly bodies, the moon is the nearest to us. Its mean distance is estimated at about thirty times the diameter of the terrestrial equator, or 237,000 miles. The point at which it approaches nearest the earth is called its *perigee;* the point of its greatest distance is called the *apogee.* It passes through both these points in each revolution. According as it is nearer to or further from the earth its diameter, as seen from the earth, appears larger or smaller. In the moon's revolution great inequalities are remarked. These arise mostly from the strong attraction of the sun in the various positions which it assumes relatively to the earth. This was first understood after Newton's discovery of the universality of the law of gravity. Tobias Mayer published the first accurate lunar tables. Besides the double motion of the moon round our earth, and with the earth round the sun, it also revolves on its own axis. It completes a revolution on its own axis in the same time with its revolution round the earth, as appears from its always presenting the same side to the earth. In consequence of this remarkable coincidence, the earth must appear to a spectator on the moon to be always in the zenith. One side of the moon, moreover, never receives the reflection of the sun's rays from the earth, while the other is constantly illuminated by it; both sides, however, are equally illumined by the direct rays of the sun. Some little irregularity has been perceived in the surface of the moon presented to the earth, its spots sometimes appearing more to the north, at others more to the south; a similar variation is perceived east and west. This phenomenon is denominated the *libration* of the moon in latitude and longitude. The causes of both have been discovered.

Of all the heavenly bodies, the moon, from its comparative proximity to the earth, is the one of which most is known. That it is an opaque body, receiving its light from the sun, is evident from the phenomena of solar and lunar eclipses, but more particularly from the various phases which it presents. Even the naked eye discovers, on the illuminated surface of the moon, several spots, more or less bright; and a good telescope shows us in the bright parts, on the limits of illumination, prominences and depressions, which are regarded as mountains and valleys. The numerous observations of Herschel and Schröter, through a number of years, have put the existence of these beyond dispute. The large dark spots appear, when intersected by the frontier line of illumination, always even and without prominences. Hence they are supposed to be plains, consisting of a substance which has comparatively little power of reflecting the sun's rays. That they are seas is not probable, since Huygens observed great depressions in them, and Schröter, in several of these depressions, discovered evident traces of various horizontal strata, lying one upon the other, and forming a wall around them. Schröter, who measured several of these depressions, found their diameter to be from thirty feet to more than half a mile; the diameter of one, in fact, was more than sixteen miles, and its depth 30,000 fathoms.

The shepherd Endymion, according to Pliny, first observed the course of the moon and its changes. Hence the story of Endymion and Diana. Even the Chaldeans considered the moon as the smallest among the heavenly bodies and the nearest to the earth; they knew that her light was borrowed, fixed her periodical phases with much accuracy, and attributed her eclipses to the shadow of the earth. That the moon was inhabited was conjectured by Orpheus, or rather by the author of the verses which exist under his name; and Pherecydes of Scyros, a contemporary of Servius Tullius, is said to have determined the time of her revolution. The Pythagoreans affirmed that the moon contained mountains, cities, plants, animals, and men. Anaximander knew the size of the moon, its distance from the earth, and that its light was borrowed from the sun. The spots on its surface Clearchus considered to be seas.

In modern times, this planet has occupied much of the attention of astronomers. Doctor Francis von

Paula Gruithuisen, professor of astronomy at Munich, has, of late years, paid great attention to the moon, and his discoveries and hypotheses, though wanting confirmation, have excited much interest. In his opinion, the straight lines, often of considerable length and a parallel direction, which have been observed on its surface, and which are made up of objects resembling in shape a star, an inverted Z, &c., are, in fact, roads, with cities, temples, dwellings, &c. At present, however, these conjectures can hardly be regarded as more than the creations of a lively imagination. (See ASTRONOMY.)

MORAL PHILOSOPHY. See PHILOSOPHY.

MORDANTS. The colouring substances used in dyeing have been divided by Doctor Bancroft into *substantive* and *adjective* colours. *Substantive* colours are those which communicate their tint immediately to the material to be dyed, without the aid of any third substance. *Adjective* colours require the intervention of a third substance, which possesses a joint attraction for the colouring matter and the stuff to be dyed. The substance capable of thus fixing the colour is called a *mordant*, and by Mr. Henry a *basis*. (See DYEING.)

MOROXYLIC ACID; the name applied by Klaproth to an acid found in combination with lime, forming a blackish-brown coating, on the trunk of a white mulberry tree at Palermo. Its taste and other qualities approach nearest to those possessed by the succinic acid. It crystallizes in colourless transparent prisms, and is soluble in water and alcohol.

MORPHIA; a new vegetable alkali, extracted from opium, of which it constitutes the narcotic principle. It is obtained pure by the following process:—A concentrated infusion of opium is boiled with a small quantity of common magnesia for a quarter of an hour: a considerable quantity of a grayish deposit falls: this is washed on a filter with cold water, and when dry digested in weak alcohol for some time, at a temperature beneath ebullition. In this way, a little morphia and a great quantity of colouring matter are separated. The matter is then drained on a filter, washed with a little cold alcohol, and afterwards boiled with a large quantity of highly rectified alcohol. This liquid, being filtered while hot, on cooling, deposits the morphia in crystals, and very little coloured. The solution in alcohol and crystallization being repeated two or three times, colourless morphia is obtained. It crystallizes in double four-sided pyramids, whose bases are squares or rectangles; sometimes also in prisms, with trapezoidal bases. It dissolves in eighty-two times its weight of boiling water, and the solution, on cooling, deposits regular and colourless crystals. It is soluble in thirty-six times its weight of boiling alcohol, and in forty-two times its weight of cold alcohol. It dissolves in eight times its weight of sulphuric ether. All these solutions change the infusion of brazil-wood to violet, and the tincture of rhubarb to brown. According to M. Bussy, morphia consists of

Carbon	69.0
Hydrogen	6.5
Azote	4.5
Oxygen	20.0
	100.0

With acids it forms a class of salts in like manner as do the other vegetable alkalies. *Sulphate of morphia* crystallizes in prisms, which dissolve in twice their weight of distilled water. They are composed of

Acid	22
Morphia	40
Water	38
	100

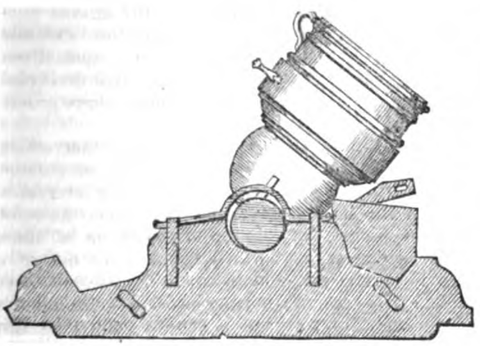
Nitrate of morphia yields needle-formed crystals in stars, which are soluble in one and a half times their weight of distilled water. *Muriate of morphia* is soluble in ten and a half times its weight of distilled water. The acetate crystallizes in needles, the tartrate in prisms, and the carbonate in short prisms. Tincture of galls is said to be a good test of morphia, free or combined. Subacetate of lead throws down all the animal matters with which acetate of ammonia may come to be associated in the stomach, without acting on that vegetable salt. The excess of lead may be separated from the clear liquor by a few bubbles of sulphuretted hydrogen; and the morphia may then be recognized by crystallization *in vacuo*, and by the red colour which nitric acid imparts to it. No morphia is found in the blood of animals killed with it. Morphia acts with great energy on the animal economy. A grain and a half, taken at three different times, produced such violent symptoms upon three young men of seventeen years of age, that Sertürner was alarmed lest the consequences should have proved fatal.

MORTALITY. The law of mortality is that which determines the proportion of the number of persons who die in any assigned period of life or interval of age, out of a given number who enter upon the same interval, and consequently the proportion of those who survive. Tables showing how many out of a great number of children, as 10,000 or 100,000, born alive, die in each year of their age, and consequently how many complete each year, and exhibiting this law through the whole extent of life, are called *tables of mortality*. The basis of such calculations must be an accurate register of the number of births and deaths, and, in the case of the latter, at what ages in a given district or extent of country. In England the bills of mortality, or abstracts from parish registers, show the numbers who are born and die in the different parishes; and in other countries similar mortuary registers are kept. The results furnished by such tables are very various, and of great interest.

If the registers were kept with sufficient accuracy and minuteness, they would enable us to determine the proportion of deaths, not only at different ages and in different regions, but at different seasons, in persons of different occupations and habits, in towns or in the country, and would afford valuable materials for the science of political economy. Although much more attention has been paid to this subject in recent times, yet the observations have not been so extensive nor so accurate as is desirable. The first table of mortality was constructed by Doctor Halley, from the mortuary registers of Breslau, for five years ending with 1691, and was inserted in his paper on the subject in the *Philosophical Transactions* for 1693, with many useful observations on the purposes to which such tables may be applied. (See LONGEVITY.)

MORTAR, in *gunnery*, is a kind of short cannon, of a large bore, with chambers. Mortars are made of stone, brass, or iron. Their use is to throw hollow shells filled with powder, which, falling on any building, or into

the works of a fortification, burst, and their fragments destroy every thing within reach; also balls of stone, carcasses, bags filled with grape-shot, &c. They were first used in sieges for throwing great balls of stone and of red-hot iron, before the invention of shells. On this account, the caliber of a mortar, in Germany, is generally estimated by the weight of a stone of the size of the bomb which it is intended to throw. In Denmark and Russia, on the contrary, the caliber is estimated by the actual weight of an iron ball fitting it; in this country and France, by its diameter in inches. In the larger states of Europe, 10, 16, 25, 30, 50, and 60 pound mortars, according to the stone weight measure, are used. In the Prussian army, 7, 10, 25, 50, 75 pound mortars are customary. Formerly they were used even of 120 lbs. weight; but these are not employed at present, except in particular cases. Their length is generally from 2¼ to 3½ times the diameter of the caliber. The best form of the mortar is shown beneath :—



The interior parts of a mortar are the chamber, the bore, the mouth, the vent. The chamber is the place where the charge of powder is lodged. The shape of the chamber varies. It is generally conical, more or less truncated. *Land mortars* are those used in sieges, and mounted on beds. The beds are made of very solid timber, and placed upon very strong timber frames. *Stone mortars* serve to throw stones into the enemy's works when near at hand. *Sea mortars* are those which are fixed in bomb-vessels for bombarding places by sea; they are made much longer and somewhat heavier than land mortars.

The use of mortars is thought to be older than that of cannon, for they were employed in the wars of Italy to throw balls of red-hot iron and stones long before the invention of shells. It is generally believed that the Germans were the inventors, and that they were used at the siege of Naples, in the reign of Charles VIII., in 1435. It is more certain that shells were thrown out of mortars at the siege of Wachtendonk, in 1588, by the count of Mansfield.

Mortar, in *building*. That species of earthy composition which is especially fitted to resist the action of water, or a damp climate, is described under the article Cement, and we now propose examining the cheaper forms known as mortar.

The mode of making the very durable material suggested by M. Loriot may be first described :— Take one part of brick-dust finely sifted, two parts of fine river-sand skreened, and as much old slaked lime as may be sufficient to form mortar with water in the usual method, but so wet as to serve for the slaking of as much powdered quick-lime as amounts to one-fourth of the whole quantity of brick-dust and sand. When the materials are well mixed, employ the composition quickly, as the least delay may render the application of it imperfect or impossible. With respect to this method, Dr. Higgins observes that M. Loriot corrects the bad quality of the old and effete lime, which constitutes the basis of his mortar, and which has regained a part of the fixed air that had been expelled from it, by the addition of fresh and non-effervescent lime, hastily added to it at the time of using the composition, which must undoubtedly improve the imperfect mass. According to Dr. Higgins, the perfection of lime prepared for the purpose of making mortar consists chiefly in its being totally deprived of its fixed air. On examining several specimens of the lime commonly used in building, he found that it was seldom or never sufficiently burnt, for they all effervesced, and yielded more or less fixed air, on the addition of an acid, and slaked slowly in comparison with well-burnt lime. Dr. Higgins also relates some experiments which show how very quickly lime imbibes fixed air from the atmosphere, on its exposure to which it by degrees soon loses those characters which chiefly distinguish it from mere lime-stone or powdered chalk, by soon attracting from thence that very principle to the absence of which it owes its useful quality as a cement, and which had before been expelled from it in the burning. Hence he concludes that, as limes owes its excellence to the expulsion of fixed air from it in the burning, it should be used as soon as possible after it is made, and guarded from exposure to the air as much as possible before it is used. It is no wonder, therefore, he says, that London mortar is bad, if the imperfection of it depended solely on the badness of the lime; since the lime employed in it is not only bad when it comes fresh from the kiln, because it is insufficiently burnt, and the air has access to it, but becomes worse before it is used, by the distance and mode of its conveyance, and when slaked is as widely different from good lime as it is from powdered chalk. For a similar reason, every other cause which tends to restore to the lime the fixed air of which it had been deprived in the burning must depreciate it.

It must receive this kind of injury, for instance, from the water, so largely used, first in slaking the lime, and afterwards in making it into mortar, if that water contains fixed air, from which few waters are perfectly free, and which will be greedily attracted by the lime. The injury arising from this cause is prevented by the substitution of lime-water, so far as it may be practicable or convenient.

From other experiments, made with the view of ascertaining the best relative proportions of lime, sand, and water, in the making of mortar, it appeared that those specimens were the best that contained one part of lime in seven of the sand; for those which contained less lime, and were too short whilst fresh, were most easily cut and broken, and were pervious to water; and those which contained more lime, although they were closer in grain, did not harden so soon, or to so great a degree, even when they escaped cracking by lying in the shade to dry slowly. It appeared, further, that mortar which is to be used where it must dry quickly ought to be made as stiff as the purpose will admit, or with the smallest

practicable quantity of water, and that mortar will not crack, although the lime be used in excessive quantity, provided it be made stiffer or to a thicker consistence than mortar usually is.

Dr. Higgins has also shown that though the setting of mortar, as it is called by the workmen, chiefly depends on the exsiccation of it, yet its duration, or its acquiring a stony hardness, is not caused by its drying, as has been supposed, but is principally owing to its absorption of fixed air from the atmosphere, and is promoted in proportion as it acquires this principle, the accession of which is indispensably necessary to the induration of calcareous cements. In order to the greatest induration of mortar, therefore, it must be suffered to dry gently and set; the exsiccation must be effected by a temperate air, and not accelerated by the heat of the sun or fire; it must not be wetted soon after it sets; and afterwards it ought to be protected from wet as much as possible, until the mortar is finally placed and quiescent; and then it must be as freely exposed to the open air as the work will admit, in order to supply acidulous gas, and enable it sooner to sustain the trials to which mortar is exposed in cementing buildings, and other incrustations.

Dr. Higgins also enquired into the nature of the best sand or gravel for mortar, and into the effects of bone-ashes, plaster, powder, charcoal, sulphur, &c., and he deduces great advantages from the addition of bone-ashes, in various proportions, according to the nature of the work for which the composition is intended.

Fresh-made mortar, if kept from the air under ground in considerable masses, may be preserved a great length of time without injury, and the older it is before it is used the better, the builder taking the precaution to beat it up afresh previous to using it; for it not only sets sooner, but acquires a greater degree of hardness, and is less apt to crack. A fact related by Mr. Smeaton remarkably illustrates these points. Having had occasion to take up a large flat stone of a close grain, of about five feet square, that had probably lain above a century at the bottom of a malt cistern, he found that it had been well bedded in mortar, which had become coagulated to the consistence of cheese; but, having never come to a perfect dryness, it so far retained its natural humidity that he found it might, with some pains, be beaten up to mortar without any addition of water; and afterwards, being suffered to dry in the air, it set to a stony hardness, and appeared as good mortar as any which that part of the country could produce. Pliny informs us that the ancient Roman laws prohibited builders from using mortar that was less than three years old; and to this circumstance he expressly attributes the remarkable firmness of the oldest buildings in the city. A similar custom prevailed, and indeed still prevails, in Vienna, requiring the mortar to be a year old before it is employed. But there is nothing which shows, in so striking a point of view, the advantage and necessity of beating mortar (and the effect produced is owing to something more than a mere mechanical mixture of ingredients) as the preparation of grout, or liquid mortar. This differs from common mortar only in containing a larger quantity of water, so as to be sufficiently fluid to penetrate the narrow irregular interstices of rough stone walls, and is generally made by diluting common mortar with water, either cold or hot. It not unfrequently happens that this refuses to set, and at all times it is a long while in acquiring the proper hardness; but if, instead of common mortar, that which has been long and thoroughly beaten is employed, the grout will set in the space of a day, and soon after acquires a degree of hardness much superior to what is made in the common manner.

Mortar which sets without cracking, whether this be owing to the due proportion of sand or to the slow exhalation of the water from mortar containing less sand, never cracks afterwards, whatever its faults, in other respects, may be. As it is the lime paste, and not the sand, which contracts and produces fissures in drying, so the more sand there is in the composition, the less the cracks will be seen. Mortar which is liable to crack becomes irreparably injured by frequent alternations of wetting and freezing; for the water imbibed by the smallest fissures, dilating as it congeals, loosens its whole texture. Where, however, it is composed of seven parts of sorted sand to one of lime, it is not disposed to crack.

To show more clearly how much our slight buildings are weakened by the agitations and percussions to which they are exposed, first in erecting the walls and settling the timbers, and then in driving those wedges to which the wainscots, mantlepieces, and other ornaments, are fastened, we must observe that the absorption of carbonic acid by mortar contributes nothing to the strength of it, if it enter before it is finally fixed in a quiescent state. A little experience is sufficient to teach us that the same matter which assists in the induration of mortar never serves to repair the fissures, or solution of continuity between the bricks and cement, which happen after it is set. When mortar is set, and before it is indurated, it may be easily severed from the bricks and crumbled; and, for want of softness, it cannot bend into the fissures, or resume its former condition in any time. Hence, by heavy blows, and in wedging, our walls must be greatly weakened; and the more so as the houses are slight, quickly built, and hastily finished.

Nothing is more common than for bricklayers to keep their mortar some time exposed to the air in heaps, before they consider it fit for use, a practice which may perhaps be accounted for if we consider that some portions of every kind of lime used in this country do not slake freely, by reason of their not being sufficiently burned, or the admixture of gypseous or argillaceous matter, which portions, like marl, slake in time, though not so quickly as the purer lime. The plasterers, who use a finer kind of mortar, made of sand and lime, observe that their stucco blisters if it contains small bits of unslaked lime; and, as smoothness of surface is with them of more consequence than excessive hardness, they take care to secure the perfect slaking of their lime by allowing sufficient time for the imperfect parts to be penetrated by the moisture. The bricklayers, trusting perhaps more to the judgment of the plasterers, in this respect, than to their own, and considering it very convenient to slake a large quantity of lime at once, follow the same practice, without caring for or apprehending the real fact, that mortar, when exposed to the air, is worse for every hour it is kept, and that they are taking such measures as will prevent it from ever acquiring that degree of hardness in which its perfection consists.

Among the circumstances which contribute to the speedy ruin of modern buildings, it may also be

observed that mortar made with bad lime, and a great excess of it, is used with dry bricks, and not unfrequently with warm ones. These immediately imbibe or dissipate much of the water; and, as the cement approaches nearer to dryness, it is still liable to be displaced by the percussions of the workmen. To make strong work, the bricks ought to be soaked in lime-water, and freed from the dust with which they are commonly covered. By this means the bricks are rendered closer and harder, the cement, by setting slowly, admits the motion which the bricks receive when the workman dresses them, without being impaired, and it adheres and indurates more perfectly. This steeping of the bricks is an imitation of the practice of the plasterers, who always wet the wall before they commence their work, because they know the cement will not otherwise adhere. This ought to be done as long as the wall is thirsty, and lime-water is the most proper liquid they can use. The same advantage that attends the soaking of bricks would attend the soaking of bibulous stones in lime-water.

Mortification, in *medicine*, is the death of a part of the body while the rest continues alive, and often in a sound state. If the part be a vital organ, as the lungs, its death must necessarily be followed by that of the whole person. Mortification is called *gangrene* and *sphacelus*, when occurring in soft or fleshy parts, as in the stomach or the limbs; and *caries* when in a bone, as in the spine, in the skull, &c. It is caused by violent inflammation, by exposure to freezing cold, by hospital fevers, by languid, or impeded, or stopped circulation, as in cases of bed-ridden or palsied persons, and by improper food, particularly the spurred or mildewed grain. It may be recognized, when preceded by inflammation, by the following signs:—subsidence of pain, heat and redness, and loss of sensibility; brown lividity, blistered skin with bloody serum in the vesicles, offensive odour occurring in the part, and by a small, rapid, intermitting pulse; by shiverings followed with cold sweat, diarrhœa, delirium, hickup, dejection of spirits, and by a wild cadaverous countenance. When a part which has been frozen is suddenly exposed to heat, mortification rapidly ensues; the part becomes florid; inflammation is unsuccessfully attempted, and sphacelus is the result. In the above species a distinctly marked line divides the dead and living portions; often a healthy separation ensues.

Mortification is common in the fevers, wounds, and injuries of the crowded jails and military hospitals of Europe. This gangrene is considered contagious by some surgeons, the nurses and orderlies suffering from ulcers and sloughs on the hands, when touched with the sponges used in cleansing the sick. The same effect is produced on the sound portions of the skin of the sick. This hospital gangrene is distinguished by its rapid spread to contiguous parts, as from the fingers to the arms, by the oozing of grumous blood, by horrible fetor, by fatal depression of spirits, and by the sullen despair of patients who on the day of battle or of amputation were the bravest of the brave. Sometimes the cutting a nail to the quick, or a slight bruise, will induce gangrene in old or debilitated persons.

Mildew mortification differs from other kinds in appearance and process, beginning with coldness and numbness in the fingers or toes without fever, but with spasms and hebetude of mind; it separates arms, legs or thighs, and nose. It is more often found in the voluptuous rich than in the labouring poor, in huge feeders than in free drinkers. It is thought to be connected with a diseased state of the digestive organs, and great nervous debility. Mr. Pott sometimes checked it by opium in a few days, and, after the dropping off of the affected parts, the patients recovered health. There is a dry gangrene to which palsied persons as well as others are liable, which slowly destroys the limb, and commonly without inflammation or putrefaction. This is sometimes explained by the absence of warmth, and moisture, and air, which are removed by preceding atrophy: the colour is livid, though sometimes nearly natural. When the bones of the leg mortify or become carious, new osseous matter is provided in sound constitutions. This process, occupying years when left to nature, is much accelerated by the artificial removal of the dead bone.

Mosaics are imitations of paintings by means of coloured stones, pieces of glass, of marble, and even of wood of different colours, cemented together with much art. The name is sometimes supposed to be derived from *Moses*, as the pretended inventor; sometimes from *Musa*, in the sense of elegance, beauty; and sometimes from *μουσειον*, museum (a grotto consecrated to the muses), perhaps from the circumstance that mosaic work was first used in grottoes. We know nothing with precision of the invention and history of this art in antiquity. Probably it originated in the East, but received its perfection from the Greeks, and was thus conveyed to the Romans in Sylla's time. In Italy, and in most of the countries occupied by the Romans, many floors ornamented with mosaic work have been found amongst the ruins. When, in the fifth century, the arts and sciences were driven from Italy by the distracted state of the country, this art was preserved by the Byzantine Greeks, and was restored to Italy in the thirteenth century, where it attained the highest perfection, particularly when Clement VIII., at the commencement of the seventeenth century, had the whole of the interior of the dome of St. Peter's ornamented with this work. Giambattista Calandra improved mosaic by the invention of a new cement. He and many succeeding artists employed the art for copying original paintings of famous artists, and thus eternizing them in their original freshness and beauty; for one of the greatest advantages of this kind of painting is its wonderful power of preservation. In this manner Guercino's Martyrdom of St. Petronilla, and Dominichino's Communion of the dying St. Jerome, were preserved. Peter Paul, of Christophoris, founded, at the commencement of the eighteenth century, a school for mosaic in Rome, and many of his scholars carried the art to a still higher degree of excellence.

In recent times two kinds of mosaic are particularly celebrated,—the Roman and the Florentine. In the former the paintings are formed by joining very small pieces of stone, which gives greater variety and elegance, and facilitates the representation of large historical paintings. The Florentine style, which makes use of larger pieces of stone, is far more troublesome, and is adapted only for simple subjects.

Mosaic in wood the Italians call *tansia* or *tarsia;* the French *marqueterie*. In the most costly mosaics, precious stones have been cut to furnish materials; but in common works of this art enamels of different

colours, manufactured for the purpose, are the material employed. The enamel is first formed into sticks, from the ends of which pieces of the requisite size are cut or broken off. These are confined in their proper places upon a plate of metal or stone, by a cement made of quicklime, pulverized limestone, and linseed oil. The cement is spread over the plate, and a drawing made on it to guide the artist, before he commences his work. He has also constantly before him the painting to be copied. After the whole has adhered it is allowed to dry for two months, and is then polished with a flat stone and emery. Inlaid works, of agate and other costly stones, are executed on the same principle as mosaic, except that the stones are cut to the shape of the different parts of the object to be represented, whereas in mosaic the pieces are of the same size and shape.

The *opus reticulatum* of the ancients, with which columns and walls were sometimes incrusted, is found to consist of small stones of a pyramidal form, the apex of which is imbedded in mortar, while the base which is polished forms the outer surface. A mode has recently been invented of sawing the plate with the mosaic paintings into two or three sheets, and thus multiplying the paintings. Should smoke or dirt soil the surface, it has only to be polished to be restored to its original beauty. In 1819, Fernbach, a native of Baden, invented a new kind of mosaic painting, imitating with surprising fidelity the colour, the juncture, the lustre, &c., of mineral bodies. Professor Blank's mosaics of moss have also attracted much attention.

Moselle Wines; a sort of clear and dry wines, with a light pleasant flavour and high aroma, produced in the countries on and near the Moselle. They are generally only first-rate ordinary wines, but are sometimes of a superior quality. They come to maturity in about five or six years, but, in a favourable season, they will keep twice that time without deterioration. The best are produced at Braunenberg, Graach, Wehlen, Zeltingen. The Drobner and Neumanger are also esteemed. They are now much used in Prussia, on account of the high duties on foreign wines. The Moselle wines are often recommended for their diuretic qualities.

Motet formerly signified a studied composition, enriched with all the beauties of the musical art. At present, the name of *motet* is given to every composition set to Latin words; such as hymns, psalms, or any small portion of scripture, in the Roman Catholic church. In Germany the name is given to figured musical pieces, generally intended only for singing, the subjects of which are passages of the Bible. There are some for four, five, and six voices. The motets of France and Italy are always accompanied by instrumental music. The subjects are also passages of the Bible, generally in rhymed Latin verses, whilst the words of the German *motet* are in prose. The German *motet* is chiefly confined to the Protestant part of Germany. The two Bachs may be said to have carried the German *motet* to its highest perfection.

Motion. The motion of a body is the change of its place in space. All changes in the material world consist of motion. The life of the organic creation and the action of inorganic bodies consist in motion: what we call *rest* is only relative. Experience alone convinces us of the motion of bodies in space. Zeno of Elea endeavoured to prove this fundamental idea of motion to be contradictory to itself, in order to overthrow the testimony of experience. If we see that a body changes its external relations, we conclude that it moves: its continuance in the same relations is called *rest*. By a change of the situation or relation of bodies we are often deceived, and confound *rest* with *motion*. In some cases it is easy to perceive the error; in others it is so difficult that many centuries have been necessary to dispel the illusion; for instance, in relation to the earth and the sun.

In motion, we must consider the cause, the moving body, the direction, the path described, the time, the velocity, and the quantity. The mass of the moving body must be taken into consideration, since the quantity of motion depends on the quantity of matter. To move twice as much matter requires twice as much power. The direction of the motion of a body is the line along which a moving point proceeds, either for the whole or a part of the way. If all the points of a body move in the same direction it is only necessary to observe the motion of a single point. The line described by this point is the path of the moving body. This path itself, if in a straight line, represents the direction of the motion; if in a curved line, the direction at every point of the curve is determined by the tangent to this point; that is, this tangent shows the direction of the moving body at that point in which it would continue to proceed if it ceased changing its direction. If all the points of a body do not move in the same direction, the motion of each point in particular ought to be observed; and thus we may consider every motion as the motion of a point. By the space described, we understand the distance passed through by the moving point. Since we always consider the motion of points, this space is represented by a line; and thus the observation of motion becomes geometrical. Time is necessary for motion, even for the smallest. By the comparison of the space described, and the time in which it is described, we find the velocity. One body moves quicker than another if it describes in the same time a larger space, or the same space in a less time.

By the *quantity of motion* we mean the velocity combined with the quantity of matter. To move two pounds requires twice as much power as to move one pound with the same velocity. To move a body with the velocity 2 also requires twice as much power as to move the same body with the velocity 1. Hence it follows that to move two pounds with the velocity 3 requires six times as much power as to move one pound with the velocity 1. Motion may be considered under several different views. With regard to change of position, by which it is ascertained, it is either *absolute* or *relative*. If a body passes from one place to another, this is called *absolute motion*; it is *relative* if we consider the objects to which we refer the motion of the observed body, whether in motion or at rest, as fixed points. With regard to change of position the motion is further either *common* or *proper*; finally, either *apparent* or *real*. With regard to the powers or causes which produce motion, it is either *simple* or *compound*: *simple* if it is produced by a single power, or by several powers acting in the same direction; *compound* if several motions meet, the various directions of which form angles with each other. With regard to the direction, the motion is either in a *straight* or a *curved* line; with regard to the velocity, it is

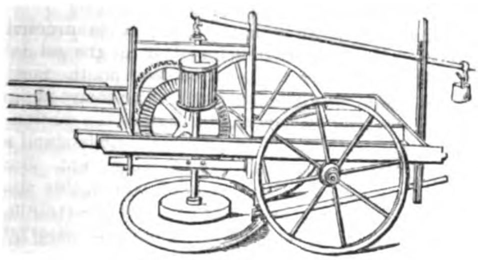
uniform, or *accelerated*, or *retarded*, and the accelerated motion again is either uniformly or variably accelerated; and the retarded motion either uniformly or variably retarded.

MOULDING. See ARCHITECTURE.

MOUND, in *heraldry*; a globe, having a cross on the top. Many heraldic eagles, as those of Austria, Russia, Prussia, have in one claw the sceptre, in the other the mound.

MOUTH; in most animals, a cavity in the anterior part of the body, but very differently formed in different sorts of animals. It commonly serves for the reception of food, and is connected by a canal with the interior parts of the body, where the food is assimilated. In the higher orders it is used for mastication, the emission of sound, deglutition, respiration, suction, and taste, being connected with organs which perform those processes. The lower jaw only is movable in this division. Some of the lower orders seem to be without a mouth, and to nourish themselves by absorption. In birds, the external parts of the mouth are a hard, bony substance, and it is not fitted for suction. In insects, the form of the mouth is very various.

MOWING MACHINE; an instrument by which a series of knives or scythes are made to perform the office of *human* power.



One of the most simple of these machines is represented above. It is intended to be driven by a single horse placed behind the carriage, and as the supporting wheels roll forward they act on a series of wheels and pinions, so as to drive forward the knives. The height of the horizontal cutting-wheel is regulated by a lever and weight, placed in the front of the machine.

Machinery, when applied to this and similar purposes, should be introduced but slowly, and with great caution. In manufacturing districts, there are new sources of employment continually arising from the artificial wants of society; but the hasty introduction of agricultural machinery, by displacing a large portion of the rural population, produces the most mischievous consequences. No one can doubt the truth of the axiom, that the man who causes two blades of grass to grow where but one vegetated before must be a great benefactor to mankind; but such a result will not be produced by machinery: on the contrary, we find that in many soils the plough has been advantageously laid aside and spade husbandry resorted to. (See PLOUGH.)

MOXA; a soft lanuginous substance, prepared from the young leaves of a species of mugwort. It is used by the surgeons in the following way:—A little cone of the moxa is laid upon the diseased part, previously moistened, and set on fire at the top. It burns down with a temperate glowing heat, and produces a dark-coloured spot, the separation of which is promoted by applying a little garlic. The ulcer is left to discharge, or is healed up, according to the object in view. The moxa is famous in the East for curing several diseases, and the French are much in the habit of using it; but, whenever English surgeons wish to produce a slough, they have recourse to caustics, in preference to actual fire.

MUCIC ACID; this acid has generally been known by the name of *saccholactic* acid, because it was first obtained from sugar of milk; but all the gums appear equally to afford it. To obtain it from a gum, we have only to heat one part of this substance with two of nitric acid, till a small quantity of nitrous gas and of carbonic acid is disengaged, when the dissolved mass will deposit, on cooling, the mucic acid. The pulverulent acid is soluble in about sixty parts of hot water. It decomposes the muriate of barytes, and both the nitrate and muriate of lime. It scarcely acts upon the metals, but forms salts with their oxides.

MUCUS; one of the primary fluids of the animal body, perfectly distinct from gelatin and vegetable mucus; transparent, glutinous, thready, and of a salt savour. It contains water, muriate of potassa, soda, lactate of lime and of soda, and phosphate of lime. The mucus forms a layer of greater or less thickness at the surface of the mucous membranes, protects these membranes against the action of the air, of the aliment, the different glandular fluids, &c. Independently of this general use, it has others that vary according to the situation of the mucous membranes: thus the mucus of the nose is favourable to smell, that of the mouth to the taste; while that of the stomach and the intestines assists in the digestion. A great part of the mucus is absorbed again by the membranes which secrete it: another part is carried outwards, either alone (as in blowing the nose or spitting), or mixed with the pulmonary transpiration, or with the excremental matter, &c.

MULATTO is commonly used to signify the offspring of a black and a white. The mulatto is of a yellow colour, with curled or woolly hair, and resembles the European more than an African. The descendants of Europeans and Indians are called *mestizos*. In Spain, the term *mulatto* is often applied to those persons in whom the Moorish blood has been mingled with the Spanish.

MULBERRY; a genus of plants allied to the nettle, and belonging to the natural family *urticeæ*. It is a native of China, and the Chinese claim the art of rearing silk-worms, and manufacturing stuffs, from a very remote period. From China, this art was introduced into India and Persia, and was practised there for many ages before it reached Europe. The Greeks became acquainted with silk subsequent to the time of Alexander; and it was not till the end of the Republic that the Romans for the first time saw this precious article. For many ages, silk bore an enormous price at Rome; but, about the middle of the sixth century, during the reign of Justinian, two monks arrived at Constantinople from India, bringing with them the white mulberry and the eggs of the silk-worm. From Constantinople, the white mulberry was introduced into Greece, and about the year 1130 into Sicily and Italy.

The first mulberry that was planted in France was living in 1802, and there still remain some stocks that are apparently of nearly the same age. It is now cultivated and naturalized throughout the south

of Europe, and in some of the central parts of that continent. In southern climates, the leaves appear to contain a less proportion of water, and more of that substance which causes the worms to produce silk in greater abundance and of a finer quality. In Greece, Asia Minor, and Persia, it is usual to give to the worms the branches, with the leaves attached to them; but in Spain, Italy, and France, the leaves are carefully stripped from the trees, taking care to despoil each tree entirely, otherwise the sap will be unequally attracted. The varieties of this tree are very numerous. The most approved mode of cultivation is from seed, and in the south of France no other mode is adopted.

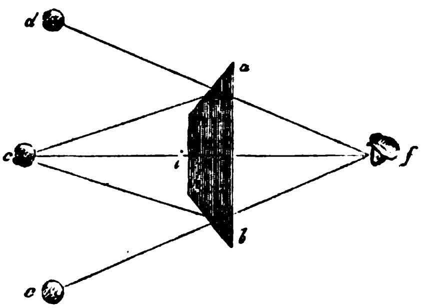
The *paper mulberry* is of a moderate size, bearing leaves which are either simple or divided into lobes more or less deep, rough above and hairy beneath. It was originally from India and Japan, but is now very commonly cultivated in Europe, and succeeds even in the more northern parts. For a long time the female plant was unknown in Europe, and at the present time it is rare in this country. The islanders of the Pacific make a kind of clothing from the bark of this tree in the following manner:—Twigs of about an inch in diameter are cut and deprived of their bark, which is divided into strips, and left to macerate for some time in running water. After the epidermis has been scraped off, and while yet moist, the strips are laid out upon a plank in such a manner that they touch at the edges, and two or three layers of the same are then placed upon them, taking care to preserve an equal thickness throughout. At the end of twenty-four hours the whole mass is adherent, when it is removed to a large, flat, and perfectly smooth table, and is beaten with little wooden clubs, till it has attained the requisite thinness. This kind of cloth is easily torn, and requires to be washed and beaten many times before it acquires its full suppleness and whiteness. The natives dye it red and yellow, and also make a similar cloth from the bread-fruit tree, but that from the mulberry is preferred.

The paper which is used in Japan and many other countries in the East Indies is made from this plant. For this purpose the annual shoots are cut after the fall of the leaves, tied in bundles, and boiled in water mixed with ashes; after which the bark is stripped off by longitudinal incisions, and deprived of the brown epidermis. The bark of the more tender shoots is separated from the rest, as it furnishes a very white paper for writing, while that produced by the remainder is coarse and gray, and serves for wrapping or similar purposes. The writing-paper is not suitable for quills, and these nations employ hair pencils, or the feathers of birds. For painting they make use of wooden blocks; and this, as well as the writing, can be executed only on one side. Silk-worms will eat the leaves of this tree indiscriminately, even when mixed with those of the white mulberry.

MULE, in *manufactures;* a machine, invented by Crompton in 1779, for producing finer yarn than was spun by the machines previously in use, and which has now nearly superseded the jenny. For producing threads of the finest kind a process is necessary which is called *stretching*, and which is analogous to that performed with carded cotton upon a common spinning-wheel. In this operation portions of yarn several yards long are forcibly stretched in the direction of their length, with a view to elongate and reduce those places in the yarn which have a greater diameter and are less twisted than the other parts, so that the size and twist of the thread may become uniform throughout. To effect the process of stretching, the spindles are mounted upon a carriage, which is moved backwards and forwards across the floor, receding when the threads are to be stretched, and returning when they are to be wound up. The yarn produced by *mule-spinning* is more perfect than any other, and is employed in the fabrication of the finest articles. The sewing-thread spun by mules is a combination of two, four, or six constituent threads. Threads have been produced of such fineness that a pound of cotton has been calculated to reach 167 miles. (See SPINNING.)

MULTIPLE, in *arithmetic*, is a number which contains another number a certain number of times. Thus eighteen is a multiple of six, or of three, or of nine, &c. A *Common multiple* of two or more numbers is that which contains those numbers a certain number of times. Thus thirty-six is a common multiple of four and nine, being equal to nine times the former, and four times the latter. To find the *least common multiple* of several numbers, reduce them all to their prime factors; then the product of the greatest powers of those prime factors is the least common multiple required.

MULTIPLYING GLASS, in *optics*, a plano-convex lens of which the rounded surface is ground into a series of small planes, and, as each plane gives a distinct pencil of rays, there will be as many images as there are plane surfaces in the glass.



Thus in the above figure *a b* represents the plane side of the glass, and *i c* a ray of light passing to the eye at *f*. Objects will appear at *d* and *e* exactly similar to that at *c*, in consequence of the rays of light impinging on the side planes, which by a new series of refractions give a distinct image to each plane. Images are not formed at the angles *g* and *h*.

MUMMIES; the dead bodies of the Egyptians, which were preserved by embalming. Owing either to the religious opinions of the Egyptians or to the nature of the country, which rendered interment inconvenient, or the want of fuel, which rendered burning difficult, they embalmed all their dead, and deposited them in subterraneous chambers, or in grottoes excavated in the mountains. An immense number of them have been found in the plain of Saccara, near Memphis; hence called the *plain of the mummies*, consisting not only of human bodies, but of various animals, or heads of animals, bulls, apes, ibises, crocodiles, fish, &c. Numerous caves or grottoes, with contents of the same kind, are

found in the two mountainous ridges which run nearly parallel with the Nile from Cairo to Syene. Some of the most remarkable of these tombs are those in the vicinity of ancient Thebes in the Lybian mountains, many of which were examined by Belzoni, and those near Eleithias (described by Hamilton), further up the river, which, though less splendid than the Theban sepulchres, contain more illustrations of the private life of the Egyptians. The sepulchral chambers are almost entirely covered with fresco paintings and bass-reliefs, and frequently contain statues, vases, &c. Some of them (the royal sepulchres) consist of suites of spacious halls and long galleries of magnificent workmanship. Those of private individuals vary according to the wealth of the deceased, but are often very richly ornamented. Many of these tombs have been ransacked by Arabs for the purpose of plunder, and great numbers of the mummies destroyed for the rosin or asphaltum they contain, which is sold to advantage in Cairo. The tombs and mummies are, many of them, two or three thousand years old, and are in part indebted for their preservation to the dryness of the soil and the mildness of the climate. The processes for the preservation of the body were very various. Those of the poorer classes were merely dried by salt or natron, wrapt up in coarse cloths, and deposited in the catacombs. The bodies of the rich underwent the most complicated operations, and were elaborately adorned with all kinds of ornaments.

Embalmers of different ranks and duties extracted the brain through the nostrils, and the entrails through an incision in the side; the body was then shaved, washed, and salted, and after a certain period the process of *embalming*, properly speaking, began. The whole body was then steeped in balsam and wrapped up in linen bandages; each finger and toe was separately enveloped, or sometimes sheathed in a gold case, and the nails were often gilded. The bandages were then folded round each of the limbs, and finally round the whole body, to the number of fifteen or twenty thicknesses. The head was the object of particular attention: it was sometimes enveloped in several folds of fine muslin, the first of which was glued to the skin, and the others to the first; the whole was then coated with a fine plaster. A collar of cylindrical glass beads of different colours was attached to the mask which covered the head, and with it was connected a tunic of the same material. The beads, both in the collar and tunic, were so arranged as to form images of divinities, of the scarabæus, the winged globe, &c. Instead of this the mummy was sometimes placed in a sort of sheath, made of paper or linen, and coated with a layer of plaster, on which were paintings and gilding. These paintings represented subjects relating to the duties of the soul, and its presentation to the different divinities; and a perpendicular hieroglyphical inscription in the centre gave the name of the deceased, and of his relations, his titles, &c. The whole was then placed in the coffin.

Those mummies which have been examined present very different appearances. One class has an opening in the left side, under the armpit, and in another the body is whole. Some of those which have been opened have been dried by vegetable and balsamic substances, others by salt. In the former case aromatic gums or asphaltum were used (the gums, when thrown into the fire, give out an aromatic odour); in these the teeth and hair are generally preserved; but, if exposed to the air, they are soon affected. Those prepared with asphaltum are of a reddish colour, and are in good preservation. Those dried with saline substances are of a black, hard, smooth appearance. On exposure to the air they attract moisture, and become covered with a saline substance. Those mummies which have no opening are also partly preserved by saline substances, and partly by asphaltum. In the latter, not only the cavities of the body are filled with it, but the flesh, bones, and every part seem to be penetrated by it: it was probably injected in a hot state. These are the most commonly met with. They are hard, black, and without any disagreeable smell. The whole mummies prepared with salt alone are white and smooth, and resemble parchment.

The coffin is usually of sycamore, cedar, or pasteboard; the case is entire, and covered within and without by paintings representing funeral scenes, and a great variety of other subjects: the name of the deceased is also repeated on them in hieroglyphic characters. The cover, which is also entire, is ornamented in the same manner, and contains too the resemblance of the deceased in relief, painted, and often gilded. The breast is covered with a large collar; a perpendicular inscription occupies the centre, and funeral scenes the sides. The coffin is often enclosed in a second, and even third case, each of which is also ornamented with similar representations.

Human bodies preserved in other ways, either by accident or by some artificial preparations, are also called mummies. The Guanches, or aboriginal inhabitants of the Canaries, preserved the bodies of their deceased friends, which have been found in great numbers in the catacombs in Palma, Ferro, Teneriffe, &c. The natives called them *xaxos*. They are dry, light, of a yellow colour and strong odour, and often injured by worms; they are enveloped in goat skins and enclosed in cases. They are supposed to have been dried in the air, after having had the entrails removed; and they were also covered with a sort of aromatic varnish. Humboldt found mummies prepared in a similar manner in Mexico. The Peruvians also had the art of preserving the bodies of their incas.

The burial-place of the Capuchin monastery at Palermo, in Sicily, is a large subterranean vault divided into several wide and lofty galleries, in the walls of which are niches containing several hundred human bodies, kept in an upright position by being fastened to the wall behind, and clothed in their usual dress. The monks have a peculiar manner of preserving bodies, which they keep secret. Natural mummies are frequently found preserved by the dryness of the air. In a vault of the cathedral at Bremen, called the *lead-cellar* (because it was formerly employed for melting lead for aqueducts and organ pipes), are bodies in good preservation. In the monastery of St. Bernard, on mount St. Bernard, the bodies of travellers who have been buried in the snow are deposited in a chapel, in which there are open windows protected by grates. They are placed in a sitting position, leaning each on another's breast. The cold prevents their putrefaction, and gives them time to dry. The Gaulish mummies, in the cabinet of comparative anatomy, in the Jardin

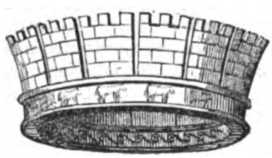
du Roi, were found in Auvergne in the last century. They bear no marks of any balsamic preparation, but are enveloped in linen, and appear to have been interred with great care. It is uncertain whether their preservation was owing to the nature of the soil or to a peculiar and now unknown process of embalming.

Mummies were formerly used in medicine, under the name of *mumia vera*, on account of the balsam they contained; but they have long ceased to be so employed.

MUMPS; the common name of the disease called, in scientific language, *cynanche parotidea*. It comes on with the usual febrile symptoms, which are soon attended with a swelling of the jaws and neck, sometimes on one side only, but commonly on both. The causes of it are not known with certainty. Children are more subject to it than adults. It seems sometimes to be the effect of cold. It is often epidemic, and, according to Cullen, is contagious. In general it runs its course without dangerous symptoms, and hardly requires any remedies; exposure to the cold should be avoided. The mean duration is from ten days to a fortnight.

MURAL ARCH; a wall, or arched wall, placed exactly in the plane of the meridian, for fixing a large quadrant, sextant, or other instrument, to observe the meridian, altitude, &c., of the heavenly bodies.

MURAL CROWN, in *heraldry*; an insignia of distinguished honour. The mural crown, of which a representation is given in the accompanying engraving, was originally given by the Roman senate as a reward to the soldier who first ascended the battlements of an enemy's wall. It was generally formed of gold; and, if the soldier placed the Roman standard on the wall, its value was considerably increased. By *murialle* is meant an ordinary that is walled.



MURIATES, in *chemistry*; a genus of salts, formed from the muriatic acid with certain bases.

MURIATIC ACID. The name of this acid is derived from *muria*, the Latin name of sea-salt, from which it is extracted. It is also called, in commerce, the *marine acid*, and the *spirit of salt*. Sometimes it is denominated the *hydrochloric acid*, in allusion to its composition. It is said to have been known as early as the time of Basil Valentine, though, as a gas, it was unknown till 1772, when it was obtained by Priestley, by heating the liquid acid, and receiving it in glass vessels filled with mercury. It is now procured in the gaseous form from the decomposition of common salt by sulphuric acid, and may be collected without the use of a mercurial cistern, simply by delivering it from the gas-bottle through a narrow tube, at the bottom of a phial or jar: the gas, being of a specific gravity of 1.259, displaces the air, and completely occupies the vessel. If an inflamed taper be immersed in it, it is immediately extinguished. It is destructive of animal life; but the irritation produced by it on the epiglottis scarcely permits its descent into the lungs. It is merely changed in bulk by alterations of temperature, but experiences no change of state. It is absorbed with great rapidity by water. A bottle full of the gas, if opened in water, is almost instantaneously filled.

Water absorbs about 500 volumes of this gas; and the solution, when cold, has the density of 1.1958. The common process for obtaining liquid muriatic acid is the following: common salt, sulphuric acid, and water, equal weights, the acid being mingled with one-third of water, and when cold poured on the salt; the gas evolved is conducted through reservoirs of water, and subjected to pressure in contact with it. The specific gravity of the acid thus obtained is 1. 17. It is generally slightly tinged with yellow, from the presence of muriate of iron derived from the vessels used in the process. It combines, like the other powerful acids, with the alkalies, earths, and metallic oxides, forming a very peculiar class of salts. The following table contains the quantity of real acid in 100 parts of liquid muriatic acid, at the temperature of 60°, according to *Dalton*.

Atoms.			Acid per cent. by weight.	Acid per cent. by measure.	Specific Gravity.	Boiling Point. 60°.
Acid.		Water.

Muriatic acid is a valuable article of the *materia medica*. It is particularly used in cases of dyspepsia that are attended with morbid secretions, in hepatic derangements, and in cutaneous diseases. It is also of considerable value as a disinfecting agent.

MURRAIN; a contagious disease among cattle, principally caused by a hot, dry season, or general putrefaction of the air, which begets an inflammation of the blood and a swelling in the throat, which soon prove mortal. The symptoms are a hanging down and swelling of the head, abundance of gum in the eyes, rattling in the throat, a short breath, palpita-

tion of the heart, staggering, a hot breath, and a shining tongue.

MUSCLE. In our article ANATOMY the reader will find a general account of the human structure, including a list of the bones forming the frame-work, which give to it form and stability; and it may now be advisable to examine the muscles, or cords, by which the motions are performed. It would, however, be too severe a tax on the reader, in a work not expressly intended for the education of medical students, to enter into a verbal list of many pages in extent merely to enumerate the muscles as they occur in the human body; we shall therefore confine ourselves to their general structure, uses, and chemical character. The parts that are usually included under this name consist of distinct portions of flesh susceptible of contraction and relaxation, the motions of which, in a natural and healthy state, are subject to the will; and for this reason they are called *voluntary* muscles. Besides these, there are other parts of the body that owe their power of contraction to their muscular fibres; thus the heart is a muscular texture, forming what is called a *hollow* muscle; and the stomach, intestines, &c., are enabled to act upon their contents, merely because they are provided with muscular fibres: these are called *involuntary* muscles, because their motions are not dependent on the will. The muscles of respiration being, in some measure, influenced by the will, are said to have a *mixed* motion. The names by which the voluntary muscles are distinguished are founded on their size, figure, situation, use, or the arrangement of their fibres, or their origin and insertion; but, besides these particular distinctions, there are certain general ones that require to be noticed. Thus, if the fibres of a muscle are placed parallel to each other, in a straight direction, they form what is called a *rectilinear* muscle; if the fibres cross and intersect each other, they constitute a *compound* muscle; when the fibres are disposed in the form of rays, a *radiated* muscle; when they are placed obliquely with respect to the tendon, like the plume of a pen, a *penniform* muscle.

Muscles that act in opposition to each other are called *antagonists;* thus every extensor has a flexor for its antagonist, and *vice versâ*. The muscles being attached to the bones, the latter may be considered as levers, that are moved in different directions by the contraction of those organs. That end of the muscle which adheres to the most fixed part is usually called the *origin*, and that which adheres to the more movable part the *insertion* of the muscle.

In almost every muscle, two kinds of fibres are distinguished; the one soft, of a red colour, sensible, and irritable, called *fleshy* fibres; the other of a firmer texture, of a white glistening colour, insensible, without irritability or the power of contracting, and named *tendinous* fibres. They are occasionally intermixed, but the fleshy fibres generally prevail in the *belly* or middle part of the muscle, and the tendinous ones in the extremities. If these tendinous fibres are formed into a round slender cord, they form what is called the *tendon* of the muscle; on the other hand, if they are spread into a broad flat surface, it is termed an *aponeurosis*. The fibres that compose the body of a muscle are disposed in *fasciculi*, or bundles, which are easily distinguishable by the naked eye; but these fasciculi are divisible into smaller ones; and these, again, are probably subdivisible *ad infinitum*. The most minute fibre we are able to trace seems to be somewhat plaited; these plaits, disappearing when the fibre is put upon the stretch, seem evidently to be the effect of contraction, and have probably induced some writers to assert that the muscular fibre is twisted or spiral.

A fibre is essentially composed of *fibrin* and *ozmazome*, receives a great deal of blood, and, at least, one nervous filament. The chemical analysis will be noticed hereafter, and it may be enough to state that the muscle is found to consist chiefly of fibrin, with albumen, gelatin, extractive matter, phosphates of soda and of ammonia, phosphate and carbonate of lime, and sulphate of potassa. Each muscle is surrounded by a thin and delicate covering of cellular membrane, which dipping down into its substance encloses the most minute fibres we are able to trace, connecting them to each other, lubricating them by means of the fat which its cells contain, in more or less quantity in different subjects, and serving as a support to the blood-vessels, lymphatics, and nerves, which are distributed through the muscles. The muscles owe the red colour which so particularly distinguishes their belly part to an infinite number of arteries, which are every where dispersed through the whole of their reticular substance; for their fibres, after having been macerated in water, are (like all other parts of the body divested of their blood) found to be of a white colour. The veins, for the most part, accompany the arteries, but are larger and more numerous. The lymphatics are numerous, as might be expected from the great proportion of reticular substance which is every where found investing the muscular fibres. The nerves are distributed in such abundance to every muscle that the muscles of the thumb alone receive a greater proportion of nervous influence than the largest viscera.

Muscular motions are of three kinds, namely, voluntary, involuntary, and mixed. The *voluntary* motions of muscles proceed from an exertion of the will: thus the mind directs the arm to be raised or depressed, the knee to be bent, the tongue to move, &c. The *involuntary* motions of muscles are performed by organs, without any attention of the mind, as the contraction and dilatation of the heart, arteries, veins, absorbents, stomach, intestines, &c. The *mixed* motions are those which are in part under the control of the will, but which ordinarily act without our being conscious of their acting; and are perceived in the muscles of respiration, the intercostals, the abdominal muscles, and the diaphragm.

When a muscle acts, it becomes shorter and thicker; both its origin and insertion are drawn towards its middle. The sphincter muscles are always in action; and so likewise are antagonist muscles, even when they seem at rest. When two antagonist muscles move with equal force, the part which they are designed to move remains at rest; but if one of the antagonist muscles remains at rest, while the other acts, the part is moved towards the centre of motion. When a muscle is divided, it contracts. If a muscle be stretched to a certain extent, it contracts, and endeavours to acquire its former dimensions as soon as the stretching cause is removed. When a muscle is wounded, or otherwise irritated, it contracts independently of the will; this power is called *irritability*, and it is a property peculiar to and inherent in the muscles. When a muscle is stimulated, either through the medium of the will or any foreign body, it contracts, and its contraction is greater or less in pro-

portion as the stimulus applied is greater or less. The contraction of muscles is different, according to the purpose to be served by it: thus the heart contracts with a jerk; the urinary bladder slowly and uniformly. The intensity of muscular contraction, that is, the degree of power with which the fibres draw themselves together, is regulated by the action of the brain: it is generally regulated by the will, according to certain limits, which are different in different individuals. A particular organization of the muscles is favourable to the intensity of their contraction: this organization is a considerable volume of fibres, strong, of a deep red, and striated transversely. The cerebral influence, and the disposition of the muscular tissue, are the two elements of the intensity of muscular contraction. A very great cerebral energy is rarely found united, in the same individual, with that disposition of the muscular fibres which is necessary to produce intense contractions: these elements are almost always in an inverse ratio. When they are united, they produce astonishing effects. Perhaps this union existed in the *athletæ* of antiquity; in our times, it is observed in certain mountebanks.

'The muscular power may be carried to a wonderful degree by the action of the brain alone: we know the strength of an enraged person, of maniacs, and of persons in convulsions. The will governs the duration of the contraction: it cannot be extended beyond a certain time, however it may vary in different individuals. A feeling of weariness takes place, not very great at first, but which goes on increasing until the muscle refuses contraction. To prevent this inconvenience, the motions of the body are so calculated that the muscles act in succession, the duration of each being but short: our not being able to rest long in the same position is thus explained, as an attitude which causes the contraction of a small number of muscles can be preserved but for a very short time. The feeling of fatigue occasioned by muscular contraction soon goes off, and, in a short time, the muscles recover the power of contracting.

The quickness of the contractions are, to a certain degree, subject to cerebral influence: we have a proof of this in our ordinary motions; but beyond this degree it depends evidently on habit. In respect of the rapidity of motion, there is an immense difference between that of a man who touches a piano for the first time, and that which the same man produces after several years' practice. There is, besides, a very great difference in persons, with regard to the quickness of contraction, either in ordinary motions or in those which depend on habit. As to the extent of the contractions, it is directed by the will; but it must necessarily depend on the length of the fibres, long fibres having a greater extent of contraction than those that are short. The will has generally a great influence on the contraction of muscles; it is not, however, indispensable: in many circumstances motions take place, not only without the participation of the will, but even contrary to it: we find very striking examples of this in the effects of habit, of the passions, and of diseases.

In *Plate* II. Anatomy, *fig.* 1, we give a front view of the outermost muscles viewed anteriorly. *a.* Platysma myoides. *b.* Deltoides. *c.* Biceps brachii. *d.* Pronator radii teres. *e.* Supinator radii longus. *f.* Flexor carpi radialis. *g.* Palmaris longus. *h.* Flexor carpi ulnaris. *i.* Pectoralis major. *j.* Obliquus descendens externus. *k.* Linea Semilunaris. *l.* Linea alba. *m.* Poupart's ligament. *n.* Sartorius. *o.* Tensor vaginæ femoris. *p.* Gracilis. *q.* Iliacus internus. *r.* Pectinalis. *s.* Triceps adductor femoris. *t.* Psoas magnus. *u.* Vastus externus. *v.* Vastus internus. *w.* Rectus.

Fig. 2. is a back view of the superficial muscles. *a.* Trapezius. *b.* Latissimus dorsi. *c.* Deltoides. *d.* Triceps extensor cubiti. *e.* Gluteus maximus. *f.* Biceps flexor cruris. *g.* Semitendinosus. *h.* Semimembranosus. *i.* Gastrocnemius externus.

The chemical character of muscular fibre must next be examined. Their basis appears to be fibrin not much changed, with which are intermingled small portions of albumen, gelatin, an extractive and saline matter, these being derived in part from the blood diffused by the medium of the blood-vessels. To this, too, the colour is owing, as when washed with water the muscular substance remains white. The water employed in this operation holds dissolved the other principles. When heated, the albumen is separated by coagulation in flakes; if these are removed, and the liquor evaporated, it becomes gelatinous, a little fatty matter separating and collecting on the surface; and by this experiment the albumen and gelatin are detected. Besides these, a portion of a peculiar extractive matter is obtained by evaporating the jelly to dryness, and treating it with alcohol, the alcohol dissolving the matter, and yielding it by evaporation, in a solid form. It is of a brownish colour, has a pungent odour, and a taste somewhat aromatic: according to Berzelius, it consists of lactic acid, partly combined with alkaline bases and with animal matter. Lastly, the saline matter is procured by pouring boiling water on the muscular fibre, previously washed; it consists of phosphates of soda and ammonia, and phosphate and carbonate of lime. The proportions of these differ at different periods of life, being more abundant in the coarse and rigid muscular fibre of adult animals than in the more delicate fibre of those who are young. In the latter the proportion of gelatin is larger than in the former. When these have been extracted, the fibre remains, which has all the qualities of the fibrin of the blood.

When the flesh, without preparation, is boiled in water, the gelatin and albumen are more completely dissolved, and the fibrin is diffused in threads in the boiling liquor. The albumen coagulates, the gelatin is detected by the precipitate formed with tannin, or, if the liquor be sufficiently evaporated, it renders it gelatinous.

When the muscular substance is exposed to the air, it soon becomes tainted, and at length putrid, a change principally arising from the presence of gelatin, which is peculiarly liable to putrefaction when humid; and accordingly, if it has been removed by washing, the flesh remains much longer sound. It may be proper to add that, for experimental purposes, when the blood is of necessity retained, the chloride of lime may be advantageously employed.

Muscular fibre, decomposed by heat, affords the usual products of animal matter. Its residual charcoal gives, by incineration, carbonate and phosphate of lime.

The acids decompose the muscular fibre. Nitric acid disengages nitrogen gas, with a portion of carbonic acid gas, and the principal product is an unctuous substance of a yellow colour, rancid smell, bitter taste, and sensibly acid. The unctuous matter

may be separated by the action of alcohol from the acid.

MUSIC. Nature seems to have established an intimate connection between the emotions of the mind and the sense of hearing. Of the two nobler senses, sight and hearing, the first seems to belong more particularly to the understanding: we owe to the eye, and to abstractions from the images which it presents, most of our general notions and ideas; while the ear appears to be more intimately connected with the feelings. Feeling expresses itself most readily in tones. Fear, joy, desire, anger, have each a peculiar tone, understood by all human beings. Man soon perceives this, and often prolongs these tones, in order to continue or heighten a certain feeling or excitement; hence the repetition of the war-cry, in the combats of rude tribes, or of the tones of mirth at their festivities. The love of excitement, moreover, soon leads to the production of these tones, even on occasions when the feeling from which they first originated does not exist: thus we find the natural tones of joy repeated, in order to produce that of which they were originally the effect,—a pleasant feeling, a contented state of the soul. This, it is true, is not yet music or song, but it is the first germ of it.

Another element of music, springing from a feeling deeply planted in the human heart, and perceptible in children and savages as well as in the most refined and accomplished, soon associates itself with tones: we mean rhythm. Whatever may be its origin,—whether it was first used to relieve the fatigue of a march, or to give connection to a series of tones, or to enable numbers to join in the utterance of the same tones, or whether it is to be referred mainly to the spirit of classification and love of order which are so universally operative,—certain it is that the love of rhythm is one of the most general principles of the human soul: it pervades all tribes, all ages, all classes. It alleviates labour, and cheers the heart.

A simple division of tones soon gave place to a more artificial one, it being readily perceived that a man might utter two short tones, and make two short steps, in the same time as one long tone or one long step. Man does this long before he reflects on it: witness the regular strokes of the smith's hammer or the thresher's flail, and the dances of the rudest nations: thus we have the two essential elements of song—tones and rhythm. As precise divisions in sciences or arts, or any of the departments of human action, are effected but slowly, and kindred branches are at first usually mingled, it is highly probable that dancing and music—two arts founded on measured time—were at first intimately connected, as we find still to be the case among most, perhaps all, tribes in a state of infancy. By degrees, the song was separated from the dance, and instruments which originally served only to accompany the song became also the object of a separate art. Tones by themselves, apart from dance or words, were cultivated; the laws according to which they must be connected, so as best to express the language of feeling, were more and more investigated, and the application of these laws further and further extended, until music was developed to that degree of perfection which we admire in the works of the greatest masters.

Every musical production, to deserve the name, must be expressive of feelings, and through them of ideas; but, though music exists wherever the human species is found, it does not follow that every good piece of music must please all men alike, or be understood by all alike, because music is an art requiring cultivation of the mind and heart, to appreciate it fully; still, however, music, even of the most elevated kind, retains so much of its character of universality that the productions of the greatest masters delight much more generally than the best performances in other arts. Witness, for instance, certain tunes of Mozart, or other great composers, which are repeated on all occasions, so that they not unfrequently become tedious from this cause. The Hunter's Chorus in the Freischütz may be heard throughout Europe and America. The reason is, that music addresses the feelings, and feeling is alike all over the world. In this point of universality, music and mathematics (incongruous as the association may seem) agree, the relations of numbers and magnitudes, with which mathematics have to deal, being every where the same, and the simple feelings of the heart, which music addresses, being common to every region. Insensibility to music may generally be referred to a defective organization in the sense of hearing; but the whole conformation of some men is probably much better fitted than that of others to enable them to receive pleasure from it. In this respect, too, music and mathematics seem to have a resemblance, that great excellence in either appears to require a marked peculiarity in the nature of the individual. Music is based on melody, rhythm, and harmony.

The effects of music are sometimes said to be merely sensual. It is addressed to the ear, indeed; but all the influences which we receive from without are conveyed through the medium of the senses, and the tones of music often speak a language to the soul richer in meaning than any words. It will hardly be pretended that feelings which cannot be expressed in words are necessarily of a lower character than those which may be so expressed. The most elevated feelings are beyond the power of even metaphorical language. Nothing is merely sensual which makes a lasting spiritual impression upon the soul; and he who denies to music such a power has not heard its sublimest strains, or has not the capacity to appreciate them.

In music, we have to distinguish the invention (called *composition*) and the *execution*. As to the latter, it may be vocal or instrumental; and, as to the purposes for which music is intended, we have *church* or *sacred* music, *theatrical* music, *concert*, *dancing*, &c.

Wherever we find music, even in its rudest beginnings, we find also instruments; so that, as far as respects the known history of this art, we must consider the developement of vocal and instrumental music as coeval. Perhaps the first instrument invented was the pipe of the shepherd, who, in his life of leisure, heard the wind whistle among the reeds. It seems probable that shepherds first cultivated music as an art, though warriors may have used the exciting war-cry and war-song before. Instruments, as before observed, served in the beginning only as an accompaniment.

According to the Mosaic records, Jubal, the son of Lamech, played on musical instruments, even before the deluge. At a later period, we find among the Hebrews, as is the case in the early periods of all nations, the character of poet and singer united in the same individual, and with them we also find the alternating chorus. The musical instruments which accompanied these songs were harps, citherns, trumpets, and drums. One of the oldest songs, with in-

strumental accompaniments, of which we have any record, is that which Miriam sung, after the passage of the Red Sea. At the time of David and Solomon, music had reached its highest perfection among the Hebrews, and part of their religious service consisted in chanting solemn psalms, with instrumental accompaniments. As far as we can judge, from the information handed down to us, and even from the structure of Hebrew poetry itself (of which a certain parallelism, or repetition of the main idea in the different members of a sentence, was the chief characteristic) it had a very distinct rhythm, a varied melody, but a monotonous though strong accompaniment, as was the case with the music of most ancient nations. They had also proper musical signs, which were put over the musical text, and which served to guide the recitation. Their music, however, was employed not only in the celebration of religious service, in which, particularly since the time of David, a great number of singers, male and female, and instrumental performers, were employed, but also at profane festivals, such as large entertain ments. At this time, the different kinds of instruments were increased, among which the *kinnor* (triangular harp), and the cymbal, are mentioned particularly.

In the tomb of Osymandyas, near Thebes, musical instruments have been found, and it has been concluded that the Egyptians must have been acquainted with music 2000 years B.C. That the Hebrews received the art from them would not, however, be proved by that circumstance, though it may be, for various reasons, probable. We pass over the mythological accounts respecting the origin and perfection of the art of music among the Greeks. The traditions indicate that they received this art, or, at least, great improvements in the execution of it, from Lydia, where Amphion is said to have learned music, and Arcadia, where the shepherds practised on the pipe, flute, and cithern.

From the provinces of Asia Minor, the different modes of Greek music—the Phrygian, Dorian, Lydian, Æolian, and Ionian—are derived. Their song, as it would appear from what we can gather from the ancient authors, consisted in a musical recitation, accompanied by one or more instruments to support the rhythm. From the sixth century B.C., music seems to have been studied scientifically, and particularly the tones were measured. Lasus, of Hermione, in the Peloponnesus, who lived about 546 B.C., and was the teacher of Pindar, is said to have written something on the theory of music.

Pythagoras, who is said to have learned music from the Egyptian priests (which, however, is considered improbable) occupied himself with the mathematical relations of tones. The instrument which he invented for the mathematical determination of sounds was called the *Pythagorean canon*. He is also said to have added the eighth chord to the harp, to which several others were afterwards added. Damon is mentioned as one of the most distinguished teachers of music in the times of Pericles and Socrates. Plato asserted that his music could not be changed without changing the constitution of the state itself.

Plato and Aristotle considered music useful as a means of education. In their time, the scale was considerably increased; but, at the same time, complaints arose against the degeneracy of music and of the national manners through its influence. A similar complaint was made against Phrygius, who lived in the time of Socrates. Probably the cause of it was the application of music to the expression of the more tender feelings, as love, &c., while it had been previously used chiefly to awaken patriotic or religious feeling, as with the Lacedæmonians. The division into theoretical and practical music was probably known even then. Theoretical music comprised as well the arithmetical calculations respecting the proportions of sound and tones as the doctrine of harmony, which teaches the general rules of all the various concords. Composition and song depended upon this branch. The latter, and thus music in general, was divided, according to the proportions of the tones required in the different sorts of music, into the diatonic, enharmonic, and at a later period the chromatic. In regard to the tones which were the basis of these compositions, certain modes were adopted, denominated, as has been already stated, from the countries whence they chiefly came. Music was divided also, in respect of composition, into, 1. the art of composing the song, that is, the art of giving to poetry the proper song, or mode of recitation, because the recitation, or declamation, was also indicated by notes; 2. the art of giving a proper rhythm to the motion of the body or the voice; and, 3. into *poetics*, the technical part of poetry, connected intimately with music in those times: to this belonged *metrics*. As to execution, music was divided into instrumental music, vocal music, and pantomimic action in connection with music. At the time of Alexander the Great, Aristoxenus, a pupil of Xenophilus and Aristotle, distinguished himself. He wrote a great number of treatises on music, of which three are still extant, and extended the scale to eighteen chords, which were divided according to tetrachords and pentachords. His pupils (called the *Aristoxenians*) rejected the strict proportions of Pythagoras, and made use of the intervals of whole and half tones, guided merely by feeling. Aristoxenus also introduced the chromatic music, the invention of which belongs to this time, instead of the enharmonic.

Euclid (277 B.C.) is the first writer who treated the mathematical doctrine of sounds. With the decline of liberty, music also sunk, like the other arts. The Romans seem to have received the music which they used at sacrifices, together with the religious service, from the Etruscans, but the instrumental music, used on the stage and in war, from the Greeks. Stringed instruments are said to have been introduced into Rome as late as 186 B.C. In general, the Romans, so warlike in their disposition, most cultivated martial music. At an early period of their history, it was a great hindrance to the progress of the art that it was practised only by slaves.

With the Romans, *canere* and *carmen* signified the musical recitation, which was accompanied by instruments, and which seems to have stood in the same relation to rhetorical recitation as the poetic *rhythmus* to the *numerus* of prose; to which we must add, however, that orators had the intonation given by instruments at the beginning of their speech and during the same. The Romans made use of their capital letters as notes. On the stage, the song was accompanied with flutes. The instruments first preluded; then the actor began; and probably the instrumental accompaniment continued in simple concords, or made short pauses and supported or heightened the emphatic expression by recommencing.

The choruses seem to have been accompanied differently from the monologue and dialogue. This accompaniment consisted of flutes and other wind instruments, comprised with the Romans under the name of *tibiæ;* sometimes, also, of the lyre and cithern. The flutes were different, according to the comic or tragic poem which they had to accompany; hence there were *tibiæ dextræ* and *sinistræ*, the former particularly intended for the serious, the latter for the comic passages, and for comedies. Horace, in his *Epistola ad Pisones,* says that formerly only simple wind-instruments, with a few holes, had been used; no flutes which vied with the trumpets (*tubæ*). Rhythm and melody, he says, had become less strict. At later periods, still louder complaints were raised against the noise of the instruments, which obliged the actor to raise his voice extremely. In all this, the Greeks had preceded the Romans. Under the four emperors, particularly Nero, music was cultivated as an object of luxury. After his death, 500 singers and musicians are said to have been dismissed.

From the sixteenth and seventeenth centuries, there grew up at the courts of monarchs the free chamber style, and, from this, the theatrical style. The invention of the opera, in the sixteenth century, has chiefly contributed to the splendour and variety of modern vocal music, and the astonishing improvement in the mechanical structure of various instruments greatly advanced instrumental music, and at the same time harmony, in the latter half of the eighteenth century. The merit of the advancement of vocal music is claimed particularly by the Italians; the improvement of instrumental music by the Germans, French, and English.

The invention of the *lyric drama* of the moderns is considered by many persons to be of very distant date; that is to say, if by the lyric drama we are to understand every representation accompanied by music. And in fact, although these older representations differ widely from the lyric drama of our time, still the musical observer cannot fail to remark in the former the foundation and essential principles of the latter.

An *Orfeo* of Angelus Politianus was composed as early as the year 1475, and a musical tragedy is spoken of as having been performed at Rome in 1480. It is said that, in 1555, Alphonso della Viola set to music, for the court of France, "*Il Sacrifize,*" a pastoral drama by Agostino Beccari; and in 1574 an opera was performed at Venice for the reception of Henry III., when, on his return from Poland, he passed through that town, in order to take possession of the crown of France, to which he succeeded on the death of his brother Charles IX. These facts are so remote, and so very few vestiges of them remain, that it is impossible to deduce any thing positive as to the state of this branch of the musical art at that early period.

The real epoch to which the birth of dramatic music, properly so called, may be fixed, is that of the invention of the recitative or recited music, which gave to the lyric drama a peculiar language and construction. The following, it is said, was its origin.

Three Florentine gentlemen, J. Bardi, P. Strozzi, and J. Corsi, amateurs of the art, being little satisfied with the attempts made up to their time to bring dramatic poetry to perfection, conceived the idea of having a lyric drama written by their best lyric poet, and composed by the most eminent of their musicians. They consequently selected Ott. Rinuccini and Jacq. Peri, both of them Florentines: the former wrote a poem entitled *Daphne*, to which the latter applied a sort of recitation, in notes, having all the sounds of music, without its regular support and marked time. The work, thus arranged, was performed in 1597, at the house of Corsi, and obtained the utmost success; so much so as to determine Rinuccini to write two other works of the same kind, namely, *Euridice* and *Ariana*. In the same year in which *Ariana* was performed at Florence, an oratorio, with the same description of recitative, composed by Emilio del Cavalière, and entitled *Di Amina e di Corpo,* was performed at Rome. This work, together with that of Peri, was published in 1608; and in their prefaces the two authors claim the honour of the invention of recitative, which they both maintain to be the revival of the chanting declamation of the Greeks. Each of them, in support of his claim, cites different works written previously to the time of which we have just been speaking; and Emilio, especially, mentions a drama of his own, entitled *La Disperatione del Satiro,* composed and performed in private since the year 1590, and another represented in 1595. If we may credit J. B. Doni, the invention or revival of recitative belonged neither to the one nor the other, but to Vincent Galileo, father of the celebrated Galileo the astronomer, who feeling, as well as Bardi and the other amateurs of Florence, the defects in the music of that age, and inspired with the ardour of research, occupied himself in recovering the musical declamation of the Greeks, and, having studied the recitative, applied it to the episode of the *Count Ugolino* of Dante. He composed also, in the same style, *The Lamentations of Jeremiah,* and sang them himself, with a viol accompaniment, before a numerous assembly. Julius Caccini, of Rome, a young singer, who frequented, with many other musicians, the house of Bardi, was enthusiastic in his admiration of this new style, and himself composed several pieces, with recitative of a very improved description. J. Peri became his rival in improvements, and both, according to Doni, cooperated in setting to music the *Daphne* of Rinuccini. Peri afterwards composed *Euridice,* and Caccini *Cephalus.* These pieces were followed by *Ariana,* which was put into recitative by Cl. Monteverde. Of all the above-named works, the *Euridice* of Peri was most successful when performed in public. This representation took place in 1600, at Florence, on the occasion of the marriage of Henry IV. of France with Mary de Medicis. In the preface to the poem, which was printed the same year, Rinuccini states that the music composed by Peri to his *Daphne* had made him cease to fear that he should never witness the revival of the musical declamation of the Greeks. In fact, nearly the whole of this work is in recitative; and it is difficult to discover any difference from the rest of the music in those passages at the head of which is placed the word *aria.* The same observation applies to all the works composed up to the middle of the same century. It is only in the opera of *Jason,* written by Cicognini, and set to music in 1649 by Cavelli, that we begin to perceive airs having a melody differing from that of the recitative; yet still these airs are usually insipid, and generally (to give

some idea of them) a kind of minuet, written in the time of *two-three*, and varying repeatedly. A greater degree of progress is perceptible in the operas of Cesti, who, in his *Doria*, composed in 1663, began to introduce airs in which the talents of the singer might be displayed to advantage. But what is particularly remarkable at this epoch is, that the opera began to degenerate into a *spectacle* calculated to please the sight alone; insomuch that, in the works represented about the end of the seventeenth century, no mention whatever is made either of the poet, the composer, or the singers, but only of the machinist and the decorator. This, however, did not discourage an immense number of composers from devoting themselves to this style. Among these, there were many who had both practical knowledge and genius, to prove which it is sufficient to name Fr. Gasparini, Perti, Collonna, Lotti, and, above all, the celebrated Alessandro Scarlatti, to whom the invention of the *obligato* recitative is generally attributed. The principal characteristic of these celebrated composers of operas is however their science; and perhaps this was all they could do at a period such as that in which they wrote.

In the midst of this confusion, some few among them, and particularly Scarlatti, felt the necessity of making the melody conformable to the expression of the words; and some attempts made to this effect were very successful. This great improvement was, however, left to be completed by the composers of the eighteenth century; and it is to the illustrious pupils of Scarlatti, namely, to Leo, Vinci, Sarrow, Hasse, Porpora, Feo, Abos, and especially Pergolese, that this approach to perfection is attributable. They were well seconded by the poets of their time, and particularly by Apostolo Zeno, and his pupil Metastasio, who presented them with poems, written with purity and elegance, and full of interesting incident. Three generations may be considered to have followed this same system, profiting by the successive embellishments of melody and of the orchestra.

Didactic authors, such as Bernardi and Padre Martini, usually distinguish three styles of chamber music, namely, simple madrigals, accompanied madrigals, and cantatas. To these we may with propriety add a fourth, namely, fugitive pieces, containing an immense number of different sorts and varieties.

The madrigal is a species of composition much resembling the fugue (see FUGUE), but the style, being less dry than that of the latter, is susceptible of every kind of expression. It was so called from being usually set to a peculiar kind of short poem, known also by that name. There are two kinds of madrigals: namely, simple madrigals, or those executed by voices alone, and accompanied madrigals, or those in which the voices are supported by the organ or piano-forte.

Simple madrigals appear to have been invented at the beginning of the sixteenth century. During the whole of the succeeding century this style was very much cultivated, but since the early part of the eighteenth it has been completely abandoned, as much from the recognized difficulty of equalling the early composers in this kind of music as on account of the attention given exclusively to dramatic and instrumental music, which are, in some respects, completely the antipodes of this system.

Accompanied madrigals are, necessarily, a more modern invention; they can have existed only since the time when the custom was introduced of putting an instrumental bass, differing from the vocal one, below the voices. The most celebrated composers of this species of madrigal flourished between the middle of the seventeenth and beginning of the eighteenth centuries. These are Frescobaldi, Carissini, Lotti, Scarlatti, Clari, Marcello, and Durante; the last three of whom in particular have left some *chefs-d'œuvre* in this style of composition.

A cantata is a short poem which, considered in a literary sense, has no very determinate character, though it is usually the recital of a simple and interesting fact, interspersed with reflections, or the expression of some particular sentiment. It may be in all styles and all characters, sacred, profane, heroic, comic, and even ludicrous; representing the action or feeling of either a single or several persons; it even sometimes assumes the character of the oratorio; as, for instance, in the sacred poem of *The Passion*, *The Creation* of Haydn, and others. The cantata is supposed to have been invented about the commencement of the seventeenth century. Like the madrigal, this style of composition has been generally abandoned and neglected for nearly two generations; so much so that learned amateurs alone now deign to study the masterpieces left to us in this style.

Fugitive pieces consist, as we have before said, of an immense number of styles, and an amazing variety of subjects. Every nation has its peculiar style of music. Italy has the *canzonette*, the *villanelle*, the *flotole*, the *estrambotte*, &c.; Spain the *bolero*, &c.; France the *romance*, the *vaudeville*, &c.

We may now notice the introduction of the *gamut*, and the origin of counterpoint. With regard to the former, the invention of the *gamut* presupposes a certain degree of progress in the musical system, in the same manner that the alphabet conveys the preliminary idea of the existence of a language. We make this remark that the scale of music may not be confounded with the *system*, which might otherwise easily be the case. It was in the commencement of the eleventh century, in the year 1022, that the musical scale first took the form which it still retains. This reformation was chiefly owing to Guido, a Benedictine monk of the monastery of Pomposa, born about 990, at Arezzo, a little town of Tuscany, for which reason he is commonly called in France Guy d'Arezze. Between the death of Pope Gregory and the period of which we are now speaking, many attempts were made to improve musical notation. Indeed, it may be easily conceived that letters placed on syllables, to indicate sounds, could not be quickly understood; it was therefore found necessary to seek some more intelligible method. That which most naturally occurred was to place the letters at different degrees of height from each other, analogous to the elevation or depression of the voice, and to mark these degrees in a more accurate manner by means of parallel lines. This was the method employed before Guy, and he only simplified and regulated it. Instead of repeating the letter, Guy merely wrote it at the commencement of the line, and, whenever it afterwards occurred, simply put a dot in its place. Shortly after, he rendered this still plainer, by placing dots in the intervals of the lines; using these intervals to denote degrees, by which he reduced the distances from one note to another, and made the scale much easier to perform at sight. Guy likewise

added to the ancient system a bass note answering to *sol*, on the first line of the clef *Fa*; he designated this note by the *gamma* of the Greeks (Γ), and it is from this sign that the series of sounds in the system take their name of *gamut*. To these inventions he added another, that of counting by hexachords instead of tetrachords, and of designating by the syllables *ut, re, mi, fa, sol, la*, the *major* hexachord, upon whatever degree of the system it was placed: this was the foundation of his method of sol-faing which, however, it would be tedious to explain here. The invention of counterpoint is likewise attributed to him, though without any foundation. It is true he was one of the first who wrote on the subject, but he was not the inventor; for, although this art had made little progress, still it was known before Guy's time.

It may be proper to state that the organ was introduced into France in the year 757, and soon became universal in the churches of the west. It was directly used as an accompaniment to the voice. This accompaniment was at first entirely in unison; but the facility with which several sounds could be distinguished at once occasioned the remark, that, among the various union of sounds, many were agreeable to the ear. The minor third was one of the first remarked for its pleasing harmony, and was therefore generally used, though only at the close of an air; and this method was called *organizing*. There were likewise many other methods; for instance, holding on the sound of the organ on some note below the chant or singing part, or playing the air a fourth below or a fifth above, and frequently both together, which last was called *double organization*. Soon after, this method was adopted in singing without the organ; and from thence the terms *descant*, meaning double chant, *triple, quadruple, medius, motet, quintet, quartet*, &c., all of which preceded the term *counterpoint*. An uninterrupted series of authors anterior to Guy, as Notker, Remi of Auxerre, Hucbald, and Odon de Cluny, testify the origin and progress of this art, and historically demonstrate its being a modern invention, totally unknown to the ancients. Their writings, as well as those of Guy, and of J. Cotton (his commentator), are to be found in the valuable collection which the prince abbé Gerbert published under the title of *Scriptores Ecclesiastici de Musicâ Sacrâ potissimum*, &c.

The introduction of *time*, or the relative values of the notes in music, forms an important feature in its progress as a science. The first music divided into bars appeared about the beginning of the seventeenth century, though the system was not generally adopted till the eighteenth. The distance between the bars was in time diminished, till they enclosed but one measure, as in the present day; the only exception now being in the *à capella* time, namely, in two semibreves, with a quick movement, when the bars are still marked only every second measure, to avoid their too frequent repetition. The introduction of bars, with their gradual increase, has produced the natural result of bringing into disuse notes of great value; and at the present period the note of highest value is the semibreve, if we except the breve in *capella* time. As for the round and the maxim they are now no longer known, except by the musical antiquary. The form of the notes has likewise sustained an alteration, though scarcely worth noticing. Formerly, the head of the note was square; towards the middle of the seventeenth century they were formed round, or of an inclined oval; and in the course of 100 years the round became universal, and is the form retained up to the present time. Rhythm, as we have previously seen, has sustained but slight variation; but it has been quite the reverse with sounds, and consequently with harmony and counterpoint.

Till the close of the fifteenth century, the degenerated tones of the Greeks, as preserved in the chant of the Roman church, not only served as a foundation to ecclesiastical chanting, and to the works of composers who endeavoured to harmonize those chants, or to compose according to that system, but various profane songs of that time which we still possess, and some of which are to this day popular, appear to have partaken of the ecclesiastical modes. In the course of the sixteenth century, however, a movement appeared, which led the art to that state of perfection which it has now attained. To dispel whatever may appear vague or obscure in this remark, it is necessary to give a clear idea of what is meant in music by tone or mode, and subsequently to demonstrate the relations subsisting between the modern and ecclesiastical modes. No one endowed with the most ordinary musical organization, or capable of the slightest observation, can fail to have remarked the tendency that every musical piece has to terminate on some particular note or sound, for which no other could be substituted, without rendering the air incomplete. This experiment may be tried on the most simple tunes known. We say of a piece of music, It is in the *key* of such a note, when it ends on that note or sound, and which note is called the tonic or principal; now, if we decompose a piece of music which is supposed to be, throughout, in the same key, it will be found that it is composed of a certain number of different keys, each having a direct affinity to the principal key note. The *ensemble* or system of these affinities constitutes the *musical mode;* and if, from the tonic to the octave, we place all the intermediate sounds in regular succession, we shall form the scale of the mode. It is possible to imagine a great number of different modes, from which may be formed a variety of systems. Each of these systems of modes will constitute essentially the same number of idioms or musical languages, which will belong to various races of men. Thus the eastern nations appear to have had a system of modes quite different from ours, and, indeed, we have not to this day any very distinct idea of them. At the present day we have but two modes, namely, the major mode, the scale of which is contained in *ut, re, mi, fa, sol, la, si, ut;* and the minor mode, in which the ascending scale is *la, si, ut, re, mi, fa, sol, la;* and in descending, *la, sol, fa, mi, re, ut, si, la;* this is, at least, according to the notions at present existing, though there is still much want of precision and accuracy in the theory of this subject. However this may be, these modes are entirely modern, it being hardly more than 100 or 150 years since they have become prevalent, and to the extent of rendering it a doubtful question whether or not the modern nations of Europe can ever accustom their feelings to any other system of tones, and further whether all other such systems are not, for them, rather systems of modulation, that is to say, of concatenation of modes, than a *system* of modes, properly so called. The ancient contrapuntists

had an established and almost exclusive rule to add the third and fifth to all the notes of the scale, with the exception of that which bears the minor fifth, to which thy put the sixth: they looked upon all harmony as allowable which was exempt from a succession of fifths and octaves: but the doctrine of the new modes soon displayed the errors of this harmony, which formed an infinity of bad combinations, such as the sixth with the third, or frequently on many other degrees of the scale: it was on the above principle that Palestrina and all his school wrote.

A schoolmaster in Lombardy (Charles Monteverde), who flourished about 1590, invented the harmony of the dominant; he was also the first who used the seventh and even the ninth of the dominant; he likewise employed the minor fifth as a consonance, which had always before been used as a dissonance. Thus the tonal harmony became known; and, his principle being once admitted, all its consequences were naturally deduced, and musicians arrived almost insensibly at the conclusion that only three essential harmonies were to be acknowledged in the mode, namely, that of the tonic, of the dominant, and of the sub-dominant, which are all that should be placed, either direct or inverted, on these notes and on those comprised in their harmony. Charles Monteverde likewise introduced into composition double dissonances, which were soon succeeded by triple dissonances, and diminished and altered chords. It must naturally be supposed that counterpoint was in some degree affected by these innovations; it now became usual to employ intervals in melody which had till then been totally interdicted; and the intervals in harmony soon succeeded each other in a way till then unknown. About this time L. Viadana de Lodi formed the idea of giving to the instrumental bass a different melody from that of the vocal, to which it had previously strictly adhered; he further proposed to make this new bass reign throughout the piece, to consider it as the basis of the whole composition, and to represent by figures the chord it was to carry. In these points alone can he be considered as the inventor of fundamental bass; for it does not appear he in any way added to harmony. All these innovations excited the indignation of the masters attached to the ancient rules; but at length sense and experience overcame their vague and abstract reasonings. At first, indeed, these new methods were merely applied to profane and modern music, and the ecclesiastical chants continued to be formed on the ancient rules, somewhat mitigated, however, according to the method of Palestrina and the Roman school; but, towards the close of the seventeenth century, they began, in practice, to consider the church tones merely as a form to enchain or keep within bounds the modern tones, and according to this principle they applied tonal harmony to their ecclesiastical compositions. It is thus that the school of Naples, particularly Durante, considered the subject, and the modern tones are now universally acknowledged in church music. Practice has ever, in all the arts, preceded theory, or rather doctrine; and indeed it should always be thus, for doctrine should merely observe the operations of genius and reduce them to principles; it should not advance too quickly, thereby exposing itself to be contradicted by experience. If we examine the successive doctrines of the period we have been surveying, we shall find an additional proof of the truth of these observations. P. Aaron, L. Fogliani, and all those who wrote during the first two generations of the sixteenth century, added little to the improvements of the fifteenth. Zarlino, who published in 1571 his *Harmonic Institutions*, collected and developed all the theories and precepts established up to his time; and his work was then considered, and for long after, as the most eminently classical ever written on music. Far, however, was he from exceeding in knowledge the composers of his day, for he appears not to have heard of Palestrina, who flourished about 1552. All Zarlino's doctrine was established on the practice of the masters of the Flemish school, of whom he himself was a pupil. In this he was followed by Artusi, Zacconi, and others, who wrote towards the close of the sixteenth century. D. P. Ceroni, who published at Naples, in 1613, his *Melopeo y Maestro*, narrowed the boundaries of the doctrines of music. He modified his instructions according to those of Palestrina and other masters of the Roman school. Galeazzo Sabbatini, who, in 1644, gave rules for thorough-bass, wrote on the same principles. But it was not until we possessed the treatises of Bernardi, Buononcini, and Gasparini, towards the close of the seventeenth or commencement of the eighteenth century, that the practices in counterpoint introduced at the close of the sixteenth century were reduced into a theoretical system; from that time to this, these doctrines have remained nearly the same as they were established by the last-named authors. Towards the commencement of the eighteenth century, a French writer, M. Rameau, affirmed that all rules, up to his time, were merely blind traditions, without connection or foundation, and proposed reducing them to a few precepts, which he pretended to deduce from the laws of physics. As the opinions of this celebrated man have for some time been much in fashion in France, and have had a useful influence on certain points of musical doctrine, it may be proper to give some idea of them. If we examine the various chords used in accompaniment, we shall find they may all be traced to different combinations of certain groups of sounds. For example, the chords *ut, mi, sol, mi, sol, ut, sol, ut, mi,* are evidently but three combinations of the sounds *ut, mi, sol;* the chords *sol, si, re, fa, si, re, fa, sol, re, fa, sol, si, fa, sol, si, re,* are four combinations of the sounds *sol, si, re, fa,* in which each sound becomes successively the bass, the arrangement of the higher sounds being perfectly indifferent. Now, if we consider one of the chords which are composed of the same sounds as principal, the others may be viewed merely as dependents. With this idea the ancients were perfectly acquainted, and they considered that chord as principal in which all the sounds were placed at intervals of thirds, the remaining chords (composed of the same sounds) being inversions of the first. Some ignorant writers have attributed the origin of this idea to Rameau. In this they are mistaken, and to be convinced of their error they have only to glance at the writings of Zarlino, Bernardi, and others, when they will find that the above idea, which is indeed founded in truth, had long been familiar to the ancients. What may with truth, however, be attributed to Rameau is, his having endeavoured to include all the laws of harmony in those laws which govern the principal chords. To this end, he names these chords *fundamental chords;* the note which acts as bass he calls the *fundamental*

note; and finally he terms *fundamental bass* that hypothetical bass which is formed solely by the fundamental note. This being decided, he next proceeds to prescribe rules for the formation of this bass, or rather for the succession of fundamental chords; and, according to his doctrine, harmony will be regular whenever the chords of which it is formed, being brought back to their fundamental chords, offer successions in the bass correspondent to the rules which he has established. When the conservatory, established at Paris towards the close of the eighteenth century, determined, for the benefit of the pupils, to invent and adopt an elementary work, a professor of that establishment (Catel) proposed a treatise on harmony, which of all those hitherto published agrees best with the practice observed for nearly two centuries past. He considers as *natural* chords all such as are commonly termed consonances, also all dissonant chords used without preparation; he examines in a summary manner their principal successions, and demonstrates in what way, by means of the anticipations, retardations, and alterations of which they are susceptible, they produce all *artificial* chords or dissonances properly so called. This doctrine had been previously taught by the school of Durante, as we find from the small treatise of Fenaroli, entitled, *Regole per li Principiante*, &c., and was likewise established in Germany; but Catel produced it in a much clearer and more decided form, and it has been adopted in France by all able musicians: indeed it must be considered a most important step in the doctrine of harmony.

The subject of musical instruments, as a branch of scientific accompaniment, should be considered under two heads:—first, as to the sonorous principle which forms the basis of each one separately; secondly, as to the mechanism of execution. First, in respect to the sonorous principle, instruments are divided into stringed, wind, and vocal instruments, &c.; as relates to their mechanism, they may be divided into six classes, namely, bowed instruments, wind instruments, keyed instruments, stringed instruments, instruments of percussion, and, lastly, mechanical instruments. At the head of these six divisions must be placed the human voice, the first, the most beautiful of all instruments, and which serves as a model for the construction of every other.

Without entering into unnecessary detail, it will be sufficient to enumerate the instruments now most in use amongst those nations whose musical system resembles our own. These are, first, amongst bowed instruments, the violin, the viola or tenor, the violoncello or bass, and the double-bass; secondly, amongst wind instruments, the German flute, the clarionet, the hautboy, the bassoon, the horn, the trumpet, the trombone, the serpent, the fife, and the flageolet; thirdly, amongst keyed instruments, the piano-forte and the organ; fourthly, amongst stringed instruments, the harp, the guitar, the lyre, and the mandolin; fifthly, amongst instruments of percussion, drums of different kinds, and cymbals; sixthly and lastly, amongst mechanical instruments, the self-playing organ, *ælophon*, &c.

Instrumental music is nothing more than a melody or a system of melodies appropriated either to a single instrument or to several together. This leads us to consider it in two points of view: first, as single music; secondly, as concerted music.

Single music is that which is composed or adapted peculiarly for a single instrnment, whether it be, in fact, produced by that one instrument, or, in order to increase the effect, be accompanied by one or more additional instruments, they being entirely subservient to the principal. This music is the *solo* properly so called, and the *accompanied solo*, of which the *concerto* is the most brilliant style. There are as many styles of *solos* as there are of instruments; but, as it is impossible that we should enter into all the details which this variety presents, we shall confine our notice to the solo of the violin, which is regarded, and justly, as the first of all instruments.

Solos, whether simple or accompanied, comprehend, under the name of *studies, fantasias, capricci, sonatas, concertos*, &c., &c., an infinite number of pieces in various forms and styles. The construction of solos, whether simple or accompanied, comprehends their melodic form and the choice of instruments, both which objects have varied repeatedly previously to attaining their present degree of perfection. The form, indeed, is still constantly changing, so much so that there appears to be no fixed rule on this head. With regard to the selection of instruments, a subject that concerns the whole series of accompanied solos, from the sonata (which is the simplest of all) to the concerto, there have also been a vast number of changes. The sonata, in the course of the seventeenth century, was in many respects fixed by Corelli. The concerto was invented by Torelli, his contemporary, under the name of *concerto grosso*, and employed at first only five instruments, namely, the quartet and the leading part. F. Benda and J. Stamitz made the addition of wind instruments, forming it thus into a kind of symphony. In every thing relating to the execution of instrumental music, it is of the utmost importance to dispel a very common error which consists in believing that music was formerly very simple, and easily performed. This error arises from the circumstance of the old writers having made use of notes of very great value, and its not being remembered, at the same time, that these notes were executed with great rapidity, so that they had, in fact, no greater value than those in use at the present time. Besides which, if we cast our eyes upon the collections of pieces remaining to us from the preceding centuries—for example, upon the *Virginal Book* of Queen Elizabeth, published in 1578—difficulties will be found which would puzzle the most able of our modern performers.

There have been the same revolutions as to taste and style in instrumental music as in singing; it has indeed always been influenced by the existing style of vocal composition. Without referring to the periods anterior to the seventeenth century, concerning which we have little or no information, we know that, during the first two generations of that century, music was entirely in the madrigal style. When dramatic music began to prevail under Corelli, the contemporary of Perti, Colonna, and Scarlatti, it was scientific and rather dry; Geminiani first enriched it by expression, both as to composition and execution. Soon after this period the concerto, in particular, was greatly improved in the hands of the elegant Jarnowick and of the graceful Mestrino, both of whom were still surpassed by Violti, who gave to this style the character which seems so peculiarly his own, and brought it to a degree of perfection which it seems scarcely capable of exceeding.

All we have said concerning solos applies equally

to concerted music, by which term we understand instrumental music with different parts, in which all the instruments are equally obligato, either because each of them has its appropriate part or because each takes up the strain successively, the others alternately becoming accompaniments. These two methods are practised alike in the duet, the trio, the quartet, the quintet, and other pieces where each instrument has its separate part, and in the symphony, where all the parts are doubled for effect, according to justly determined proportions. Boccherini was the first who, in 1768, gave to the trio a fixed character; after him came Fiorèllo, Cramer, Giardini, Pugnani, and, lastly, Violti. It is also Boccherini who, at the same period, first fixed the *quartet;* he was followed by Giardini, Combini, Pugnani, and, in another school, by Pleyel, Haydn, Mozart, and Beethoven. Boccherini likewise about this time fixed the *quintet*, in which he has no rival but Mozart.

The symphony, improved since the middle of the same century, by Gossec, Toeski, Wanhall, and Emmanuel Back, was perfected by Haydn, who, following the steps of Bach, brought this branch of music to a degree of superiority till then unknown, and which has since become, for his followers, a model scarcely to be equalled. (See SINGING, and the various musical instruments in their alphabetical order.)

Music, Sacred. Almost all nations who have an established religious service have made music an important part of it; and, in a general sense, we might give the name of *sacred* music to all music employed in religious festivals, even before the Christian era, as that of the Egyptians, Hebrews, Greeks, and Romans, as well as to the religious songs of the bards and scalds. The early Christians, who were led by various passages in their sacred writings to employ religious songs, introduced at their religious meetings (particularly in the Eastern churches) the singing of the psalms and hymns which are to be found in the books of the *Old Testament*, and to which the Jewish converts had been already accustomed in their assemblies. They sang also at the Lord's supper and at the agapes. At the synod of Laodicea (364), regular songs were introduced, which were sung from notes by persons appointed for this purpose. The Western churches received through Ambrosius, bishop of Milan, a regular church music, similar to the Eastern. Probably this possessed a regular modulation and rhythm, only that both were defective through the imperfection of the music at that time; the latter appears to have been limited to long and short tones; the former was founded upon the Grecian modes remaining in Italy, and was very poor. Perhaps many of the melodies of Grecian and Roman hymns now received words adapted to the religious worship of the Christians. The Christian fathers bear witness to the use of songs in the Christain communities in the first century, and many of them, as Ambrosius and Augustine, were great admirers of them.

In regard to the manner of singing in the first assemblies, it was sometimes in solo, sometimes alternately, and sometimes there was a chorus of the whole assembly, who united in repeating short passages, before sung or read, from which, probably, the female sex was at first excluded. For the regular ordering of the singing, precentors were instituted in the fourth century, who were considered as inferior officers of the church. Schools appropriated to singing were instituted later, and only in a few places Pope Gregory the Great (590—604) distinguished himself in the Roman church as the founder of a new singing school, in which boys were instructed. It was the model of many other institutions of this kind. In consequence of this education of persons for singers, the singing was not only more artificial, but the people were also for the most part excluded, particularly as the hymns were in Latin. Gregory collected in his *Antiphonarium* the existing songs of the church, which he selected from the best ancient melodies, improved and increased by the addition of new ones.

The *Gregorian Chant*, so called after him, was sung in unison with loud notes of similar value, with rhythm and metre (by which it is particularly distinguished from the Ambrosian), or in the old Grecian modes, but with a more complex modulation. This Gregorian or plain chant, which, by means of Gregory and his successors, has been extended throughout the west, is the foundation of the Christain church music. It was also called *choral song*, because it was sung by a choir. The Gregorian Chant was afterwards adopted both in England and France. Charlemagne, who laboured particularly for its diffusion, caused several singing schools to be established in France, and united them with the monasteries. The Gregorian Chant was probably introduced into Germany by Boniface, but it was first generally diffused there in the time of Charlemagne. The developement of the music for four voices may have been assisted by the choral; but musical instruments contributed yet more thereto, as well as to the formation of perfect harmony; among these, the organ particularly, which soon took the first rank in the churches. Now figured music arose, and likewise figured song, which, in the fifteenth century, began to become general, as the custom grew up of varying, extending, and embellishing the accompanying voices of a melody, while the chief voice, upon which the fundamental melody depended, remained unchanged (hence it was called *cantus firmus, canto fermo*, plain-chant); but still the chief voice often became the under voice. This happened afterwards, also, with melody. The invention of measured music caused the choral to be performed in a more regular measure, and gave greater extent to harmony. Choirs of singers now became necessary, and singing was often applied, especially in Italy, to heighten the splendour of religious worship. (See ITALIAN MUSIC.)

The organ was continually improved, after the fifteenth century, and other instruments, also, were introduced into the church, against which complaints were often made, as well as against the new figured music in general, which found peculiar support in the instrumental music. Yet these complaints were chiefly directed against the abuse of the figured and instrumental music, and they were not able to banish them from the church. The fifteenth and sixteenth centuries form a new period of church music, which was extended by the great masters in Italy, France, the Netherlands, and Germany. Luther's services to the German church music are well known, for which he laboured, by means of his friend Senffel. During the seventeenth and eighteenth centuries, church music became continually more brilliant and always more corrupted by the intermixture of profane music. In the Roman Catholic church, the sacred music is confined to fixed forms of text; for instance, the text

of the mass, the *Offertoria*, *Te Deum*, *Salve*, *Requiem*, *Psalms*. In the Protestant church, poets and composers allow themselves new forms.

MUSK. This valuable article in the materia medica comes to our country in round thin bladders, which are generally about the size of a pigeon's egg, covered with short brown hairs, lined with a thin brown membrane, well filled, and without any appearance of having been opened. The musk itself is dry, with a kind of unctuosity, of a dark reddish brown or rusty blackish colour, in small round grains, with very few hard black clots, and perfectly free from sandy or any other visible foreign matter. If chewed and rubbed with a knife on paper it looks smooth, bright, yellowish, and is free from grittiness. Laid on a red-hot iron it catches flame and burns almost entirely away, leaving only an exceedingly small quantity of light grayish ashes. The largest and fullest bag seldom contains more than two drams of musk. Its taste is somewhat bitter, and its smell extremely powerful and peculiar. Neumann got from thirty grains of musk twelve of watery and four of alcoholic extract; and, inversely, ten of alcoholic and six of watery. Its smell and taste were elevated in distillation with water, but not with alcohol. Neither the fixed nor volatile oils dissolve it.

The very great price of musk has given rise to many modes of adulterating it. To increase its weight, sand, and even particles of lead, are introduced through very small openings into the bags. The real musk is frequently abstracted from the bag and its place supplied with dry blood coarsely powdered, or some mixture with asphaltum. These adulterations are to be detected by discovering that the bag has been opened. The presence of blood is also known by the fetid smell it emits when heated sufficiently, and by the formation of ammonia when rubbed with potass. Asphaltum is known by its shining fracture and melting on hot iron, while musk is converted into charcoal. But there are even artificial bags filled with a composition containing some real musk. These are in general thicker and covered with longer hair, and want the internal brown membrane which lines the real musk bag.

Musk is said to be a medicine of very great efficacy, and one for which, in some cases, there is hardly any substitute. When properly administered it sometimes succeeds in the most desperate circumstances. It raises the pulse without heating much; it allays spasms, and operates remarkably on the brain, increasing the powers of thought, sensation, and voluntary motion.

It may be employed in every instance of typhus fever, especially when attended with delirium, or spasmodic affection of any particular organ or of the whole system, or subsultus tendinum, &c. It is also used with the greatest benefit in exanthematous and phlegmonic diseases, accompanied with typhoid fever; and in many spasmodic affections, as chincough, epilepsy, trismus, &c.

It is most conveniently given in substance in powder, in doses of three grains or upwards, repeated every one or two hours. Its best preparation is the tincture.

MYRRH; a gum resin. The best myrrh is brought from Troglodytitia, a province of Abyssinia, on the borders of the Red Sea; but what we receive comes from the East Indies, and is produced on the eastern coast of Arabia Felix.

The best myrrh is in the form of tears, of a yellow or reddish yellow colour, becoming redder when breathed on; light, brittle, of an unctuous feel, pellucid, shining; presenting white semicircular striæ in their fracture; of a very bitter aromatic taste, and a strong, peculiar, not unpleasant odour. It is not good if whitish, dark-coloured, black, resinous, ill-smelled, or mixed with impurities, which is too commonly the case.

Neumann ascertained that water and alcohol are both of them capable of taking up the whole of the taste and smell of the myrrh, the extract made by either after the other being insipid. The alcohol distilled from the tincture elevated none of the flavour of the myrrh; but during the inspissation of the decoction a volatile oil arose, containing the whole of the flavour of the myrrh, and heavier than water, while the extract was merely bitter. From 7680 parts of myrrh, he obtained 6000 watery extract, 180 volatile oil, and 720 alcoholic: and, inversely, 2400 alcoholic, and 4200 watery. Braconnot found that myrrh chiefly consisted of a gum, differing from all others. 1. It acquires cohesion by heat, which renders it partly insoluble in water, when the solution is evaporated; 2. It furnishes ammonia by distillation, and azote with nitric acid. 3. It precipitates lead, mercury, and tin, from their solution. Myrrh also contains 2.3 parts in 100 of a bitter, very fusible, resinous matter. I have observed that the tincture is transparent, and when poured into water forms a yellow opaque fluid, but lets fall no precipitate, while the watery solution is always yellow and opaque; and that myrrh is not fusible, and is difficultly inflammable. Mr. Hatchett found it soluble in alkalies.

Vauquelin obtained from the root of the *Andropogon Schoenanthus*, by means of alcohol, a thick brown oil, having an acrid, burning taste, like an essential oil, and exactly the smell of myrrh. It differs from myrrh chiefly in having less solidity; but Vauquelin thinks that if it were united to a gummy matter it would exactly resemble it. He does not suppose, however, that this is the plant which produces the myrrh of commerce, but considers it as a proof that myrrh is formed in various vegetables.

Myrrh is a heating stimulating medicine. It frequently occasions a mild diaphoresis, and promotes the fluid secretions in general. Hence it proves serviceable in cachectic diseases arising from inactivity of the system, and is supposed to act especially upon the uterine system, and to resist putrefaction.

It is employed medicinally, in the form of powder, or made up into pills, in doses of ten to sixty grains. 2. Dissolved in water, as in Griffith's celebrated but unchemical myrrh mixture; and 3. Dissolved in alcohol.

NACRE, or MOTHER OF PEARL, is the inner part of the shell of the pearl muscle. This is of a brilliant and beautifully white colour, and is usually separated from the external part by aqua-fortis, or the lapidary's mill. Pearl muscle shells are on this account an important article of traffic to China and many parts of India, as well as to the different countries of Europe. They are manufactured into beads, snuff-boxes, buttons and spoons, fish and counters for card-playing, and innumerable other articles. The pearl muscles are not considered good as food; though, after having been dried in the sun, they are sometimes eaten by the lower classes of people in the countries near which they are found.

NAIL-MAKING. The art of preparing metallic bolts or pins for building. Formerly, the nail-maker's process was very tedious, every nail being made by the hand, and each begun and finished by the same individual; it was afterwards discovered in this manufacture, as in many others, that by the division of labour, and by assigning to different persons the pointing, heading, &c., a greater quantity of work was done by the same number of hands; of course the processes were much simplified and expedited, and the article could be sold on much lower terms.

Since the commencement of the present century, ingenious mechanics have not only improved the method of manufacturing nails, but have thought it expedient to secure to themselves the exclusive right of their inventions by obtaining the king's letters patent: of some of these we shall proceed to transcribe an account from the *Circle of the Mechanical Arts*:—

In the year 1790 Mr. Thomas Clifford, of the city of Bristol, obtained two patents for the manufacture of nails of every kind. The principle on which his first invention is founded is that of making the nails in a die; that is, by having a die or the impression of the nails to be cut, composed of one or more pieces of iron. The iron of which the nails are to be formed is drawn and rolled into the proper form and thickness, and, by a force adapted to the purpose, is pressed into the cavity or die so as to form the nails, either complete or so nearly complete as that they can be finished with a very little labour. This operation may be done in several ways, but the one particularly recommended by Mr. Clifford is by rollers of iron or steel, and worked by water, steam, wind, horses, &c. The two rollers are to be made of iron and cased with steel, each of the same diameter, and the diameter proportioned to the length and size of the nail intended to be made. Each roller should have one or more cog-wheels, the cogs of one roller to work into those of the other, so that the rollers may both perform the same exact revolution. One half of the impress of the nail is to be cut with one roller, the other half with the other, so that the two impressions form a cavity or die of the exact form of the nail, extending the lengthways of the nail on the circumference of the rollers; and as many impressions of the same kind may be cut in the rollers, one at the end of the other, as will complete the circumference, and continue the cavity all round the rollers, the point of one nail joining the head of the next, or the two points and two heads joining each other. The rollers must in this, as in other cases, be made to work very true, and close to each other.

The mode of operation is this:—A rod of metal, iron for instance, rolled or drawn to a convenient size, is to be heated, and, while hot, the end of it is put between the rollers, into the cavity or die which forms the impression of the nail. The rollers, being now put in motion, will draw the iron through, pressed into the cavity which forms the impression of the nail, the one jointed to the other, which must be afterwards separated by means of instruments acting as nippers, shears, chisels, &c. The rollers being made to work very close to each other, where the edge of the nail is formed, will prevent much of the metal from being pressed out on each side of the nail, and what is pressed out may be cut off by instruments adapted to the purpose. Several pairs of rollers may be made to work together, and each pair may have several rows of dies cut on them, so as to form the impression for several strings of nails; and a rod of iron, being put into each of them, will roll out as many strings of nails with one revolution of the rollers. A pair of rollers may also have the greater part of their surface cut with dies, and a flat bar or piece of iron be made to pass between the rollers, so as to form sheet nails; the whole of them connected with one another by thin plates of iron, of which they are composed, and this would require each nail to be cut out or separated from the sheet by proper instruments.

Mr. Clifford's second invention consists, 1. In drawing the iron, or other metal, into a tapering wedge-like form, according to the length and thickness of the different sizes of nails to be made. 2. The nails are to be cut out of those wedge-like plates, by means of a punch, the face of which is made according to the size, taper, and form of the nail to be cut out; as also, having a hollow bolster, the hollow or aperture of which must also be made of the size and form of the nail, and consequently to fit and receive the punch above mentioned. The punch thus fitted to the bed, and sliding in the frame to keep it steady, will, by a blow or by pressure, cut or force a part of the taper-plate into and through an aperture of the bed fitting to it, and by which the nail is formed. This operation is, by the manufacturers of buttons, buckles, &c., generally called cutting out. 3. To form the heads of horse-nails, called rose heads, and others of nearly a similar kind, after the operations of drawing and cutting out, the nail is to be put into a heading tool, which is also called a bed, which bed receives the nail, excepting a small portion at the thick end of which the head is formed by a punch. This punch, by a blow or pressure, forms the head as required; and, when the nails are made of hard iron, after they are cut in the way described, the thick end is made hot before they are put into the bed or heading tool. Another method adopted in the manufacture of nails is by cutting them out of iron plates of equal thickness, and afterwards pointing them either by a hammer or other pressure. In making nails that are of a triangular form, the plate or strip of iron is pressed into a die, having impressions to the form of such nails, after which they are cut out by a punch.

At about the same period in which the foregoing patents were obtained, Mr. William Finch, of Woombourne, in Staffordshire, invented another method of making nails and spikes by machinery, to be worked by steam, &c., by which all manual labour was to be saved. In his specification he describes his power as consisting of one main shaft, caused to revolve in either a horizontal or perpendicular direction by means of a water-wheel or a steam-engine. Such main shaft will put in motion, by means of cog and pinion wheels, other countershafts or barrels, on which are fixed arms, &c., and on these are hammers that are worked in either a lift or a tilt manner. He also makes three divisions of hands in the manufacturing of headed nails, namely, one man, woman, or child, stationed before the hammer, which person, by mere activity, will with one hand not only form the larger size nail, but a far greater number in the same given time: when the third person will, with the same kind of hammer, head and finish a great number of the same shanks together, leaving them truer made,

and better for use than by the old mode. Also, by a division of hands, the same apparatus will make such nails as require no tool or frame to be headed in; namely, the one to carry the iron from the fire, and the other stationed before the hammer to finish them. In enumerating the advantages and savings of this method, above the others then in use, Mr. Finch says that, by heating many rods in one fire, there will be a saving of coal: by the more speedy motion of machine hammers, several nails will be made by once heating the rod, whereas by the old method only one is made: again, the motion being regular, independently of strength, a child will be able to make the largest nail or spike. (See SCREWS.)

NANKEEN, or NANKING; a sort of cotton cloth, which takes its name from the city of Nanking, where it was originally manufactured. It is now imitated in most other countries where cotton goods are woven; but those of the East are superior, on account of the natural colour of the cotton (*gossypium religiosum*) being reddish, while in those countries where white cotton is used it is necessary to give it the proper hue by artificial means.

NAPHTHA, a liquid bitumen. It is very light, of a pale yellow-green colour, transparent, thin, and liquid. It is highly inflammable and volatile. It is intimately connected with the following bodies: petroleum, or mineral tar, which is semi-liquid, often of a thicker consistence, tenacious, semi-transparent, of a reddish-brown colour, and fœtid odour. Maltha, which is solid, but soft, has a degree of tenacity, and a strong bituminous smell. Its colour is black, its lustre highly resinous. It is sometimes elastic, forming what has been named the elastic bitumen. Asphaltum is the last of the series, and forms the connection with pitch coal. It is of a black colour and resinous lustre, without transparency; its fracture is conchoidal; it is light, and has a bituminous smell when rubbed or heated. It melts easily, takes fire, and burns without leaving any ashes. Through all these substances there is a perfect gradation; naphtha, by inspissation, becoming petroleum, and this, by the same operation, passing into asphaltum; and even the different specimens of these are frequently found in the same situation. They also agree in their chemical characters, are inflammable, insoluble in water and in alcohol, but combine with fixed and essential oils, and are partially soluble in ether. They are not dissolved by the alkalies, and are decomposed by the more powerful acids.

Petroleum is at present very rarely employed as a medicine; though, if the finer kinds could be procured genuine, they seem to deserve some notice. They are more agreeable than the oil of amber, and milder than that of turpentine, of the virtues of both of which they participate. They are principally recommended by authors for external purposes, against pains and aches, in paralytic complaints, and for preventing chilblains. For these purposes, some of the more common mineral oils have been made use of with good success. An oil extracted from a kind of stone-coal has been extolled among the common people, under the name of British oil, for rheumatic pains, &c.; even this is often counterfeited by a small portion of oil of amber added to the common expressed oils.

The Barbadoes tar is found in several of the West India islands, where it is highly esteemed by the inhabitants as a sudorific, and in disorders of the breast and lungs; though in inflammatory cases it is improper.

NAPLES YELLOW, a dye, is prepared by exposing lead and antimony with potash to the heat of a reverberatory furnace. It stands tolerably well, but turns black upon the contact of iron. A native pigment of this kind is also obtained from a species of lava.

NARD, among the Greeks and Romans; a sort of aromatic oil; and also a sort of plant. Pliny mentions several species of the latter. The ancients were accustomed to anoint themselves with nard at their feasts. In the Scriptures the use of it is also mentioned (*John* xii. 3, and *Mark* xiv. 3), where different substances seem to be intended.

NATRON; a salt which is found in the ashes of several marine plants; in some lakes, as in the natron lakes of Egypt; and in some mineral springs, &c. (See SODA.)

NAUMACHIA, among the Romans; a public spectacle, representing a naval action. Cæsar was the first who exhibited a spectable of this sort, which soon became the favourite amusement of the Roman people. The *circus maximus*, in which they were at first represented, being found inconvenient, buildings were erected by the emperors, particularly calculated for the purpose: these edifices were likewise called *naumachiæ*. They resembled the amphitheatres, and, like them, were at first built of wood. Domitian appears to have been the first who erected one of stone. A *naumachia*, built by Augustus, was 1800 feet long and 200 wide, and was capable of containing fifty ships with three banks of oars, besides many small vessels. They were suddenly laid under water by means of subterraneous canals, so that the ships were raised at once from the dry floor before the eyes of the spectators. The water was usually brought from the Tiber, near which the *naumachiæ* were generally built, but sometimes from aqueducts. The *naumachiarii*, or persons who fought in these exhibitions, were gladiators, slaves, criminals, &c., who were doomed to die, unless they were saved by the interposition of the people, or of the person presiding at the show.

NAVAL ARCHITECTURE. The commerce and political existence of Great Britain in a great measure depend on the scientific skill displayed by our artisans in ship-building. Prior to the close of the last century but little attention was paid to the principles of flotation and displacement, on which the science of the subject may be said to rest. Now, however, we have regular academies where young men are educated for the purpose. In these establishments they acquire a perfect knowledge both of the theory and practice of ship-building, and there is no doubt but that the results of such a system of education will be highly advantageous to our marine force.

The navy of England does not date its origin prior to the time of our Saxon ancestors. It is now, however, the best defence for our sea-girt shores. The navy may indeed be considered as the natural strength of the British empire, nor need we apprehend any danger from foreign invasion while Britain retains the sovereignty of the seas. To ensure this important desideratum, the art of ship-building must receive that assistance from theoretical science without which foreign navies will ultimately excel us on our own peculiar element.

The first authentic testimony which we find of the existence of a navy in this country occurs at the in-

vasion of Normandy by Henry, surnamed Beauclerc, in the year 1106; and the crusading expeditions, which immediately followed, contributed, in some degree, to cherish the embryo giant in its youth. Selden has given the event just mentioned as the æra of the first assertion on the part of Britain to the right of what is called the dominion of the sea; and adduces, in proof, the orders given by Henry to his Butescarli, or sea officers, that they should take particular care no vessels from Normandy approached the English coast.

The variety of improvements and inventions which took place during the fourteenth and fifteenth centuries, tended to render general nautical knowledge much more respectable than it had been. To the invention of the compass is most probably owing the discovery of America. To that of cannon, and their introduction into ships, may be attributed those improvements in naval architecture which distinguish a modern ship of war from the ancient galley.

The celebrated Sir Walter Raleigh, speaking of the ability and knowledge possessed by the British shipwrights, observes, "To say the truth, a miserable shame and dishonour it were for our shipwrights, if they did not exceed all others in the setting up of our royal ships, the errors of other nations being far more excusable than ours; for the kings of England have for many years been at the charge to build and furnish a navy of powerful ships, for their own defence, and for war only; whereas the French, the Spaniards, the Portuguese, and the Hollanders, till of late, have had no proper fleet belonging to their prince or state."

To render our description of the modern improvements in ship-building intelligible to the reader, it will be necessary for us to examine what naval architecture was in ancient times.

The vessels used on the Nile appear to have been formed of small planks cut out of the acantha or Egyptian thorn: these were not, as might be naturally supposed, cut into lengths, as planks, but nearly square, measuring about three feet each way; they were lapped over each other like tiles, and fastened together by a proper number of wooden pins nearly of the same shape with the trenails of modern times. This mode of construction was found sufficiently strong for the purposes to which it was applied, even without the obvious assistance of any internal frame of timber, and, proving equal to the necessities and ambition of the inventors, they for a long time troubled not themselves with attempting any additional improvement.

The hull of the vessel being completed, a competent number of seats, or benches, for the accommodation of the rowers, were added; and when the joints or seams were carefully caulked with the papyrus, so as completely to exclude the water, the floating fabric become fit for immediate use. We must not, however, forget to mention that experience very easily suggested the necessity of some directing as well as impelling power, in aid of human labour. A mast formed out of a straight stick of the acantha, and a sail made of papyrus, supplied the latter; at the same time a rudder, which is said to have passed through the keel or bottom of the vessel, remedied the defect occasioned by the want of the former.

As the Egyptian vessels are the earliest of which any well authenticated graphic illustration has been preserved, we give at *fig.* 1, *plate* I. NAVAL ARCHITECTURE, a view of one of their earliest sailing vessels from a bass-relief. An Egyptian vessel of the present day is represented at *fig.* 2, and beautifully illustrates the difference between the naval architecture of ancient and modern times.

Among a people so destitute of ambition as we find the Chinese described, little variation could be expected to take place either in ship-building or any other art connected in the most distant way with war, and extension of territory, since that time when experience taught them that their different rude contrivances fully answered the humble ends to which they were applied. On comparing the account given by Sir George Staunton of their smaller vessels with those in use among the aboriginal Britons, their similitude will be found extremely striking. "The boats," says he, "commonly in use among them, consist of five planks only, joined together without ribs or timbers of any kind. These planks are bent to the proper shape, by being exposed for some time to a flame of fire. They are brought to a line at each end, and the edges are joined together with wooden pins, and stitched with bamboo split into flexible threads, and the seams afterwards smeared with a paste made with quick-lime from sea shells and water. Others are made of wicker-work, smeared all over, and rendered water-tight by the same composition as is used for the former. The owners affect to paint eyes upon the heads of all these boats, as if to denote the vigilance requisite in the conduct of them. They are remarkable for standing the sudden shock of violent waves, as well as for being stiff upon the water, and sailing expeditiously. The boat belonging to the chief of the district was built upon the same plan, but upon a larger scale; it had a carved and gilt head, bearing some resemblance to that of a tiger, and a stem ornamented with sculpture and painted with a variety of designs in lively colours. In these boats the principal sitters are generally at the stem, instead of being near the stern, as is the custom in Europe."

The Chinese are said, by modern travellers, to build vessels which trade as far as Manilla, Japan, and Batavia, the burthen of which frequently amounts to 800 or even to 1000 tons. All well-informed writers agree, as already stated, that no alteration has been made in the naval architecture of this extraordinary people for several centuries past; and it has excited their wonder, in no small degree, that though Canton is visited by the ships of various nations, the superior construction of which, it might be apprehended, must be necessarily acknowledged, yet they have never thought proper to adopt any improvement whatever in the art. It is rational, however, to believe that if no innovation has been made in the form and rigging of their vessels the size and burden of them have been nevertheless permitted to increase with the spirit of trade and foreign commerce which the example of Europeans cannot but have diffused. This supposition will reconcile the account just given of the tonnage of the modern Chinese vessels with the seemingly contradictory authority of former visitors, from whom it has been understood that the capacity of the Chinese vessels, or junks, never exceeded 300 tons. A Chinese vessel similar to those employed by that people for more than 2000 years is shown at *fig.* 3, *plate* I. NAVAL ARCHITECTURE.

The keel is reported to have been generally omitted during the early ages of navigation; in vessels

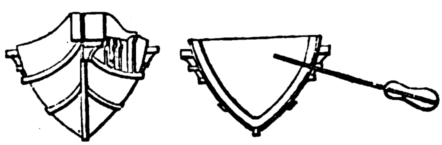
intended merely for commercial purposes. The form of these, from the most authentic descriptions, appears to have borne greater similitude to those at present employed in the same line among the Dutch than to any others now in use. They were flat-floored, round, broad, drawing little water, and of very great breadth in proportion to their length, so that they might be capable of containing a greater freight than would be the case under the adoption of any other form. Their floor-timbers were continuous; and with the addition of one futtock only on each side (called by the Greeks the ribs, from that portion of the animal body) the frame was completed.

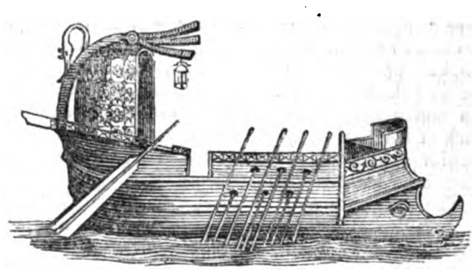
Some persons, indeed, have gone so far as to assert that by a peculiar mode, known only to the ancients, the timber was rendered so flexible that the frame was formed of one piece only. This secret, however, appears to have been nothing more than bringing it by force into its proper curve, and either confining it till time had in a great measure subdued its elastic efforts to regain its original and naturally straight form, or, as a more expeditious method, by adding cross-pieces, now called beams, and bolting them strongly to the timbers, thus completing the vessel by one uninterrupted operation. This practice being soon found extremely laborious and inconvenient was quickly discontinued with regard to vessels of burthen, and the keel universally and indiscriminately applied to them, as well as to vessels of war. To the keel, improvement and subsequent experience suggested the addition of the keelson, which, confining the heads of the floor-timbers, then in two parts, jointed and divided by the keel, very materially contributed to the strength and safety of the vessel. Close to the keelson was the well, contrived as the receptacle for the bilge-water which the working of the vessel through the rough sea caused the admission of, and which, from the impossibility of closing the joints or seams completely by caulking, found its way in in considerable quantities. The part immediately above the keelson was called the hold, and from thence is derived the English word keel, which forms the bottom of it. Aloft, beams were fixed, as already stated, which served to strengthen the vessel, and support that necessary covering well known by the name of deck. The complete arrangement of the interior of one of these ancient vessels will, however, be best understood by a sectional view.



One figure represents the galley taken at midships, and the curve formed by the timber frame is creditable to the talent of their naval architects. The other figure serves to show the forms of the head and stern of the galley.

The principal dimensions of different classes of vessels in use among the ancients, as well as of those which were of such extraordinary magnitude as to be extremely uncommon and rarely constructed, have been transmitted to posterity with much apparent certainty and precision. The celebrated Egyptian vessel called the Isis is said to have been in length 180 feet, in breadth forty-five, and in height, from the upper edge of the deck to the bottom of the well, forty-three feet. The well known ship of Hiero, king of Syracuse, was of nearly 4000 tons burthen. The rules of construction in general use for those which were usually employed in commerce, after the art had progressively advanced toward what was then supposed perfection, were in the following proportion: supposing the breadth twenty-five feet, the length was 100. The galleys which were intended entirely for the purposes of war were twice that length, but of the same breadth; nor can that very extensive difference be deemed incredible, or even wonderful, when it is known that, even in modern times, vessels no less extravagantly proportioned have been built for particular purposes, and have proved by no means ill adapted to them.

In the accompanying engraving we give a view of a second-rate Roman galley.



Meibomius gives the following dimensions of these vessels: "They were," says he, "in length 125 feet; in breadth eleven; but according to new regulations, adopted after the time of Julius Cæsar, they were built only ninety feet in length, and ten in breadth. The Quadrireme was 125 feet long, and thirteen broad: the height of the Octoreme (as the same author asserts) measured, from the upper surface of the deck to the lower edge of the keel, eleven feet: the Hexereme nine." Their first requisite was swiftness: on that principally depended the success of all their naval encounters; and every other quality was of little consequence to them. For this reason, the minds of those ingenious men who considered the science of constructing vessels as a national art, which the well-doing of their country particularly demanded should be carefully cultivated, were constantly applied to the discovery or advancement of some improvement. As soon as it was practically found that the narrowness of their vessels contributed, in a great degree, to their swiftness, and this established as a fixed and invariable principle, the next care was to dispose the rowers so commodiously within the vessel that they might not, in the first place, impede each other in their motions, and, in the second, that no part of the side should be left vacant where it was possible to employ or work an oar. The attainment to this degree of perfection is attributed to the Sidonians; and the variety of the different services which repeated warfare created gave birth to all those different classes into which the ancient galleys were divided.

Curtius gives a very circumstantial account of a fire-ship, equipped by the Tyrians at the time their capital was besieged by Alexander. "Having selected," says the author, "one of the largest galleys

they possessed, they loaded it by the stern, with stones and other ballast, so that the prow became considerably elevated above the surface of the water. The whole of the vessel which was above water was thickly coated with sulphur, and other substances easily inflammable, which operation being completed, advantage was taken of a wind favourable for the attempt, and all the sails being set the crew, who in aid of the sails made use of their oars also, directed it towards the mole which Alexander had with so much difficulty laboured to construct. When they had approached sufficiently near to the destined object of destruction, the vessel was set on fire, and the crew jumped into boats which had followed for the purpose of receiving them." This project, at that time new in theory as well as practice, proved completely successful: the hopes of Alexander were frustrated, at least for a time, and every trace as to the labour of so many thousand men vanished almost in an instant, for the whole of the stupendous work was completely destroyed. Nor was it on such an occasion alone as the preceding that these destructive engines of war, as they might without impropriety be styled, were used. Various were the occasions on which they were employed, especially in the attack of fleets when lying in harbour; for in this particular application of them the ancients appear to have been most expert.

The following account given of a Scottish ship of war may stand as the summary history of the northern royal navy:—

"The king of Scotland rigged a great ship called the Great Michael, which was the largest and of superior strength to any that had sailed from England to France; for this ship was of so great stature, and took so much timber, that, except Falkland, she wasted all the woods in Fife, which were oak wood, with all timber that was gotten out of Norway; for she was so strong, and of so great length and breadth, all the wrights of Scotland, yea, and many other strangers, were at her device by the king's command, who wrought very busily in her, but it was a year and a day ere she was completed. To wit: she was twelve score foot of length, and thirty-six foot within the sides; she was ten foot thick in the wall and boards, on every side so slack and so tight that no cannon could go through her. This great ship cumbered Scotland to get her to sea. From that time that she was afloat, and her masts and sails complete, with anchors offering thereto, she was counted to the king to be thirty thousand pounds expense by her artillery, which was very great and costly to the king by all the rest of her orders. To wit: she bare many cannon, six on every side, with three great bassils, two behind in her dock and one before, with three hundred shot of small artillery, that is to say, myand and battered falcon, and quarter falcon, flings, pestilent serpentens, and double dogs, with hagtor and culvering, crossbows and handbows. She had three hundred mariners to sail her; she had six score of gunners to use her artillery, and had a thousand men of war by her, captains, shippers, and quarter-masters."

We may now proceed to the practical part of our subject, which is in fact of the greatest importance. Stability and "flotation" are the first and principal points which strike the consideration of the naval architect; and, of these, stability evidently claims precedence, even before flotation or speed, because the safety of the human race depends on the former, and only the political or pecuniary advantage of it on the latter. Supposing a vessel drawing six feet water, and having a length of keel amounting to forty feet, it is too evident to need explanation that such a vessel must make infinitely more leeway than if it drew twelve feet, or was eighty feet in length, the lateral resistance being increased according to the squares of the side or surface presented to the water. From this cause is derived the reason why vessels of great length are less apt to make leeway than those which are shorter. The hope of increased advantage may, however, be productive of evil in some respects, provided the system be not properly confined within reasonable bounds. The inconvenience to be dreaded is material, and may be attended with the worst consequences. The reason is easily demonstrable in plain and very few terms. The action of the rudder, and its influence on the motion or course of the vessel, are exactly that of the lever; and, if the hull becomes extended to an immoderate length, the force of such lever is gradually weakened and less capable of effecting its office, till, in the end, it becomes totally useless; so that unless its own power be increased by an extraordinary addition, which would be inconvenient, or if very far augmented impracticable, on account of the power required to govern and regulate it, the ship will become the sport of the winds and waves, refusing to obey the wishes and will of its pilot.

To remedy this inconvenience, vessels were introduced having an exceedingly narrow breadth of floor, and built in every respect what is termed sharp; so that, by their sinking considerably lower beneath the surface of the water than those of flatter construction, they might, though much shorter, continue to present the same face, in square inches or feet, to the fluid as a lateral resistance, and consequently be rendered equally as little liable to fall to leeward. This system of construction is, however, pregnant with quite as many inconveniences as the former. It experiences infinitely more resistance, in the first instance, in its passage through the water; its very contracted capacity, in proportion to its measurement and expense of construction, renders it inconvenient and unadvisable, even as a vessel of war, and totally incompatible with the ideas as well as interests of commerce. Added to these considerations is that scarcely less consequential objection arising from its great draught of water, its incapability of sailing where vessels of a flatter construction would pass with safety, and the extreme danger to which it would be exposed in case of touching the ground, even in that slight degree which would be unattended with apprehension in the instance of a flat-floored vessel.

If we compare the hull of a ship to the skeleton of the human body, the keel may be considered as the backbone, and the timbers as the ribs. The keel therefore supports and unites the whole fabric, since the stem and stern posts, which are elevated on its ends, are, in some measure, a continuation of the keel, and serve to connect and enclose the extremities of the sides by transoms, as the keel forms and unites the bottom by timbers. The keel is generally composed of several thick pieces, placed lengthways, which, after being scarfed together, are bolted and clinched upon the upper side. When these pieces cannot be procured long enough to afford a sufficient depth to the keel, there is a strong thick piece of timber bolted to

the bottom thereof, called the false keel. The figure of vessels is an object of great importance, with regard to their motion, sailing, &c.; and, in the determining what form is most commodious, the doctrine of infinites becomes of apparent service to navigation and commerce. A body moving in an immovable fluid is obliged to sever the parts thereof: and they resist such separation.—Now, setting aside a certain tenacity, by which they are, as it were, glued together, and which is different in different fluids, the whole force of the resistance depends on that of the shock or impulse, for a body that is struck may be said to strike at the same time; but a perpendicular stroke is that which a fluid resists the most readily, and for a body to move freely therein it must be of such a figure as to present itself as obliquely as possible. If it were triangular, and moved with the point foremost, it is certain all its parts would strike the fluid obliquely: but they would all strike it with the same obliquity; and it were more advantageous that each should strike more obliquely than the next adjacent. Now, such a perpetual augmentation of obliquity can nowhere be had but in a curve line, each point of which is considered as an infinitely small right line, always inclined to the other little right lines contiguous to it. These brief observations will account for the curvilinear figure assumed by all perfect vessels, the form and proportions of which we may now proceed more particularly to explain.

When it is proposed to build a ship, the proportional size of every part of her is to be laid down, from which the form and dimensions of the timbers, and of every particular piece of wood that enters into the construction, are to be found. As a ship has length, breadth, and depth, three different plans at least are necessary to exhibit the form of its several parts; these are usually denominated the sheer-plan, the half-breadth-plan, and the body-plan.

The *sheer-plan* or *draught*, otherwise called the plan of elevation, is that section of the ship which is made by a vertical plane passing through the keel. Upon this plan are laid down the length of the keel; the height and rake of the stem and stern posts; the situation and height of the midship and other frames; the place of the masts and channels; the projection of the head and quarter-gallery and their appendages; and in a ship of war the position and dimensions of the gun-ports. Several imaginary lines, namely, the upper and lower height of breadth lines, water lines, &c., are also drawn on this plan.

The *half-breadth* or floor plan, or, as it is frequently called, the horizontal plane, contains the several half breadths of every frame of timbers at different heights; ribands, water lines, &c., are also described on this plane.

The *body-plan*, or plane of projection, is a section of the ship at the midship-frame or broadest place, perpendicular to the two former. The several breadths and the particular form of every frame of timbers are described on this plane. As the two sides of a ship are similar to each other, it is therefore unnecessary to lay down both; hence the frames contained between the main frame and the stem are described on one side of the middle line, commonly on the righ-hand side, and the after frame is described on the other side of that line. Several lines are described on these planes, in order the more readily to assist in the formation of the timbers, the principal of which are the following:—

The top-timber line is a curve limiting the height of the ship at each timber.

The top-timber half-breadth line is a section of the ship at the height of the top-timber line, perpendicular to the plane of elevation.

The height of breadth lines are two lines named the upper and lower heights of breadth. The lines are described on the plane of elevation to determine the height of the broadest part of the ship at each timber, and, being described in the body-plan, limit the height and breadth of each frame at its broadest part.

The main half-breadth is a section of the ship at the broadest part, perpendicular to the sheer-plan, and represents the greatest breadth at the outside of every timber.

Water-lines are lines supposed to be described on the bottom of a ship, when afloat, by the surface of the water, and the uppermost of these lines, or that described by the water on the ship's bottom when sufficiently loaded, is called the *load water-line*. According as the ship is lightened, she will rise higher out of the water; and hence new water-lines will be formed. If she be lightened in such a manner that the keel may preserve the same inclination to the surface of the water, these lines will be parallel to each other; and, if they are parallel to the keel, they will be represented by straight lines parallel to each other in the body-plan; otherwise by curves. In the half-breadth plan, these lines are curves limiting the half-breadth of the ship at the height of the corresponding lines in the sheer-plan. In order to distinguish these lines, they are usually drawn in green.

Riband lines are curves on a ship's bottom by the intersection of a plane inclined to the plane of elevation, and are denominated diagonal or horizontal, according as they are measured upon the diagonal or in a direction perpendicular to the plane of elevation. Both these answer to the same curve on the ship's bottom, but give very different curves when described on the half-breadth plan.

Frames are circular pieces of timber bolted together and raised upon the keel at certain distances, and to which the planks are fastened. A frame is composed of one floor-timber, two or three futtocks, and a top-timber on each side, which, being united together, form a circular enclosure, and that which encloses the greatest space is called the midship or main-frame. The arms of the floor-timber of this frame form a very obtuse angle; but in the other frames this angle decreases with the distance of the frame from midships. Those floor-timbers which form very acute angles are called *crutches*. The length of the midship floor-timber is in general about half the length of the main-frame.

A frame of timbers is commonly formed by arches of circles called *sweeps*. There are generally five sweeps. 1. The floor-sweep, which is limited by a line in the body-plan perpendicular to the plane of elevation, a little above the keel; and the height of this line above the keel at the midship-frame is called the *dead-rising*. The upper part of this arch forms the head of the floor-timber. 2. The lower-breadth sweep, the centre of which is in the line representing the lower height of breadth. 3. The reconciling sweep. This sweep joins the two former, without intersecting either, and makes a fair curve from the lower height of breadth to the rising line. If a straight line be drawn from the upper edge of the keel to touch the back of

the floor sweep, the form of the midship-frame below the lower height of breadth will be obtained. 4. The upper-breadth sweep, the centre of which is in the line representing the upper height of breadth of the timber. This sweep described upwards forms the lower part of the top-timber. 5. The top-timber sweep is that which forms the hollow of the top-timber. This hollow is, however, very often formed by a mould, so placed as to touch the upper-breadth sweep, and pass through the point limiting the half-breadth of the top-timber.

We may commence by giving the dimensions of a ship of war, proposed to carry eighty guns upon two decks.

	Feet.	Inches.
Length on the gun or lower deck from the aft part of the rabbet of the stem to the aft part of the rabbet of the post	182	0
Length from the foremost perpendicular to dead-flat	63	11¾
Length from the foremost perpendicular to next timber	4	0
Length from after perpendicular to timber thirty-seven	3	4
Room and space of the timbers	2	8¾
Length of the quarter-deck from the aft part of the stern	95	0
Length of the forecastle from the fore part of the beak-head	49	0
Length of round-house deck from the aft part of the stern	51	8
Height of the gun or lower deck from the upper edge of the keel to the under side of the plank at dead-flat	24	0
Height of the gun or lower deck from the upper edge of the keel to the under side of the plank at foremost perpendicular	26	0
Height of the gun or lower deck from the upper edge of the keel to the under side of the plank at after perpendicular	26	3
Height from the upper side of the gun-deck plank to the under side of the deck plank, all fore and aft	7	0
Height from the upper side of the upper deck plank to the under side of the greater deck plank — afore.	6	10
— abaft.	6	11
Height to the under side of forecastle plank afore and abaft	6	6
Height from the upper side of the quarter-deck plank to the under side of the round-house plank — afore.	6	9
— abaft.	6	10
Height of the lower edge of the main wales at foremost perpendicular	24	6
Height of the lower edge of the main wales at dead-flat	20	0
Height of the lower edge of the main wales at after perpendicular	26	6
Height of the lower edge of the channel wales at foremost perpendicular	32	6
Height of the lower edge of the channel wales at dead flat	29	0
Height of the lower edge of the channel wales at after perpendicular	34	0
Height of the upper side of the wing-transom	28	4
Height of the touch of the lower counter at the middle line	33	5
Height of the touch of the upper counter at the middle line	36	2

	Feet.	Inches.
Height of the top-timber line at the after part of the stern timber	44	7
Main wales in breadth from lower to upper edge	4	
Channel wales in breadth from lower to upper edge	3	0
Waist rail in breadth	0	7
Distance between the upper edge of the channel wales and the under edge of the waist rail	2	9
Sheer rail in breadth	0	6
Distance between the sheer rail and the rail above, from timber thirteen to the stern	2	5
Distance between the sheer rail and the rail above, from timber seven to timber eleven	1	4
Distance between the sheer rail and the rail above to the forepart of beak-head	1	2
And the said rail to be in breadth	0	6
Plank sheer to be in thickness	0	2½
Centres of the mast.—From the foremost perpendicular to the centre of the main-mast on the gun-deck	103	2
From the foremast perpendicular to the centre of the foremast on the gun-deck	20	5
From the after perpendicular to the centre of the mizzen-mast on the gun deck	28	6
Height of ditto from the upper edge of the keel	26	1
Stem moulded	1	3
Foremost part of the head afore the perpendicular	2	4
Height of ditto from the upper edge of the keel	38	3
Aft part of the rabbet afore the perpendicular on the upper edge of the keel	3	4
Aft part of the port abaft the rabbet at the upper edge of the keel	2	6
Aft part of the port abaft the rabbet at the wing-transom	1	1
Stern-post fore and aft on the keel	3	1
Ditto square at the head	2	0½
The touch of the lower counter at the middle line, abaft the aft part of the wing-transom	7	6
Round aft of the lower counter	1	4
Round up of the lower counter	0	9
The touch of the upper counter at the middle line abaft the aft part of the wing-transom	9	9
Round aft of the upper counter	1	3½
Round up of the upper counter	0	10
Aft part of the stern-timber at the middle line, at the height of the top-timber line, abaft the aft part of the wing-transom	12	6
Round aft of the wing-transom	0	6
Round up of the wing-transom	0	5½
Load draught of water from the upper edge of the keel — afore.	20	5
— abaft.	20	5
The channel to be in length	37	0
And in the thickness at the outer edge	0	4½
The dead-eyes to be twelve in number, and in diameter	1	6
Foremost end of the main channel afore timber	0	10
The channel to be in length	38	0
And in the thickness at the outer edge	0	4½

The dead-eyes to be fourteen in number, and in diameter	1	6
Foremost end of the mizzen channel abaft timber twenty-seven	2	4
The channel to be in length	20	0
And in thickness at the outer edge	0	4
The dead-eyes to be seven in number, and in diameter	1	0

Having in the previous table given the relative proportions of every part of a ship of war constructed in one of his majesty's dock-yards, we come now to what may be considered as a new era in the art of ship-building. Sir Robert Seppings, to whom we are indebted for some of the most important improvements in marine architecture which have characterized the present century, claims a prominent place in our pages, and the elaborate calculations by Dr. Young will form the best supplement to his ingenious labours.

Several large ships have already been built on the principle about to be explained; and, from the favourable reports of those ships, the Lords of the Admiralty have given their orders for the building of other ships upon the same principle.

To show, in as clear a light as possible, the advantages of the application of this new principle to ship-building, it may be necessary, for the information of those who are not acquainted with that art, to give the following general outline of the structure of a ship on the old principle.

1. The frame of a seventy-four-gun ship is formed of more than 800 different timbers, placed at right angles to the keel, which may be considered as the back-bone of an animal, and the frame timbers as its ribs. Each rib is composed of several pieces of the thickness of fourteen inches, or thereabouts. Between the several divisions of the frame, or ribs, is a space from one to five inches wide.

2. The exterior frame is covered with planks of different thicknesses, or, to carry on the figure, the ribs are covered by a skin of greater or less substance from the extreme ends of them to the keel or back-bone. The inside of the frame is also almost entirely lined with planks, within which is another partial range, as it were, of anterior ribs, at a considerable distance from each other, termed riders.

3. Across this frame are pieces of timber called beams, united together so as to be of sufficient length to reach from one side of the ship to the other. The use of these beams is to secure the sides of the ship, so as to prevent her upper works from spreading, and to keep that part which is under water from being compressed by the fluid. They are also the supports or bearers of the decks (or what we call in houses the girders for the floors), and must therefore be of such strength as to endure the weight of the cannon, and whatever else is to be placed upon them. The mode of fastening these to the sides has, generally speaking, been merely local, by two angular pieces of timber or iron (called knees) bolted to each beam, and also to the sides of the ship, by which means they were only partially held to the side, and there was wanting that continuity of materials, and consequently of strength, which the new system gives.

Between the beams and at right angles with them are placed pieces of wood called *carlings*, and at right angles with these (consequently parallel to the beams) ledges, which correspond with joists in a house. The planking or flat of the deck (flooring) is laid nearly in parallel lines from head to stern, upon and at right angles with the beams, and is fastened to them and to the carlings and ledges by bolts, nails, or wooden pins called *trenails*. From this statement it will appear evident that the decks, according to the old construction, are in nowise connected with the sides of the ship.

Having thus briefly described the common mode of ship-building, it will next be proper to point out such of its defects as the new principle tends to remove.

In the first place, it will be perceived that all the materials composing the fabric of a ship are disposed nearly at right angles to each other. This disposition, which in every wooden fabric is well known to the humblest mechanic to be the weakest, is particularly so in a ship, the immense body of which, subject to violent action from impulses in every direction, is sustained by a greater pressure on the centre than the extremities, arising chiefly from the difference in the fore and after parts of the body to that of the midship, or middle part.

From the want of a continued succession of support from the centre to the extremities originates the tendency to arching, or hogging. This tendency shows itself in a ship from the moment of her launching; from which some idea may be formed as to the extent to which it will be carried in a troubled sea, when in the act of pitching she is borne up by the fluid only in her central part, while the head and stern are forsaken, and therefore unsupported by the water.

If a straight line be drawn from the head to the stern of a ship, whilst on the slip or in the dock, no sooner has she entered her own element than each end of this line will be found to have dropped from two to five or six inches, in consequence of the weakness of the fabric, and the two extremes wanting the quantum of support which the fluid gives to the central part.

The length of a seventy-four-gun ship being between 100 and 200 feet, it requires but little knowledge of the strength of timber to perceive that planking of that length, however thick, or in whatever way joined or put together, must, under the present system, bend with its own weight. The fastenings, and consequently the connection of the several parts of the fabric, must therefore suffer for the want of *stiffness*, and a change of form is the consequence. This may be shown by putting together four pieces of wood, and securing them with iron pins in the form of a square, which on the least pressure may be made to change its form to the rhombus; but let another piece be fixed to it diagonally, and the figure of the frame will be found immovable. Place a bar in the middle parallel to two of the sides, and secure it firmly by iron pins, still the figure will easily be moved by the hand, like a parallel ruler, and assume the rhomboidal shape of *fig.* 1 or 2. *plate* II. NAVAL ARCHITECTURE; but apply to the frame what the carpenters term the brace in a common field-gate as shown at *fig.* 3, and the figure will remain as before immovable. If this brace or diagonal piece is not fixed to it, the outer part of the gate (or that part most distant from the hinges) will have a constant tendency downwards, until at length it will reach the ground.

Let *figs.* 4 and 5 represent two frames of wood composed of parts strongly connected by bolts and iron pins.

Fig. 4 will represent the principle on which the present system of ship-building is conducted.

Fig. 5 the new principle.—Now if we attach two weights for the purpose of ascertaining the comparative strength or stiffness of each frame, it will be seen that the stiffness of *fig.* 5 is to that of *fig.* 4 as 6 is to 1, and the strength as 3 to 1.

The greater the length of the frames, the greater will be the advantages of the new principle, both in stiffness and strength.

The substitution of the triangle, as in the frame of *fig.* 3, for the rectangle in the frame *fig.* 1, comprehends the principle of the new system, the use and advantages of which will be sufficiently evident.

The arrangement of the materials in the triangular mode is such that the pieces disposed horizontally are acted upon as ropes are by a strain of the fibre, whilst the other parts, composing a series of triangles, are pressed upon as pillars: in other words, the pressure acts in the direction of the fibres of the wood; whereas upon the rectangular, or old plan, the fibres are acted upon transversely, or across the grain, in the same manner as a stick is when placed across the knee and pressed by the hands at each end, which first bends, and then breaks.

To prevent any transverse action upon the fibre of the timber is one of the benefits arising from the new system, and to impede a longitudinal extension of the structure is another.

For as the diagonal frame, composed of a series of triangles, aided by diagonal trussing between the ports, prevents the fabric from being acted upon transversely to the fibres of the materials horizontally placed, so the wales, the planking, the shelf-pieces, the improved waterways, and the deck systematically secured, become the tie-beams of the structure. In a word, the system of triangles is so constructed, in conjunction with the planking of the ship, as conjointly to possess that property of a triangle already explained, viz. that its figure is as unalterable as the compression or extension of the fibre of timber will admit it to be.

The strength of the principle has hitherto been considered as applying to or resisting an alteration of the figure, by giving great stiffness. It is now to be taken in another point of view, that of rendering the strength of the fabric as general and united as possible. For, let it be again observed, the strength of any body is but equal to that of its weakest part.

In the new system, the openings between the ribs are filled in with slips of timber nearly to the height of the orlop or lower tier of beams, which being then caulked, and peyed or pitched over, make the frame from head to stern, and within a few feet of the greatest draught of water, one compact and water-tight mass of timber; so that, were any of the outer planking of the bottom to be knocked off, the ship would not only still keep afloat, but would be secured from sinking. In the old system the starting of a plank would be and often has been fatal.

The mode of filling in these openings between the frame, where the width of the space does not exceed three inches, is by driving in slices of wood cut wedge-like; two of these being driven, one from the outside, the other from within, form the parallel space of the opening, thereby bringing the parts into the closest contact. In the openings exceeding the width of three inches, the space is occupied by pieces corresponding with the openings, the fibre of such pieces being laid in the same direction as that of the frame-timbers. These fillings occasion no consumption of useful timber, as one-fourth of the produce of slab and other useless wood now sold as fathom wood, would supply a sufficient quantity for the consumption of the whole navy.

The advantages obtained by filling in the openings are these:—To add to the strength and durability of the fabric; to preserve the health of the crew from the effects of the impure air arising from the filth which soon collects in these openings; to render the ship less liable to leakage, as well as to facilitate the stoppage of any leak; and, lastly, to increase, as it may be said, the thickness of the bottom from four inches or four and a half (the usual thickness of the plank) to about sixteen, thereby lessening very considerably the danger to be apprehended from getting on shore, or foundering at sea. That it tends also to the durability of the ship will be inferred from the following positions:—

1. That the openings on the old principle are, after a ship has had any considerable length of service, choked up in many parts with an accumulation of filth.

2. That no free circulation of air can be obtained in these openings by any means.

3. That timber being either freely exposed to the air, or entirely excluded from it, is equally preserved.

4. That it has been found, on examining the frame and plank of old ships, that those parts (now filled in) generally decay sooner than the rest, viz. from the floor-heads in the midships, and from the dead-wood forward and abaft, to the height of the orlop clamps.

If the above positions be true, it will follow that by filling in these openings much will be added to the durability of the ship, which also will be further promoted by omitting in these parts the inside plank, leaving thereby the surface of the frame-timbers exposed to a free admission of air as often as the ship's hold is unstowed, and, by filling in, excluding the air from two of the sides of every timber.

By omitting the inside plank, much is added to the internal capacity of the ship's hold. For though the trussed frame projects from the timbers more by five inches than the thick stuff at the floor-heads, yet, as in the old system the perpendicular riders are brought upon the thick stuff, their projection into the hold is more by eight inches than that of the new; the advantage therefore as to stowage is in favour of the diagonal frame. A tier of iron ballast will also be disposed of on this principle many inches lower, whereby an increase of stability will be given with less weight, which will favour the ship in carrying her ports out of the water, inasmuch as greater stability will be given with less ballast.

An accurate conception of the state of the ship's hold may be formed by referring to the longitudinal section (*Plate* II. *figure* 6) of the internal part of one side of a seventy-four-gun ship in a complete state, with fillings in the openings between the timbers of the frames instead of the planking over them. In this state the diagonal timbers are introduced, intersecting the timbers of the frame at about the angle of forty-five degrees, and so disposed as that the direction in the fore is contrary to that of the after part of the ship (as may be seen in the engraving), and their distance asunder from six to seven feet or more, their upper ends abutting against the hori-

zontal hoop or shelf-piece of the gun-deck beams, and the lower ends against the limber strakes, except in the midships, where they come against two pieces of timber placed on each side of the keelson for the purpose of taking off the partial pressure of the main-mast, which always causes a sinking down of the keel, and sometimes to an alarming degree. These pieces of timber are nearly as square as the keelson, and fixed at such a distance from it as that the main-step may rest upon them. They may be of oak or pitch-pine, and as long as can be conveniently procured. Pieces of timber are next placed in a fore and aft direction over the joints of the frame-timbers at the floor and first futtock-heads, their ends in close contact with and coaked or douelled to the sides of the diagonal timbers. In this state the frame-work in the hold presents various compartments, each representing the figure of a rhomboid. A truss-timber is then introduced into each rhomboid with an inclination opposite to that of the diagonal timbers, thereby dividing it into two parts. The truss-pieces so introduced into the rhomboid are to the diagonal frame what the key-stone is to the arch; for no weight or pressure on the fabric can alter its position in a longitudinal direction, till compression takes place at the abutments, and extension of the various ties. This arch-like property of the diagonal frame not only opposes an alteration of position in a longitudinal direction, but also resists external pressure on the bottom, either from grounding or any other cause, because no impression can be made on its figure in these directions without forcing the several parts of which it is composed into a shorter space. The connection which is kept up by means of this trussed frame firmly attached to the timbers of the ship by circular coaks and bolts, together with the shelf-pieces united to the sides and to the several beams by means of the same sort of fastenings, gives such unity to the whole as to bear no comparison with that heterogeneous and badly connected mass of materials for which it is substituted.

It has hitherto been a generally received opinion that stiffness or inflexibility in a ship is not strength, but that a yielding or bending of the fabric is an essential quality to preserve it from being destroyed by the shocks which it is destined to sustain. This misconception must have arisen from an equally incorrect idea, which is, that a ship must be an elastic body because there is a degree of elasticity in the materials of which it is composed. But it should be remembered that this elasticity of the materials is in fact very inconsiderable, inasmuch as the minute degree of elasticity in each piece is neutralised in the fabric by the various directions and tendencies of the numerous parts of which it is composed, so that a ship, let her construction be what it may, either loose or firm, is not in any case elastic. It follows, then, that every action and reaction of the sea operating upon different parts of the fabric at different times occasions, for the want of unity of the whole of the parts, a constant and increasing weakness, which by some may have been taken for elasticity.

When a sea strikes a ship forward, the bow will rise with the sea, which, passing aft, lifts the midships in succession, leaving at this time, in a great measure, the fore and aft parts of the ship with comparatively little or no support. Such shocks, acting upon a body whose parts are not firmly connected, produce a bending and rebending of the fabric, so that the several planks of the sides play over each other, and the fastenings are strained and loosened by a repetition of this action and reaction. On the contrary, when a body is constructed with such general unity and fixedness of all its parts as that if one be moved the whole must move with it, then it may be said that all the parts of the structure bear their portion of the strain.

The decks come next under consideration, the beams of which are disposed in the new system nearly as usual, except that in midships, where a ship necessarily requires the greatest security, two additional beams have been introduced. The beams of the several decks are attached to the ship's side in the following manner:—

1. By shelf-pieces or internal hoops. These shelf-pieces are composed of several lengths of timber scarfed or joined together by coaks, or circular douels, so as to form a kind of internal hoop, extending from the hooks forward to the transoms abaft, to the under side of which, as well as the under parts of the beams, they are securely coaked, and, being then firmly bolted to the side, instead of becoming a mere local fixture of the beam to the ship's exterior frame, as the knees were, they form one continued and general security. The shelf-piece is also a tie to the top side in a fore and aft direction, co-operating with the trussed frame, as already explained.

2. By chocks, which are placed under all the shelf-pieces in wake of the beams, except the orlop, in such a manner as to receive the up and down arm of the iron knees. The lower ends of those under the gun-deck shelf-piece rest on the ends of the orlop beams, and those of the several decks above rest on the projecting part of the spirketting below. The chocks, particularly those between the orlop and gun-decks, admit of their being driven into their respective places very tight, thereby acting like pillars. Another advantage attending them is their great tendency to stiffen the ship's side, and to prevent the beam ends from playing on the fastenings when the ship is rolling, or straining under a press of sail.

The flat or planks of the several decks being, on the old system, each of them a mere platform, or, in other words, a cover to a box unconnected with the sides, are here not only so disposed of as to oppose an alteration of figure from a force acting on the ship in a lateral direction, but are also made subservient in securing the beams to the sides of the ship.

The framing and flat of the decks (excepting the quarter-deck, forecastle, and round-house, which are laid upon the old plan) are disposed of, as represented in the plate, the former, that is, the framing or ledges and beams, in lines, the latter or planks in black, those of the starboard side being laid contrarywise to the larboard. The midship ends of the diagonal planks abut against two strakes laid in a fore and aft direction outside the comings of the hatchways; the other ends approach the timbers of the frame, and the buts at each end are secured to a tier of carlings placed for that purpose. The flat or plank of the deck so disposed is connected with a certain number of coaks to the hooks, beams, and transoms. When the decks are thus laid, waterways, as already described, are brought upon and coaked to the ends of the plank. These waterways being then bolted through the ship's sides, and also,

in an up and down direction, through the flat and shelf pieces, combine the whole in one homogeneous mass of great strength.

Few ships are without some complaint of apparent weakness after three or four years' service. These defects, which principally show themselves at the beam ends, proceed in a great degree from the local attachment of the beams to the ship's side, and the flat or covering being altogether unconnected, as already explained. The extreme ends of the beams, not being properly secured, play and work upon the fastenings, so that it is not unusual to see the bolt-holes cut to an oval figure by the friction of the bolts. The remedy usually applied to a ship in this state is to load her with additional materials, such as iron knees, standards, breast-hooks, &c., thus adding greatly to the original weight of the fabric. Now it is evident that with the first gale of wind the ship encounters, after being thus partially strengthened, she must be reduced to the same state of weakness she was in before the remedy was applied. This mode of strengthening ships may be compared to that of a raft firmly secured in the first place by strong lashing, which after some time works loose, or rather by working is stretched. As it might be too tedious a business to secure the raft by re-tightening the lashing, a small cord, or some twine, would be used to answer the purpose. It is clear that whilst the small cord or twine remained tight no part of the strain could bear upon the strong but loose lashing, till the other stretched or broke; so it is with a ship that has additional securities given her without refastening those which had worked, or were much strained.

The tendency of the ship to stretch or draw asunder in her upper works being by no means obviated by the short planks on the inside, between the ports, a truss-piece of plank is substituted in lieu of them, which, being well secured at the abutments, very materially aids the trussed frame, and gives stiffness, thereby opposing the inclination to arch or hog aloft.

Those essential qualities of strength, safety, and durability, having been detailed, a few observations with respect to the *economy* of the new principle may not be misplaced. Though this is only a secondary consideration, yet, as the royal navy cannot be kept up without a supply of foreign timber, it evidently becomes a subject of considerable moment, when we recollect that upwards of 180 oak trees might be saved in a seventy-four, and a greater number in larger ships, allowing each tree to measure a load, or fifty feet rough contents. The consumption of this scarce article might be further considerably lessened in the new system by the use of inferior and old ship timber, which cannot be employed in the other; and if old ship timber were to be generally introduced, as was done in the Ramillies, one-seventh part of the English oak required for a new seventy-four-gun ship might be saved. The facility of ascertaining the state and making good the defects of the frame in the lower part of the ship, in consequence of omitting the inside planking, will also occasion a considerable saving of timber and workmanship: indeed the great ease with which any part of the diagonal frame may be replaced justifies the making use of fir timber, particularly for the longitudinal pieces and trusses. But, should the well-grounded hopes of durability be realized, the saving of timber, and indeed of every article required for this enormous branch of the national expenditure, would be great indeed.

Sir Robert Seppings concludes his paper by observing that the appointment of most excellent and meritorious officers to the ships already completed on his principle may be considered as a most favourable circumstance towards ascertaining the real merits of the construction. Indeed, the orders for carrying this new principle of constructing His Majesty's ships into effect were directed by such an honourable spirit of liberality, and so unshackled was the authority given to enable Sir Robert to carry his plans into execution, that no subterfuge could have availed him had any failure been found in the system.

The advantage derived from the employment of forces acting obliquely with respect to each other, in a variety of cases which occur in practical mechanics, has been demonstratively established by theoretical writers on the subject, and attempts have often been made to extend the application of the principle very considerably in the art of ship-building, but hitherto with very little permanent success. Sir R. Seppings's arrangements are in many respects either new or newly modified. The question respecting the best disposition of the timbers of a ship is by no means so easily discussed as may be supposed by those who have considered the subject but superficially; and, if we allowed ourselves to be influenced by a few hasty arguments or experiments, we might be liable to the most dangerous errors: on the other hand, it may easily happen that objections which may occur at first sight to the application of those arguments or experiments may be capable of being removed by a more minute investigation; and the importance of the subject requires that no assistance which can be afforded by the abstract sciences should be withheld from the service of the public, even by those who have no professional motives for devoting themselves to it.

The first consideration that is necessary for enabling us to judge of the propriety of any arrangement respecting the construction of a ship is to determine the nature and magnitude of the forces which are to be resisted; and the second is to enquire in what manner the materials can be arranged so as best to sustain the strains which these forces occasion.

The principal forces which act on a ship are the weight of the whole fabric with its contents, the pressure of the water, the impulse of the wind, and the resistance of the ground or of a rock; and we must endeavour to ascertain the degree in which any of them has a tendency to bend the ship longitudinally or transversely, or to break through any part of her texture, and enquire into those causes which are likely to promote or to obviate the decay of the substances employed.

It is unnecessary to explain here the well-known inequality of the distribution of the weight and pressure, which causes almost all ships to have a tendency to arch or hog, that is, to become convex upwards in the direction of their length. It is possible that there may be cases in which a strain of a very different nature is produced; but in ships of war this tendency appears to be universal. It is, however, very different in degree in the different parts of a ship; and, of course, still more different according to the different modes of distribution of the ballast and stores which may occur in different ships; but in ordinary cases

it will probably be found nearly such as is represented in the calculations from data which were originally furnished by an acute and experienced member of the Navy Board. To this strain another is added, from a cause which, although not very inconsiderable, appears hitherto to have escaped notice; that is, the partial pressure of the water in a longitudinal direction affecting the lower parts of the ship only, and tending to compress and shorten the keel, while it has no immediate action on the upper decks. The pressure thus applied must obviously occasion a curvature, if the angles made with the decks by the timbers are supposed to remain unaltered, while the keel is shortened, in the same manner as any soft and thick substance, pressed at one edge between the fingers, will become concave at the part compressed. This strain, upon the most probable supposition respecting the comparative strength of the upper and lower parts of the ship, must amount to more than one-third as much as the mean value of the former, being equivalent to the effect of a weight of about 1000 tons acting on a lever of one foot in length, while the strain arising from the unequal distribution of the weight and the displacement amounts, where it is greatest (that is, about thirty-seven feet from the head) to 5260, in a seventy-four-gun ship of the usual dimensions; and although the strain is considerably less than this exactly in the middle, and throughout the aftermost half of the length, it is nowhere converted into a tendency to "sag," or to become concave. It must, however, be remembered that, when arching actually takes place from the operation of these forces, it depends upon the comparative strength of the different parts of the ship and their fastenings whether the curvature shall vary more or less from the form which results from the supposition of a uniform resistance throughout the length. An apparent deviation may also arise from the unequal distribution of the weight through the breadth of the ship: thus the keel may actually sag under the step of the main-mast, even when the strain, as here calculated, indicates a contrary tendency with respect to the curvature of the whole ship.

The magnitude of the strain on the different parts of a ship is subjected to very material alterations when she is exposed to the forces of the wind and waves. The effect of the wind is generally compensated by a change of the situation of the actual water line, or line of flotation, so that its amount may be estimated from the temporary or permanent inclination of the ship; and the force of the waves may be more directly calculated from their height and breadth. These two forces can seldom be so applied as to combine their effects in producing a strain of the same kind in their full extent; it will therefore be sufficient for our purpose to determine the probable amount of the force of the waves, which is more materially concerned in effecting the longitudinal curvature than that of the wind. As a fair specimen of the greatest strain that is likely to arise from this cause in any common circumstances, we may consider the case of a series of waves twenty feet in height, and seventy in breadth, the form being such that the curvature of the surface may be nearly proportional to the elevation or depression: a single wave might indeed act more powerfully than a continued series, but such a wave can scarcely ever occur. We shall then find upon calculation that the greatest strain takes place in a seventy-four-gun ship at the distance of about eighteen feet from the midships, amounting to about 10,000 tons at the instant when the ship is in a horizontal position; while in more common cases, when the waves are narrower, the strain will be proportionally smaller and nearer to the extremity. Hence it appears that the strain produced by the action of the waves may very considerably exceed in magnitude the more permanent forces derived from the ordinary distribution of the weight and pressure, being, according to this statement, nearly three times as great; so that when both strains co-operate their sum may be equivalent to about 15,000 tons acting on a lever of one foot, and their difference, in opposite circumstances, to about 5000. There may possibly be cases in which the pressure of the waves produces a still greater effect than this; it may also be observed that the agitation accompanying it tends to make the fastenings give way much more readily than they would do if an equal force were applied less abruptly. At the same time it is not probable that this strain ever becomes so great as to make the former perfectly inconsiderable in comparison with it, especially if we take into account the uninterrupted continuance of its action. It appears therefore to be highly proper that the provision made for counteracting the causes of arching should be greater than for obviating the strain in the contrary direction: for example, if the pieces of timber intended for opposing them were, on account of the nature of their fastenings, or for any other reason, more capable of resisting compression than extension, they should be so placed as to act as shores rather than as ties: although it by no means follows, from the form which the ship assumes after once breaking, that the injury has been occasioned in the first instance by the immediate causes of arching, since, when the fastenings have been loosened by a force of any kind, the ship will naturally give way to the more permanent pressure, which continues to act on her in the state of weakness thus superinduced.

The pressure of the water against the sides of a ship has also a tendency to produce a curvature in a transverse direction, which is greatly increased by the distribution of the weight, the parts near the sides being the heaviest, while the greatest vertical pressure of the water is in the neighbourhood of the keel. This pressure is often transmitted by the stanchions to the beams, so that they are forced upwards in the middle. When they are unsupported, the beams are more generally depressed in the middle, by the weight of the load which they sustain; while the inequality of the pressure of the water co-operates with other causes in promoting the separation of the sides of the ship from the beams of the upper decks. On the other hand, the weight of the main-mast often prevails partially over that of the sides; so that the keel is forced rather downwards than upwards in the immediate neighbourhood of the midships. The tendency to a transverse curvature is observable when a ship rests on her side, in the opening of the joints of the planks aloft, and in their becoming tighter below; although this effect depends less immediately on the absolute extension and compression of the neighbouring parts than on the alteration of the curvature of the timbers in consequence of the pressure. In such a case there is also an obvious strain, tending to produce a lateral curvature: and shores are sometimes employed to prevent its effects, when a ship is 'hove down" on her side. This, indeed, is com-

paratively a rare occurrence; but, when a series of large waves strike a ship obliquely, they must often act in a similar manner with immense force: the elevation on one side may be precisely opposite to the depression on the other, and the strain from this cause can scarcely be less than the vertical strain already calculated; but its effects are less commonly observed, because we have not the same means of ascertaining the weakness which results from it, by the operation of a permanent cause. When a ship posseses a certain degree of flexibility she may, in some measure, elude the violence of this force, by giving way a little for the short interval occupied by the passage of the wave; but it may be suspected that her sailing, in a rough sea, must be impaired by such a temporary change of form.

When a ship takes the ground, she may either give way at once to the stroke of a rock, or rest on a bottom more or less soft, until she is wholly or partially abandoned by the water. In the former case her resistance must depend, in a great measure, on the parts in the immediate neighbourhood of the injury; in the latter it may happen that she may be supported by so large a surface as to be more in danger of parting aloft than of being crippled below. Commonly, however, the floor-timbers are forced in at one end, the first futtucks, which are their immediate continuations, being broken off; and sometimes the opposite ends of the floor-timbers are forced out, especially in large ships without riders, their attachment to the keel remaining unimpaired.

The causes which promote the decay of timber are only so far understood as we are acquainted by experience with their effects. A partial exposure to moisture appears to be by far the most general of these causes: it is well known that total submersion does not accelerate decay; a surface which is kept moist by imperfect contact with another, so that a portion of water is retained between them by capillary attraction, seems always to be the part at which the timbers begin to rot; while both the surfaces completely exposed either to the drier air or to the water, and those which are wedged closely together and press strongly against each other, remain perfectly sound.

We are next to enquire into the comparative advantages of different angular positions of the timbers of a ship, for resisting the forces which have been described; and in particular how far the arrangements which have been proposed by Sir R. Seppings are better calculated for the purpose than the common modes of construction. Sir Robert's experiments show that when two parallel planks have loose pieces interposed, extending perpendicularly from one to the other, they are incomparably weaker, with respect to any transverse force, than when the intermediate pieces are in an oblique direction, so as to constitute a frame which can only be bent as a whole. But it cannot for a moment be imagined that the planks of a ship are connected with the timbers in as loose a manner as these transverse braces, which will scarcely support their own weight, for the purpose of the experiment; and in fact the comparison would have required that the whole space included by the parallelogram should be filled up, in each case, by similar braces, or at least that the two planks should have been firmly united at the loose end to the transverse braces; and it is demonstrable that in this case the same weight would have broken the pins as if one of the planks had been oblique, or as if the planks had remained parallel and had been connected by oblique pieces. Such a result would, however, be far from proving the inutility of the addition of oblique braces to a rectangular frame; for the kind of strength required for any particular purpose is not always determined by the magnitude of the force which would be capable of breaking the substances concerned, although the power of resisting such a force is properly called strength, in the most limited sense of the term: but there are many occasions on which stiffness, or inflexibility, is of material advantage. A coach spring, consisting of ten equal plates, would be rendered ten times as strong if it were united into one mass; and at the same time 100 times as stiff, bending only $\frac{1}{100}$ of an inch with the same weight that would bend it a whole inch in its usual state, although nothing would be gained by the union with respect to the power of resisting a very rapid motion. Now it appears to be extremely difficult to unite a number of parallel planks so firmly together, by pieces crossing them at right angles, as completely to prevent their sliding in any degree over each other; and a diagonal brace of sufficient strength, even if it did not enable the planks to bear a greater strain without giving way, might still be of advantage in many cases, by diminishing the degree in which the whole structure would bend before it broke. The strength of a simple rectangular frame, firmly fixed at one end, is rendered somewhat less than double by perfectly fastening the joints at the other, and the stiffness is nearly quadruple. The comparative security obtained by the addition of the diagonal brace is almost without limit. Supposing any number of planks of equal dimensions to lie simply on each other without any adhesion, and to be firmly fixed at one end, their aggregate strength will be very little greater than that of a single plank of one-sixth part of the common depth or thickness of each, supported by a brace a little stronger in the direction of the diagonal of the whole; and the stiffness of the parallel planks will be as many times less than that of such a frame as there are planks in one-third of the whole series. Thus, if we had twelve planks, six inches deep and one thick, with friction rollers interposed, it is demonstrably true, however surprising, that they would be very little stronger in supporting a weight at the end than a single tie an inch square in its section, assisted by a diagonal brace of equal relative strength; and also that this apparently slight structure would be nearly four times as stiff as the twelve planks, being depressed only one-fourth as much, with a given weight, as the planks with a similar force acting on them.

It is well known that if the planks were firmly united into one mass their strength would be rendered twelve times as great by the union, and their stiffness 144 times. But this is not the greatest resistance of which the materials are capable, even without any extension of their base of support; for if the planks were connected in pairs at half the distance of the whole depth, and allowed to move freely round fastenings perfectly secure, their strength, speaking theoretically, would be greater by one-half than if they formed a compact mass, while their stiffness would be only about one-fourth as great: and an effect nearly similar might be produced if the respective pairs were united by oblique braces, ex-

tending over half the depth of the whole structure, although it would be very difficult, in practice, to make the strength of an arrangement of this kind even equal to that of a compact mass, since the fastenings could never be so perfect as to bring every fibre of each plank into its full action at once, as the theory supposes. If the planks were already united into a compact mass, so as to be incapable of bending, except as a whole, it is of importance to enquire whether any advantage would be gained by the further addition of oblique braces: and it will appear that, if the braces were fixed to the outermost planks of the series only, they would have no manner of effect, either on the strength or on the stiffness, whatever might be their direction; but, if they were sufficiently fastened throughout the extent to each plank with which they come into contact, they would add both to the strength and to the stiffness, very nearly in the same degree as if they were fixed in the direction of the planks, at a distance from each other equal to their shortest actual distance, so as to constitute as many ribs as there are braces in a transverse line. Hence, although there is obviously no economy in such an employment of oblique braces, yet it is by no means true that oblique braces are incapable of adding to the strength of a structure composed of pieces arranged at right angles; the assertion might, however, be very nearly correct in circumstances approaching to those of one of the experiments which have been exhibited for the purpose of illustrating the utility of such braces. On the other hand, the advantage of employing oblique braces must depend, in a great measure, on the degree in which the angular position of the structure would be susceptible of variation without them, since, when properly fastened, they must universally tend to preserve the form unaltered, although they are somewhat less calculated to add to the ultimate strength of the principal tie or shore than if their direction had been longitudinal. To take, for example, the case of a ship's arching, or hogging: if the strength were overcome without any deficiency of stiffness, the upper decks and wales would be elongated, and the butts of the planks aloft parted; while the keel would be somewhat shortened, and the planks near it crippled, so that a ship of 176 feet long and forty feet deep, arching one foot with a uniform curvature, would have the length of the parts aloft, on the level of the quarter-deck, twenty-two inches greater than that of the keel. If, on the contrary, the strength were not overcome, but only the stiffness failed, the angular situation of the parts being altered, and the joints simply becoming loose without parting, the planks would slide on each other, and their square ends would no longer remain in the same vertical line at the ports, while there would be no material alteration in the comparative length of the decks and keel, nor any permanent parting of the butts of the planks. This comparison, therefore, brings the question respecting the general utility of oblique riders into a very narrow compass; and we have only to enquire in what way it is most usual for ships to exhibit symptoms of weakness, in order to decide it. Now it will appear that in cases of arching in general some of the butts of the planks are always found to have parted aloft, at the same time that the angular position of some parts of the structure has as uniformly been more or less altered; and very generally a certain degree of sliding is observable in the planks, at the sides of some of the ports.

It appears, therefore, to be sufficiently established that the principle of employing oblique timbers is a good one, provided it be so applied as to produce no practical inconvenience. We must next enquire whether Sir R. Seppings has introduced it in a manner likely to be effectual, and not liable to any material objections. He places on the sides of a seventy-four gun ship several series of oblique braces, principally between the ports, in the place of the internal planking, making an angle of about twenty-four degrees with the decks, consisting of planks four inches thick and about eleven wide, coaked and bolted to the timbers, and abutting against upright pieces similarly fastened. Now it follows, from what has already been stated, that these pieces have about four-fifths as much effect in co-operating with the neighbouring parts, which act horizontally, as if they had been placed in the same situation with them, even on the supposition that the relative angular situation of the pieces is unalterably fixed; but, for preventing the alteration of this situation, there is no doubt of their being very advantageously arranged, so far as their strength is sufficient; and the existence of a tendency to such an alteration, in a very material degree, appears to be altogether indisputable. Below the gun-deck, the oblique timbers are considerably stronger, although they act under circumstances somewhat less favourable.

Having thus, with the assistance of Dr. Young, fully elucidated Sir Robert Seppings's mode of constructing large vessels, we should be wanting in justice to this improver of our navy did we omit to notice his admirable paper "on a new principle of constructing ships in the mercantile service." And, first, as to the principle on which mercantile ships are at present built, and particularly as regards putting together their ribs or frames, and the arrangement of the materials. In forming the frames or ribs, half of the timbers only are united so as to constitute any part of an arch, every alternate couple being connected together, the intermediate two timbers (termed fillings) being unconnected with each other and merely resting upon the outer planking, instead of giving support to it. Now, it must be very evident that ships so constructed can by no means possess equal strength with those that have the whole of their timbers formed into frames or arches. This loose practice is peculiar to the English merchant-ship builder; and indeed was pursued till very lately even in his majesty's navy, while the preferable system of connecting the ribs was common to other maritime powers.

The principle of uniting the frames, lately introduced in the construction of English ships of war, might, no doubt, be also introduced into the mercantile navy, which would give to the ships in that employ additional strength and increased durability, without adding to the expense of building. But the present mode of joining together the several pieces of the same rib is also highly objectionable. It is done by the introduction of a third piece, technically termed a *chock* or *wedge-piece*, of which pieces the number amounts to upwards of 450 in a seventy-four gun-ship, and not fewer than that number in an Indiaman of 1200 tons. Of these chocks, not one in 100 is ever replaced in the general repair of a ship; for they are not only found

defective, but very generally to have communicated their own decay to the timbers to which they are attached. Besides this, the grain of the rib-pieces being much cut, to give them the curvature required, has a considerable share in weakening the general fabric. That they occasion a great consumption of materials is obvious, as the ends of the two rib-pieces must be cut away, and then be replaced by the chock.

This mode of putting together the frame is also peculiar to the English ship-builder; and Sir Robert says, "I find, from an old work in my possession, dedicated to George I., that the practice was introduced in the construction of English ships about the year 1714: and having heard that so unfriendly to it was the builder (Mr. Naish) of the Royal William that he refused to adopt it, and being desirous of ascertaining the fact, when that ship was taken to pieces at Portsmouth, in 1813, I found that she was built without the wedge-pieces or chocks, to which, in a certain degree, I ascribe her strength and durability, her ribs being by her structure less grain-cut, and for want of chocks less liable to decay in those parts where they are inserted."

Another great defect arising out of the present plan of constructing mercantile ships is that the ends of the lower ribs, or timbers, commonly termed the lower futtocks, are not continued across the keel, so that no support is given in a transverse direction when the ship touches the ground, nor any aid to counteract the constant pressure of the mast. This great sacrifice of *strength* and *safety* is made for no other purpose than that of giving a passage for the water to the pumps.

The floor-timbers, which by this mode of construction are the only timbers that cross the keel, are also weakened for the same purpose. This mode also makes the conveyance of the water very uncertain; for the passage is not unfrequently choked, and the pumps (from its not being practicable to continue them sufficiently down) always leave from six to eight inches of water in the ship; so that these compartments constantly contain a certain quantity of putrid bilge water, offensive and injurious to the health of those on board.

The deficiency of strength causes also an alarming insecurity in the plank of the bottom, as shown at that part termed the garboard strake, which consequently has no other fastening to the general fabric than its connection with the keel: hence it is obvious that, in the event of the keel being disturbed, the garboard strake, from its being attached to it, must share the same fate as the keel, and in that case the loss of the vessel would be inevitable.

To obviate these serious defects is Sir Robert's principal object. By the principle he recommends the component parts of each rib are of shorter length and less curvature, and consequently less grain-cut; they are also more firm and solid by the substitution of coaks, or douels, for chocks or wedge-pieces; and the mode of connecting the lower timbers is better adapted, in the event of a ship grounding, to give support and strength to the fabric.

The plan of connecting the ends of the timbers by circular douels, or coaks, is simply that which has, from time immemorial, been practised to unite the fellies of carriage-wheels; and we learn from Mr. Wood that the same method has been observed in joining together the separate pieces of the shafts of the stone columns in the ruins of Balbec. "Little more of this great edifice (says this author) remains than nine lofty columns supporting their entablature. It is remarkable that the shaft of these columns consists of three pieces most exactly joined together without cement, which is used in no part of the buildings, they being strengthened *with iron pins received into a socket*. How much this method contributed to the strength of the building is remarkably seen in the most entire temple, where a column has fallen against the wall of the cell with such violence as to beat in the stone: it fell against and broke part of the shaft, *while the joinings of the same shaft have not been in the least opened by the shock*.

That the frame of the Talavera, which is built on this principle, is superior in point of strength to a frame constructed on the common system, is fully established by a report from the officers of his majesty's yard at Woolwich to the Navy Board, who directed them to compare the strength of the frames so united with those of the Black Prince, constructed in the usual way with chocks or wedges.

It may be necessary to observe that the frame of the Talavera is composed of small timber, hitherto considered applicable only for the frames of frigates. Sir Robert was prompted to attempt the introduction of the plan on which she is built from there being a surplus store of small timber in the yard, and from a conviction that a well-combined number of small timbers might be made equal, if not superior, both in strength and economy, to the large, overgrown, and frequently grain-cut materials, made use of in constructing the frames of large ships; and the result has shown the correctness of the principle, the adoption of which cannot fail to prove of great national advantage in the application of sloop timber to the building of frigates, and of frigate timber to ships of the line, whenever larger timber cannot be procured. On this principle, also, may frigates and small ships of war, or merchant vessels, be built of straight fir, without the assistance of oak or elm, which were formerly employed to give the necessary curvature to the sides. As it respects the general safety of the ship, it may be proper to state that the timbers uniformly cross the keel; that the frame of the ship is filled so as to form one compact body to the height marked *k*, *plate* III. *figs*. 1 and 2; and that only certain internal streaks of plank, or thick stuff, as it is termed, are introduced, which are those on the joints of the timbers, for the purpose of giving strength where every alternate timber necessarily joins, as shown at *l*, *fig*. 2. All the rest of the inner planking may be omitted, and dunnage battens brought in a perpendicular direction upon the timbers *between* the plank, as shown at *m*, forming regular spaces between each, as is usual at present *upon* the plank, thereby giving an increase of stowage in proportion to the thickness of the plank omitted. Water-courses, as shown by dotted lines at *n*, are to be left in the joints of the timber under the plank, for the purpose of conveying the water to the pumps, which by this plan will reach below the water, instead of being some inches above, as is the case with the present mode above described; consequently, by the proposed system, no stagnant water will remain: and, further, the timber-passage, or water-course, will be one smooth uniform channel, which can be cleared with ease, should it be required, whenever the hold is un-

stowed; whereas, at present, it is accessible in places, and forms compartments of putrid water, without there being any means of removing it.

Passing from the important improvements in the framing of the hull which have originated with Sir Robert Seppings, we have next to examine Captain Schanck's suggestions for a *sliding keel.* The speed of a vessel does not depend so much upon the form of the bow as it does on the depth to which it is immersed in the water. Captain Schanck has stated, very properly, that in the case of a frigate drawing seventeen feet water, and another frigate of the same burden drawing only eleven feet, the latter will have a body of six feet less fluid to divide, opposing only one, two, or three keels, as may be found necessary, to make her hold a good wind, while the former has six feet perpendicular depth of her hull depressed, being about one-third of her real size. It follows, therefore, that she has a body of water to displace, and force herself through, equal to the difference between eleven and seventeen; when it is considered, in addition to this, that the resistance of the fluid rapidly increases in proportion to the depth it is acted against, the disparity is almost incredibly increased. North-country-built vessels, or those in the coal-trade, are a strong proof of this observation. These, in general, draw one-third less water than any other vessels of British construction; yet, when employed as transports, they are generally found to sail as fast as any others; and when going before the wind in ballast, or half loaded, frequently beat the ships belonging to the royal navy. When, however, they are close hauled on a wind they will drop to leeward; but, were they furnished with sliding keels, it is most likely that they would have the advantage over all other vessels. The Dutch, who bestow little pains in making their trading vessels sail, are nevertheless fortunate in this respect; for, when they are light, they sail fast before the wind, owing to their small draught of water. They have also other vessels built almost totally flat, such as pilot boats, yagers for carrying the first herrings to market from Shetland, and pleasure yachts. All these have lee-boards, by the assistance of which they sail as fast as the generality of those which navigate the Northern Seas. These facts are manifestly in favour of flat-floored vessels and sliding keels.

In regard to the sailing trim of a vessel, it is the decided opinion of most scientific men that ships of the larger classes should always be so constructed as to sail on or nearly on an even keel, that is, so that the ship, when trimmed for sailing, should have her keel parallel to the surface of the water; therefore by as much as the effort of the wind on the sails and masts in forcing the ship through the water has a constant tendency to depress the bow, so much should the ship be trimmed by the stern, as that will be found most advantageous both to their sailing and steering.

It is a point too well known to every person conversant in naval architecture to need explanation that the different constructions of vessels will occasion a considerable variance in the quantity which those actually of the same measurement will carry. Ships built sharp forward and aft lose a considerable portion of stowage; while some vessels have the floor so straight throughout the whole of their length that by looking down in the holds of one, and of the other, the difference is easily discernible by the eye. For this reason it is impossible a true measurement ever can be made; and the assertion may be regarded as true that, notwithstanding all which the respectable and learned men of different nations have written on the subject, no certain method will ever be discovered of ascertaining the true capacity of vessels, until they shall be built with a greater resemblance to each other, even in the upper works, as well as in the lower part of the hull. It has frequently been observed by officers, and others who have had occasion to inform themselves practically on the subject, that many ships of the same measurement will not take in nearly the quantity they are estimated to carry; while others, exclusive of the quantity of goods or stores which their constructors allotted to them, can receive a still greater cargo, and carry it with ease. It has been observed, too, that if sharp-built vessels are at any time capable of containing the amount of their calculated tonnage they are never able to carry it with the same ease as vessels of flatter construction, inasmuch as their form forward and aft will inevitably occasion their pitching and shipping water. This inconvenience has been observed to proceed invariably from the cause just assigned; for a sharp-built ship sinks under its cargo so fast that by the time it comes to its bearings it is frequently not nearly loaded. Those which have flat and long floors, on the other hand, sink slowly; and, after having taken in the quantity they measure, will frequently have plenty of room, and remain high out of the water: so that it has happened, not only that an additional cargo has been taken in, but that when two vessels of the same measurement, but of contrary construction, have been laden at the same time, the flat-floored vessel has been enabled to carry what was necessarily rejected by her companion; and, after taking on board the whole of her additional cargo, still continued in the best state of trim. It appears, indeed, to be the opinion of many ingenious naval architects, and of Captain Schanck in particular, that one of the first desiderata in the improvement of the art of ship-building would be to try experiments on the general use of long flat floors, which are supposed by many to promise, under certain regulations, the most extensive advantages.

The only objection that can be advanced against this system is the inaptness of a flat-floored vessel to hold a good wind, a difficulty which may be entirely removed by the adoption of sliding keels, provided they are found, on more critical enquiry, to answer the intended purpose, without occasioning injury to the vessel or material inconvenience to the mariners.

In 1663, Sir William Petty constructed a double ship, or rather a single ship with a double bottom, which was found to sail considerably faster than any of the ships with which it had an opportunity of being tried. Her first voyage was from Dublin to Holyhead; and on her return "she turned into that narrow harbour against wind and tide, among rocks and ships, with such dexterity that many ancient seamen confessed they had never seen the like." This vessel with seventy more was lost in a dreadful tempest.

This subject was again revived by Mr. Gordon, in his *Principles of Naval Architecture,* printed at Aberdeen, anno 1784, where, having delivered his sentiments on the construction of large masts, he says: "These experiments likewise point out to us methods by which two vessels may be laterally connected together, though at a considerable distance

from each other, in a manner sufficiently strong, with very little increase of weight or expense of materials, and without exposing much surface to the action or influence of the wind or the waves, or obstructing their motion in any considerable degree, and consequently without being much opposed by them on that account under any circumstances; and if vessels are judiciously constructed, with a view to such a juncture, it would be no easy matter to enumerate all the advantages that may be obtained by this means." He then enumerates the advantages that double vessels would have over those of the common construction. Soon after double ships were actually built by Mr. Miller, of Dalswinton.

Another plan was proposed by Mr. Gordon to make a ship sail fast, draw little water, and keep a good wind. For this purpose "the bottom," he says, "should be formed quite flat, and the sides made to rise perpendicularly from it, without any curvature; which would not only render her more steady, as being more opposed to the water in rolling, but likewise more convenient for stowage, &c., while the simplicity of the form would contribute greatly to the ease and expedition with which she might be fabricated. Though diminishing the draught of water is, of all others, undoubtedly the most effectual method of augmenting the velocity with which vessels go before the wind, yet, as it proportionally diminishes their hold of the water, it renders them extremely liable to be driven to leeward, and altogether incapable of keeping a good wind. This defect may, however, be remedied in a simple and effectual manner, by proportionally augmenting the depth of keel, or, as so large a keel would be inconvenient on many accounts, proportionally increasing their number; as, in the place of adding a keel eight feet deep to a vessel drawing six feet water, to affix to different parts of her flat bottom, which would be well adapted for receiving them, six different keels of two feet deep at equal distances from each other, with proper intervals between, which will be found equally effectual for preventing these pernicious effects. Four such, indeed, would have answered the purpose as well as the eight-feet keel were it not for the superior pressure or resistance of the lower water."

Thus then it appears that a vessel drawing eight feet water only, keels and all, might be made to keep as good a wind, or be as little liable to be driven to leeward, as the sharpest built vessel of the same length drawing ten or fifteen, if a few more keels were added, at the same time that she would be little more resisted in moving in the line of the keels than a vessel drawing six feet water only. These keels, besides, would strengthen the vessel considerably, would render her more steady and less liable to be overset, and thereby enable her to carry more sail.

This plan has been put into execution by Captain Schanck, with this difference only, that, instead of the keels being fixed as proposed by Mr. Gordon, Captain Schanck constructed them so as to slide down to a certain depth below the bottom or to be drawn up within the ship, as occasion might require.

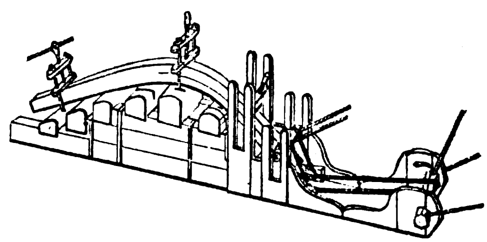
Captain Schanck having communicated his plans to the Navy Board, two vessels were in consequence ordered to be built of thirteen tons each, and similar in dimensions, one on the old construction and the other flat-bottomed, with sliding keels. A comparative trial in presence of the commissioners of the navy was made on the river Thames, each having the same quantity of sail; and although the vessel on the old construction had leeboards, a greater quantity of ballast, and two Thames pilots aboard, yet Captain Schanck's vessel with three sliding keels beat the other vessel, to the astonishment of all present, one-half of the whole distance sailed.

The attention of the reader has hitherto been directed almost exclusively to the form of the vessel: we may next notice the preparation of the timbers.

Mr. Hookey has invented a mode of bending the timbers of a large vessel which promises to be of great practical utility. It is intended principally for the preparing of floor-timbers, futtocks, breast-hooks, long riders, beams, and knees.

In the building of a seventy-four-gun ship on Mr. H.'s plan, a saving will be made of many hundred pounds.

The timber is first sawn down to the middle as far as it is to be bent, as shown by the line in the different timbers, which greatly increases the power of bending it, and permits the one part to slide over the other, so as to lessen the tear of the different parts, which are afterwards secured together by bolts passed through them, and may be still farther stiffened by additional pieces let into them.



The above engraving affords an opportunity of showing the handspikes or levers placed in the holes of the capstans, by the joint action of which the timbers are forced into the requisite curves, to suit which the blocks must be previously arranged, as well as the beams which support them, and which are so managed as to form buttresses to prevent the blocks from shifting their places in the act of bending the timbers, and the whole is securely united together by iron bands.

Having pointed out some important improvements in the construction of vessels, we may now direct our readers' attention to the means of preserving them and their crews from the most fatal of all occurrences, namely, their *foundering* at sea.

Many suggestions have been offered for this purpose, but there appears but one at all fitted for the intended object, and that is founded on the unerring law of nature that whatever is specifically lighter than the quantity of water which its own bulk will displace by immersion will swim, a position exemplified in a variety of ways. For the invention to which we refer the country is indebted to a very distinguished scientific individual named Watson, who has gratuitously devoted himself to the subject from purely philanthropic motives. This important invention consists in the employment of tubes made of copper of a cylindrical form, terminating at each extremity by convex or semi-globular ends; the whole to be hermetically sealed, and to contain, in number and capacity, a bulk or quantity of atmospheric air equal, by its displacement of water, to counterbalance that *extra*

portion of the weight or specific gravity of the ship and her contents which otherwise, in case of leak and the ship filling with water, causes her to sink. It is designed to place the safety-tubes in the spaces between the beams of the decks, also between the timbers or ribs, the shelf-pieces, and the planking, and in all other places below the decks which may be thus occupied without inconvenience.

From presenting a uniform circular surface, the safety-tubes, when immersed, would be perfectly secure against the weight or pressure of the water; and, from spreading their buoyant power equally over the whole range of the ship's several decks, they, in the event of the ship filling, are calculated to preserve her equilibrium or centre of gravity. With regard to that part of the hull of the ship which would, in case of filling from leak, become submerged, it is obvious, from the timber of which it is composed being specifically lighter than water, that the hull itself would not only float without the aid of the tubes, but would support, in that position, a considerable incumbent weight.

Several of the articles on board ships of war under the head of provisions: namely, water, wine, spirits, &c., when immersed, produce no tendency to sink the ship, but on the contrary, from being of less specific gravity than the sea, they afford an assisting buoyancy; and, although some of the remaining provisions are to a certain degree heavier, the greater part, together with the casks (with the exception of the hoops), are lighter than sea water; hence it follows that a very immaterial difference of weight exists between the specific gravity of the provisions and that of the sea, in the event of their submersion. The material weight which the "safety tubes" would have to support in case of the ship filling consists in the various metallic substances used in the building of, and those contained within the ship: namely, the guns, the shot, the chain cables, the pumps, the ballast, the tanks, the gallery apparatus, the bolts, nails, and other iron works, together with the masts, yards, and rigging; but as several of these substances would, in case of the ship filling, become immersed, so would their weight also be reduced to an extent equal to the weight of the bulk or volume of water which they would displace.

These counteractions to buoyancy, which are the inseparable appendages of a ship of war, exist in a very limited degree on board a merchant vessel; and as in most cases a portion of the cargoes of merchant vessels is, upon immersion, known to be specifically lighter than sea water, and as the generality of their cargoes, when immersed, are not very materially heavier than the body or volume of sea water they would displace, it follows that a comparatively small quantity or bulk of atmospheric air would be found requisite to keep vessels of this description afloat, in the event of their filling with water.

Hence, from the aggregate weight or specific gravity of the ship and her contents (whether a ship of war or a merchant vessel) being so materially diminished, when immersed, a sufficient bulk or quantity of atmospheric air, contained within the safety-tubes, the extent of which—reduced by a perfectly correct arithmetical calculation for every size and description of ship—can readily be placed in the parts referred to, so as, in case of the ship filling, to keep her afloat with her main deck above the surface of the sea. So great, indeed, would be the displacement of water, and consequent reduction of specific gravity, that even an eighty-gun ship, when immersed from leak, would not require the application of safety-tubes more than sufficient to support 240 tons of its immense weight.

The application, therefore, of this simple principle to the decks of ships, making them, in case of the ship filling, repose, as it were, upon air-filled tubes, must effectually prevent the possibility of a ship foundering at sea.

With regard to the best mode of applying the tubes, it may be proper to state that they are placed against the timbers and beams which constitute (like the bones with reference to animal life) the whole strength of the ship, and under those strong holds or fastenings which spread over the whole range of the ship, in three distinct divisions, widening where weight accumulates and diminishing where weight decreases: indeed, had the safety-tubes been the first invention of the mind, and had the ship been required to be suited to the reception of the tubes, the general construction of the ship, according to its present build, could scarcely have been better adapted to the object now proposed. Their arrangement will however be better understood by a reference to *plate* III., *figs.* 3 and 4, NAVAL ARCHITECTURE, in which a view is given of the vessel with her safety-tubes. They are represented as placed beneath the decks at *a a*, and a similar series protecting the sides are shown at *b*, thus taking off the strain which would otherwise cause the vessel to "blow up" on her being submerged.

This will, however, be placed in a clearer point of view by the following statement, showing the acting and counteracting effect of weight and buoyancy upon an eighty-gun ship fitted with tubes of this description, supposing the immersion to take place in consequence of a leak.

Counteraction of the Excess Weight, by means of the Safety-tubes.

Safety-tubes, containing 10,000 cubic feet of atmospheric air, hermetically sealed, displacing the like quantity of sea water upon the hull's immersion from leak, equal, at 64¾ lbs. per cubic foot, to - - - - -	289 1 1 0
Excess of buoyancy, which may be considerably augmented by instantly cutting away the masts, sails, and rigging, and by throwing overboard the upper deck guns, &c. - - - - - - - - - -	51 9 1 22

That the ship's equilibrium or centre of gravity, in case of immersion from leak, cannot be disturbed, must be apparent when it is considered that all the principal weights, viz. ballast, &c., would continue in the same part of the ship in which they are now put to keep her upright and her keel sufficiently low; and that the only difference is that the air is to be confined within the safety-tubes, in order to support the ship afloat in case of immersion, whilst in her ordinary state of sailing that same element, which is actually the main cause of her present flotation, freely circulates in the whole interior of the ship.

In further support of the impossibility of the ship's centre of gravity being destroyed, it should be observed that the safety-tubes, which are thus wholly above the greater mass of dense substances, rise in an even line with the particular weights attached to each of the several decks, which consequently have no material preponderating weight above them, except the upper-deck guns, with the masts, yards, and rigging, most of which, in the hour of storm, or on the ship springing a severe leak, would in all probability be instantly thrown overboard, and thereby, be it observed, a considerable elevation of the ship from her state of immersion would instantly ensue. Again, upon the ship, in the state of immersion from leak, lurching either to the starboard or the larboard, it is obvious that whilst the tubes on the upward side of the ship would be in part above the surface of the water, and to a certain extent go out of action, the tubes inclined with the ship's side downwards, from the increased bulk of water above them, would come into more powerful operation, and produce a counteraction tending to make the ship instantly right herself.

For the purpose of affording a clear view of the value of the tubes as applied to merchant ships, we add the following statements, with reference to two of their principal classes, the accuracy of which may be relied on.

EAST INDIAMAN OF 1300 TONS MEASUREMENT.

Statement showing the acting and counteracting effect of the weight of this ship, when immersed from leak, and fitted with the proposed safety-tubes.

Counteraction of the Excess Weight, by means of the Safety-tubes.

	Tons. cwt. qr. lb.
Safety-tubes, containing 6000 cubic feet of atmospheric air, hermetically sealed, displacing the like quantity of sea water upon the hull's immersion from leak, equal, at $64\frac{1}{4}$ lbs. per cubic foot, to - - - - - - - -	161 10 0 20
Excess of buoyancy, which may be considerably augmented by instantly cutting away the masts, sails, and rigging, and throwing overboard the guns, &c. - - - - - - - - - -	68 3 2 16

The preceding statement, comprising the particulars of an actual cargo, demonstrates the successful result of the calculation with reference to an East Indiaman, laden with as large a portion of dense weight as, upon almost any occasion, she would be likely to carry.

The whole displacement of water produced by this ship, when drawing twenty-two feet, would be 96,458 cubic feet.

The total area of space below the main-deck is about 114,900 cubic feet, of which about 25,000 become occupied by various substances appertaining to her, leaving a clear area of about 89,900 cubic feet for the reception of cargo, and for general purposes, viz.—

	Cubic Feet.
In the hold for cargo	64,613
Under the middle deck, for cargo and general purposes	15,298
Under the upper deck, for general purposes	9,975
	89,886

If every minute portion of the hold be, as generally stated, filled with cargo, it is calculated that, upon the immersion of a ship of this measurement from leak, 48,000 cubic feet of water (a proportion of only three-fourths of the space in the hold) would become displaced by such cargo.

The following spaces, independently of others that may be found, without any material encroachment upon the ship's room, may be appropriated for the reception of the safety-tubes, viz.—

	Cubic Feet.
Between the timbers	2800
Between the beams of the lower deck .	2091
Between the beams of the middle deck	1958
Between the beams of the upper deck	1360
	8209

Of these 8209 cubic feet, it is calculated that 6000, occupied by safety-tubes, will be sufficient to counteract the effect of the excess of weight of the ship, upon her immersion from leak.

The outlay for the supply of these 6000 cubic feet of safety-tubes is estimated at 2400*l.*, the interest upon which sum, with a charge of one per cent. for wear and tear of the copper, would be 144*l.*; and calculating 33,000*l.* as the cost of the ship when completely fitted for sea, and estimating the value of the ship and her cargo together to be 100,000*l.*, the real charge resulting from the adaptation of the plan to this class of ships would not exceed three shillings per cent. per annum upon the property thus secured from foundering. We need hardly add that this sum is but as dust in the balance compared with the advantages to be derived from the general adoption of this plan on the score of humanity.

WEST INDIAMAN OF 450 TONS MEASUREMENT.

Statement showing the acting and counteracting effect of the weight of this ship, when immersed from leak, and fitted with the safety-tubes.

Space below the main deck occupied by the cargo, &c., which, upon immersion from leak, will displace 26,500 cubic feet of sea water, or		766 0 1 7	
			1166 8 3 17
Super-specific gravity, or excess weight - - - - - - - - - -			34 2 3 24

Counteraction of the Excess Weight, by means of the Safety-tubes.

Safety-tubes, containing 1700 cubic feet of atmospheric air, hermetically sealed, displacing the like quantity of sea water, upon the hull's immersion from leak, equal, at $64\frac{1}{4}$ lbs. per cubic foot, to - - - - - - -	49 2 3 7
Excess of buoyancy, which may be considerably augmented by instantly cutting away the masts, sails, and rigging, and throwing overboard sundry weighty substances - - - -	14 19 3 11

In the foregoing statement no particulars of cargo are given, but in place thereof the total weight which a vessel of this tonnage could carry.

The whole displacement of water produced by this ship, when drawing eighteen feet six inches, would be 41,996 cubic feet.

The total area of space below the main-deck of a merchant vessel of this measurement is about 45,500 cubic feet, of which about 6700 are occupied by various substances appertaining to her, leaving a clear area of about 38,800 cubic feet for the reception of cargo, and for general purposes, viz—

	Cubic Feet.
In the hold for cargo . . .	32,986
Between the upper and the under deck, for general purposes . . .	5,799
	38,785

Assuming the hold to be filled with cargo, both upon the outward and homeward voyage, the for-

mer composed of a variety of articles, of comparatively small specific gravity, the latter of rum, cotton, sugar, or coffee, two of which articles afford an actual buoyancy, it is calculated there would be a displacement equal to 26,500 cubic feet of sea-water.

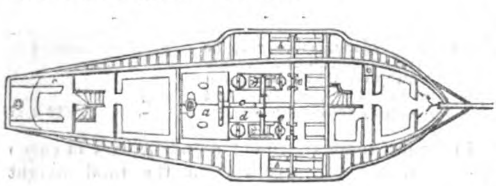
The spaces, independently of others which may be readily found, for the reception of the safety-tubes, are as follow, viz.—

	Cubic Feet.
Between the timbers	1400
Between the lower deck beams . .	400
Between the upper deck beams .	300
	2100

Of these 2100 cubic feet it is computed that 1700 occupied by safety-tubes will suffice to counteract the effect of the excess weight of the ship upon her immersion from leak.

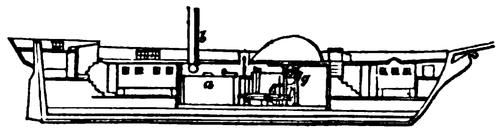
The outlay for the supply of these 1700 cubic feet of safety-tubes is estimated at 680*l.*, the interest upon which sum, with a charge of one per cent. for wear and tear of the copper, would be 40*l.* 16*s.*; and calculating 15,000*l.* as the cost of the ship when completely equipped for sea, and estimating the value of the ship and her cargo together to be 50,000*l.*, the real charge to this class of ships would not exceed twenty-pence per cent. per annum upon the property thus secured from foundering.

In concluding this article, it may be advisable to furnish our readers with a general view of the arrangement of a vessel intended for the purpose of steam navigation. Great strength is one of the first requisites in this species of naval architecture. When steam-power was first employed on the Thames the vessels required to be rebuilt every third year. Now, however, thanks to the improvements that have been effected by a partial application of the diagonal bracing, and the diminished strain of the engines by which they are propelled, they last nearly as long as an ordinary sailing vessel. The accompanying diagram shows the general arrangement of the engines, boiler, &c.



The boilers at *a* should at all times be united by a common steam-pipe, so that in the event of one giving way the other may be made to furnish a supply of steam to both engines. This would of course be with diminished power, but yet it would effectually prevent the serious accidents which have arisen from one paddle-wheel being in operation and the other stationary. The main cylinder of one engine is shown at *d*, and the air-pump at *e*. The paddles are represented at *h h*, the boxes or cases being removed from above. Metal fastenings might be employed with great advantage in the construction of steam-boats, especially between the paddle-boxes and the frame of the engine.

In the best steam-boats the steering-capstan is placed in the bow instead of the stern, and the rudder is acted on by two strong ropes which run the entire length of the vessel. This great improvement was we believe, suggested by Captain Hall.



In the above section the boiler *a* is shown with its chimney *b*. The inner-works of the vessel must be arranged so as to permit of a perfect non-conducting substance being carried round the furnace: pounded charcoal mixed with salt and sand is a good material for the purpose. The engine-room is shown at *g*. If attention be paid to the matter of ventilation when the vessel is first built, there will be no difficulty in carrying on a forced ventilation from the bow to the stern. This is a desideratum in any vessel, but is more particularly so in the heated atmosphere which completely pervades a steam-boat. The best modes of purifying the air in larger ships will be illustrated under VENTILATION. (See also SHIPS.)

NAVIGATION; the art of ascertaining the geographical position of a ship, and directing her course.—Horace has well said that his heart must needs have been bound with oak and triple brass who first committed his frail bark to the tempestuous sea. Nothing, indeed, conveys a higher idea of human daring than the boldness with which man rushes forth to encounter the elements: nothing speaks louder in praise of human ingenuity than that wonderful art by which he is enabled to forsake the land, retiring from it until it fades from the horizon, and nothing visible remains but the hollow heavens above and a trackless waste below; driven from his course by adverse winds, yet by dint of perseverance wearying out the elements, and at length arriving, with unerring certainty, at the expected haven.

If, however, the daring and ingenuity of the navigator deserve our admiration, the result of his efforts will not appear unworthy of the means. It is to the exercise of his wonderful art that we are indebted for the improvement of our condition, which arises from the exchange of the superfluity of one country for that of another, the whole world being penetrated, and every clime made tributary to every other, until the globe is reduced to one common country. Above all, to navigation are we indebted for that higher and nobler advantage, the interchange of sense and sentiment, which makes wisdom common to the world, and urges man onward in the race of improvement. Yet it has not always been so. Time was when the canoe or the raft constituted the only ship of the sailor, and when the narrow precincts of a lake or river set bounds to his roving disposition, and confined him within view of familiar objects. Advancing a step further, we find him venturing from headland to headland, or from island to island, with a view of gratifying his curiosity, or bettering his condition, until a gale, driving him to some unknown coast, increases at once his knowledge and hardidood. Meantime, his bark adapts itself to nobler functions, enlarges in size, and improves in form: the rudder is added, the mast is better sustained, and the sail receives a more favourable application. And thus the art by which the ship is made, and that by

which it is conducted, advanced with equal steps. Deprived of the aid of surrounding objects, the land withdrawn from view, and nothing within the verge of the horizon but a waste of trackless water, the mariner casts his eyes in despair to the overhanging heavens. Aid is granted to his prayers: the constellations assist him in his course: among many revolving stars, he finds one stedfast, and makes it his perpetual guide.

Such do we find the actual state of navigation among the savage tribes of our own day; and such was also the progress of the art among the earliest nations that improved it. Not the least of the improvements which we have made in this art is that simplification in practice by which it is rendered available with little study and capacity. Anomalous as it may seem, yet it is true that more study, more experience, and laboriously acquired information, were necessary to form an Acestes, or a Palinurus, than are now required to furnish forth a La Perouse or a Parry. The master, or pilot, of ancient times, who had command of the sailors, and directed all the evolutions, was not merely required to know whatever related to the management of the sails, the oars, and the rudder: it was necessary for him to be familiar with all the ports that lay in the track of his navigation, the landmarks by which they were designated, and all the rocks, quicksands, and dangers of the intervening deep: he must know the course of the winds, and the indications which preceded them; also the movements of the celestial bodies, not merely for the purpose of directing his course by them, but to understand the winds and weather which some of them, as Arcturus and the Dog-star, were believed to portend. Moreover, he had to be skilled in reading the various omens which were gathered from the sighing of the wind in the trees, the murmurs of the waters and their dash upon the shore, the flight of birds, and the gambols of the fishes. A voyage was, in those days, a momentous and awful undertaking. When the time arrived for the sailing of a ship or fleet, the masts were raised, the sails bent, and all made ready with solemnity, and great parade of preparation. If, as was most usual, the ships were hauled up on the shore, the mariners placed their shoulders at the sterns, and, at the word of command, pushed their bows forward into the sea, leaping aboard when they floated. Levers were used to move the heavier vessels, and, in later times, the *helix* (probably jack-screw), which Archimedes had invented for that purpose.

Before putting to sea, the gods were ever solemnly invoked, and propitiated by numerous sacrifices; thus we find all Homer's heroes sacrificing to the gods before they undertake a voyage; and Virgil's Anchises venturing forth only after having devoted a bull to Neptune and another to Apollo. Nor did the voyagers alone supplicate protection: the crowds of friends and countrymen, who thronged the shore, joined fervently in prayer for their deliverance from danger, and, like the Venusian poet, commended their departing friends to the presiding deities of the winds and waves. All omens were carefully regarded; the entrails of the sacrifices examined, with every possible prognostic of good or evil; and a very small matter, the perching of swallows on the ships, or an accidental sneeze to the left, was enough to delay departure. As this, however, never took place without the most favourable auspices, it was always joyful. The ships were adorned with streamers and garlands of flowers; and, when the signal was given from the admiral's ship, by sound of trumpet, a shout of rejoicing rang through the fleet, sent back by the responding blessings of the friends that remained. After advancing a short space, doves, which the mariners had brought from their homes, were released, and their safe arrival—not unfrequently charged with the last adieu of a departing lover—was considered auspicious of the return of the fleet. The Admiral led the van, conspicuous by his painted sails and streamers, and opened a path in which many followed. In moderate weather, the ships often sailed side by side; but, as the wind freshened, and the sea grew rough, the order became more open, to avoid contact. At all times, they kept close to the land, following the indentations of the coast. When night approached, it was customary to anchor, or else to beach the vessels, that the crews might repose, each rower sleeping on his bench, ready to renew his labours with the returning sun. If the amenity of the weather, the friendly aid of the moon, or the open nature of the navigation, admitted of sailing during the night, the plummet or the sounding-pole directed their course, or it was shaped, as by day, from headland to headland. If the land was not visible, the known direction of the wind continued, with the aid of the stars, to guide them Cynosura was the favourite star of the Phœnicians; the Greeks abandoned themselves to the direction of Helice.

Having escaped the multiplied dangers of such a navigation, and having accomplished their object, the ships returned home with songs and rejoicings. If they were to be stranded the sterns were turned towards the shore, and the vessels forced backwards upon it with the oars, until the crew landing drew them beyond the reach of the surf. Sometimes they were taken into the beautiful moles or artificial harbours which the ancients constructed with great labour and ingenuity within the natural ones. These were in the shape of crabs' claws or horns, the ends, which formed the entrance, so overlapping as to exclude the swell of the sea. Castles defended their approach; and a light-tower, placed at the entrance, guided those who sailed along the coast, or desired to enter by night: this was called *Pharos*, from the island at the mouth of the Nile where the first tower had been erected. Here the vessels were not hauled up, but simply fastened to the rings or pillars provided for the purpose, while at the inner port were docks and stores for building and repairing. In this port, too, were temples devoted to the gods, and especially to the patron of the place, where propitiatory sacrifices were made, and vows fulfilled or recorded; here, too, were numerous taverns and places of more licentious gratification. Whether, however, they stranded their vessels on the beach, or moored them in the harbour, the mariners, before repairing to these resorts, fulfilled the vows made before departure or in seasons of peril, offered thanks to Neptune and sacrifices to Jupiter, for having granted them a release from the durance of their ships. Upon those who had escaped shipwreck gratitude was more deeply incumbent. In addition to other sacrifices, proportioned to their means, they usually offered the garment in which they were saved, together with a picture descriptive of the disaster. If nothing else remained to them, the hair was shorn from the head and consecrated to

the tutelar deity; hence offering the hair was the last vow of the distressed mariner.

There is certainly much that is beautiful in these simple acts of piety; but, except in some Catholic countries of the Mediterranean, where pictures representing the rescue, and garments, are still hung before the shrine of an invoked intercessor, and where processions are still made after escape from shipwreck, none of these touching customs now remain. What can be more beautiful than the grateful sense of divine interference with which Columbus and his followers hastened to fulfil their vows after their safe return to Palos? Such piety, if it availed not to avert present danger, at least served to inspire confidence to meet it; and, when past, the gratitude which it occasioned must have tended at once to refine the sentiments and ennoble the heart.

Imperfect as were the means and knowledge of the ancients in this noble art, yet the Carthaginians, who superadded the greatest commercial enterprize to the greatest skill which had yet been attained, achieved results which may even now be esteemed brilliant. They made the whole of the old world tributary to their city. Not contented with exploring every nook and corner of the Mediterranean, they left behind the ocean which had hitherto almost entirely bounded the excursions of their predecessors, visited the Atlantic coasts of Europe and the British isles, and, pursuing the grand idea which afterwards led the Portuguese to India, discovered a vast extent of the western coast of Africa. Pliny even states that Hanno completed its circumnavigation and returned home by the Red Sea.

Had not Carthage prematurely fallen beneath the rivalry of a nation braver and more barbarous, Vasco da Gama might have had to seek laurels elsewhere than by sailing first to India, and even Columbus been spared the most brilliant and enviable of all the achievements of navigation, the discovery of the New World. The art of navigation gained nothing after the fall of Carthage; and the invasion of the northern barbarians effectually extinguished the few gleams of science which had survived her destruction. Every thing remained stationary for centuries, until the returning day of civilization began once more to dawn upon the world. It was not until the close of the twelfth century that man became sensible of the existence of the most singular property which an ill-wise and all-beneficent Creator has provided to be his guide upon the deep; nor until a still later period that the genius to improve it—the gift of the same good Being—at length rendered it available to so noble a purpose. We allude to the polarity of the magnet and the invention of the mariner's compass. The property of that mysterious mineral to attract iron was early known to the Greeks and Chinese; but the far more singular one of assuming a particular direction was not even suspected. Pliny himself, who records every thing known or fancied in his time concerning the magnet, makes no allusion to its polarity. The first accounts of this mention it as known in the twelfth century, and as being sometimes used by mariners to ascertain their course. While the heroes of the remotest times come down to us, not only with an accurate account of battles fought and thousands slain, but with a minute detail of their private lives and most insignificant peculiarities, posterity is at a loss to know whom to bless for a recent discovery, of all others the most useful in its results, the most important in its influence upon the destinies of man. The effects of this discovery upon navigation were not, however, immediate; for the mariner, as much as any one the slave of habit, could not at once appreciate and confide in the excellence of his new guide. This is the only excuse for the uncertainty which hangs about the identity of the discoverer. The experience of half a century, however, showed the value of this new assistant.

Navigation now assumed a bolder character. Prince Henry of Portugal, son of King John, having gained a brilliant reputation in a war with the Moors, turned from these fierce pursuits to the more congenial one of science. Retiring from court, he established himself in a retreat upon the promontory of St. Vincent, and, calling round him astronomers and mathematicians from every nation, he collected and systematized all the science of the day. Nor were his researches of a merely speculative character; they were directed to enlighten the field of discovery in which he was engaged in search of a nearer route to India, and which, though he attained not the grand object of his ambition, repaid him well by the inferior discoveries to which it led. It was to aid these enterprizes that he caused charts to be drawn, which, though they involved the monstrous supposition of the earth's being an extended plane, were of no inconsiderable use to the navigator, as they brought together whatever was known of the relative position of the different points of the earth, and enabled him to see at a single glance, as in a picture, not only the direction of the port which he desired to visit, but also the various coasts, rocks, and quicksands, to be avoided in the way. He also invented the astrolabe, which at that period was simply a quadrantal arch, graduated at the rim into degrees and half degrees. One edge of the instrument was directed towards the heavenly body whose altitude it was desired to measure, and a plummet suspended from the centre was made to mark the angle of elevation. This was used at first to discover the latitude from the elevation of the pole star; for as that star is in the horizon when viewed from the equator, and rises gradually in approaching the pole, so that it would at length become vertical, it follows that the elevation is always equal to the observer's distance from the equator, which is the latitude. The error resulting from the star's not being exactly polar was of little note in those primitive days of the art. Soon after, by causing tables of the sun's declination to be computed, Prince Henry enabled the mariner to deduce his latitude more correctly from the meridian altitude of that star.

All these improvements, however, though they added much to what was already known, left the art in its infancy. Columbus was the most accurate navigator of his day; still we find him often making an error of so many degrees in his latitude that the mistake of an equal number of minutes would not be excused in a modern navigator. To mention one of many instances, he places San Salvador three degrees north of its true position. But, if Columbus made his discovery with such imperfect means, the greater was his merit: to him belongs the credit by pushing boldly forth amid the uncertainties of the ocean of forcing navigation as well as ship-building to provide against new difficulties, and march rapidly onwards in the career of improvement. From the moment that the hitherto hidden mysteries of the ocean were thus solved, we find improvements and inventions multi-

plying in rapid succession: first, the log is introduced to measure the ship's rate of sailing. Nunes, a Portuguese mathematician, next shows that the shortest distance from place to place upon the surface of the globe must always be along a great circle of the sphere; he also proves the fallacy of the plane chart. Gerard Mercator, a Fleming, nexts suggests the idea of extending the meridian lines on the plane chart, in receding from the equator, in a ratio equal to the error occasioned by supposing the meridians parallel, instead of gradually converging as they do towards the poles. By this means the advantage of a plane surface was retained without the error of the old chart or the inconvenience and imperfection of the globular projection.

Wright, an Englishman, improving the suggestion of Mercator, calculates a table of meridional parts, increasing the length of the arches of meridians in due proportion towards the poles, and furnishes, thereby, data to determine, in any latitude, the difference of any longitude from the point of departure, or the distance sailed east or west. At the same time, lord Napier's invention of logarithms wonderfully diminishes the labour of calculation, enabling the mathematician, by their help, to substitute for the tedious operation of multiplication and division the simpler ones of addition and subtraction. Now, too, Gunter presents the seaman with his admirable scale, containing the logarithmic lines, by aid of which and a pair of dividers, all the problems of geometry are easily and accurately performed. The circumference of the earth is ascertained by measuring a given portion of its arch; and, the length of a degree being known, the log-line is marked accordingly. The quadrant, or rather octant, is invented, and measures the altitude of the heavenly bodies to the nearest minute, undisturbed like the astrolabe by the motion of the ship. The sextant and circle still improve upon the octant and each other. And now the tables of the moon's motions, invented by Meyer, with a view to ascertain the longitude, are improved by Maskelyne. The idea of finding the longitude by the watch had been early suggested as an important use of that admirable machine; but it continued too imperfect until the last century, when the munificent rewards offered by our government so stimulated mechanical ingenuity that it has at last become admirably adapted to this important purpose.

To those who are ignorant of the means by which men are enabled to trace their way over a trackless deep, and to whom the whole art is a mystery, it may be interesting to learn how seamen, and often very ignorant ones, are able successfully to practise it. We shall, therefore, in conclusion, briefly explain the actual practice of navigation: and, first, it may be necessary to premise, that, in order to determine and designate positions on the surface of the globe, latitude and longitude have been invented. Nor is this system entirely arbitrary, since nature herself furnishes the data. We have the poles, determined points of that axis round which the earth performs its daily revolutions: equidistant from these poles, and midway between them, nature aids us to conceive a line called the *equator*, and about which, by the motion of the earth in its orbit, the sun seems to perform an equal movement, accomplishing the beautiful scheme of the seasons by an annual excursion on either side.

What idea more obvious, and, at the same time, more beautiful and complete, than that of measuring latitude from the equator towards the poles, upon meridional lines perpendicular to it, and formed upon the surface of the earth by planes of its axis? But the latitude, though it indicates the distance from the equator, does not alone determine the position; for the same latitude may correspond to an infinity of places, except only a latitude of ninety degrees: hence, then, the necessity of longitude, measured round the world upon the equator, and small circles parallel to it; for, crossing each other at right angles, the same latitude and longitude can only concur at one given point. Latitude and longitude are measured in degrees, minutes, and seconds; the first, from the equator to the poles, a quadrant of ninety degrees; the second, from the first meridian east and west, a semicircle, or 180 degrees, and meeting at the antipodes.

Let us now show the means by which the mariner guides his bark across the ocean, and is able, at all times, to determine his progress and position. The most important instrument used by the navigator is the compass. Having in the compass an instrument for directing our course, we next seek the means of ascertaining the distance run. This we find in the log. The log is a long cord, having a piece of wood attached to one end. This is of a quadrangular form, and being slung at the corners with line, and loaded at the circumference, when thrown overboard it remains erect and stationary, and drags the line off as fast as the ship passes through the water. The line is divided into knots and half knots, representing miles and half miles, or minutes of a degree, to which they bear the same proportion as the log-glass does to an hour. Thus the log-glass being filled with sand, to run through in thirty seconds, the length of a knot must be fifty-one feet, the first being the same proportion of an hour that the last is of a mile. As, however, the log is found to come home a little in the effort to draw the line out, it is customary to mark the knot a foot or two less than the true length.

The mode of heaving the log to measure a ship's rate is as follows:—The log-reel, upon which the line is wound, being held by one of the sailors, the officer places himself on the rail to leeward, and, a third person holding the glass, he proceeds to prepare the quadrangular float, so that the peg of one of the lines holding it in a perpendicular direction will draw out, by the force of the water, when the reel is stopped, and allow it to haul in easily. Then, having gathered a sufficient quantity of line into his hand, he throws it far to leeward, that it may not be affected by the eddies which follow in the wake. The stray-line, which allows the ship to get astern, now runs off, and the instant that the white rag, which marks its termination, passes through the hand of the officer, he cries, "Turn!" and continues to veer out line until the glass runs out, and the person holding it cries, "Stop!" Then the line is grasped, and the number of knots that have passed off mark the speed of the ship. When this exceeds five miles, it is customary to use a glass of fifteen instead of thirty seconds, counting the knots double. The rate of sailing per hour, multiplied by the number of hours, thus gives the measure of his run.

In addition to these essential instruments for directing the course and ascertaining the distance, the navigator must be provided with octants of double reflection, to measure the altitude of the

heavenly bodies; and a circle, or sextant, more delicately graduated, to measure distances between the moon and stars. He should also have with him a book containing the logarithms of numbers, sines, tangents, and secants, to facilitate trigonometrical calculation; tables for correcting altitudes for dip, parallax, and refraction; also lists of latitudes and longitudes for every part of the world; and of time of high-water at every port, at the period of full and change of the moon, from which at all times to be able to find the tide; and a variety of tables, to facilitate the various problems of navigation. He should also have with him an astronomical almanac, containing the places and declinations of the fixed stars and planets, and especially the distances of the moon from the sun and other stars, and all that relates to that body, with a view to calculate the longitude by observation. Finally, he must be provided with the general and local charts applicable to his contemplated voyage. Thus furnished, the mariner may set sail with confidence; many do so with no other aids than their compass, log, quadrant, a single chart, and a book of navigation, and arrive in safety: but it is less our business to show with how little care a ship may be navigated than to show how she may be carried from port to port with the greatest possible certainty.

Having taken leave of the port, and when the last land is about to disappear from view, in consequence either of the growing distance or the intervention of night, the mariner selects some conspicuous headland, of which the latitude and longitude are noted in his tables, and placing a compass in some elevated position, remote from any iron object to disturb its polarity, proceeds to determine its bearing, and estimate his distance from it, either by the progress made from it or by the ready estimate of a practised eye. Or, taking the simultaneous bearings of two distinct points of coast, he has still surer data for deducing his position. This is called *taking the departure*, and is carefully noted on the logslate, with the time of making the observation. Thenceforth the log is thrown every hour, and the course and distance are entered upon the slate, to be copied into the log-book at the end of the day.

The first thing which the navigator attends to, after making the offing which prudence dictates to clear the dangers of the land, is to shape his course for the port of his destination. And first he searches in the chart whether there be any point of land, island, or rock, intervening in his way. If there be, the course is primarily shaped with reference to the danger; if not, the differences of latitude and longitude between the two places being taken, the course and distance are obtained by the aid of trigonometry. The shortest distance between any two places on the surface of our sphere is the arc of a great circle passing through those two places. Thus, between Cape Henry, in latitude 37°, and the island of St. Mary, in the same latitude but 50° long. further east, the distance is thirty miles less in sailing on a great circle than in sailing due east on a parallel of latitude, and consequently on a lesser circle of the sphere. In a higher latitude, the difference between sailing on a great or small circle becomes more considerable, as the small circles grow smaller; thus, in the latitude of 60°, a distance equal to that between Cape Henry and St. Mary would offer a disparity of nearly 200 miles. But, as it is only in sailing on the equator, or on a meridian, that the compass points uniformly along a great circle of the sphere, in most cases it would be necessary to change the course at short intervals, in order to attain even an approximation towards this desideratum. For instance, in sailing from Cape Henry to St. Mary, on a great circle, it would first be necessary to sail more than a point northward of east, gradually approaching the direction towards the middle of the distance, when the course should be due east; thence declining southward, until the land would be made upon a course as much south of east as, on starting, it was north of it.

In high latitudes, when the reduction of distance would offer a sufficient inducement, it may be advantageous to attempt following a great circle; but, in the seas ordinarily traversed by mariners, the trifling increase of distance which results from following a uniform course, as obtained by Mercator's sailing, is far more than compensated by its convenience and freedom from all perplexity. For the rest, the wind not unfrequently deprives the fastidious navigator of all choice between a great circle and a loxodromic. At the first noon succeeding the time of taking his departure, the mariner works up his reckoning. This is an epoch fixed by nature, being determined by the passage of the sun over the meridian, and is therefore well chosen as the beginning of the day. The log-slate being marked, he copies the courses and distances, if from head winds or other cause they have been various; the departure from the land is also converted into a course; as is the current, if there be any known one. He next proceeds to find the difference of latitude and departure from the meridian corresponding to each course, either by geometrical calculation, or, more expeditiously, by reference to tables; then he adds the several differences of latitude and departure, and if they be of different names, as some north and some south, some east and others west, deducts the less from the greater. With the remaining difference of latitude and departure, he not only finds the course and distance made good, but also his present situation. The difference of latitude being applied to the latitude left, by adding or subtracting in sailing from or towards the equator, at once gives the latitude of the ship. But, before the departure can be thus applied to find the longitude, it is necessary to reduce it for the converging of the meridian toward the poles; for, though all degrees of longitude are divided, like those of latitude, into sixty minutes or miles, yet they decrease in length, from being equal to a degree of latitude at the equator until they become nothing at the poles. There are many ways, more or less accurate, of deducing the difference of longitude from the departure, the latitude being known; they are founded upon this principle: the circumference of the earth at the equator is to its circumference at any given parallel of latitude as the departure is to the difference of longitude.

The most easy and correct way of obtaining the difference of longitude, on an oblique course, is by the aid of a table of meridional parts; for, having taken out the meridional difference of latitude, the mariner has this simple proportion: the proper difference of latitude is to the meridional difference of latitude as the departure is to the difference of longitude. The difference of longitude, thus obtained, is applied to the longitude left, adding or subtracting,

in sailing to or from the first meridian, and the result will be the ship's longitude, which, with the latitude previously ascertained, determines her position on the chart. The method of navigating thus described is called *dead reckoning*. It is far from infallible, and leaves much to desire. It will, indeed, do pretty well in short runs; but as errors daily creep in from many causes escaping calculation, such as bad steerage, leeway, heave of the sea, unknown currents, and as these accumulate and become considerable at the end of a long voyage, it becomes necessary for the mariner, removed from all reference to terrestrial objects, to resort to the immovable guides in the heavens, whose motions the God that placed them there has given him capacity to comprehend.

Let us now see how the ship's position on the ocean, represented by latitude and longitude, may at any time, without reference to course sailed, or distance, to capricious winds or stealthy currents, be ascertained with ease and accuracy. And, in the first place, to find the latitude, we have abundant data. All the heavenly bodies are, by the revolution of the earth, daily brought to the meridian, at which time, if their altitude be measured, their declination or distance from the equinox being known, the latitude is readily deduced; it may also be deduced from single or double altitudes of bodies not in the meridian, the times being accurately known. But the meridian altitude of the sun is what furnishes at once the easiest and most correct method of finding the latitude.

The meridian altitudes of the stars, and frequently of the moon, must be taken at night, when the horizon is vaguely marked; moreover, their minuteness and want of brilliancy make observation troublesome and uncertain; but, when the sun comes to the meridian, the observer brings a brilliant and palpable object down to a well-defined horizon; then, too, he has the advantage of observing, at a self-fixed epoch, the beginning of a new day. So great, indeed, are the advantages offered by the meridian altitude of the sun, that no other means of finding the latitude are used, except when these have failed from a clouded atmosphere, or when the momentary expectation of making the land quickens the mariner's anxiety. We shall, therefore, now explain the method of deducing the latitude from the sun's meridian altitude. Furnished with a sextant, circle, or octant of reflection, the observer goes upon deck, and, having examined the adjustment of his instrument, proceeds to bring down the image of the sun reflected by its mirror, until the lower limb just sweeps the horizon. He continues to follow and measure its ascent, until it ceases to rise; the moment that it begins to fall, and the lower limb dips in the horizon, the sun has passed the meridian.

The altitude marked by the index being read off, it is next corrected. And, first, the observer adds the semi-diameter, in order to make the altitude apply to the centre of the object; next, he subtracts the dip, to meet the error caused by the extension of the horizon, in consequence of the rotundity of the earth and the elevation of his eye above its surface; also the refraction of the atmosphere, by which the object, when not vertical, is made to appear higher than its true place; lastly, he adds the parallax (a small correction, inconsiderable from the sun's distance), in order to reduce the calculation for the centre of the earth, for which point all calculations are made, and which is ever supposed to be the station of an observer. Having made all these corrections, which many mariners despatch summarily, by an addition of twelve minutes, he has the true meridian altitude of the sun. Taking this from a quadrant, or ninety degrees, gives its zenith distance, or distance from that point in the heavens which is immediately over the observer, and would be met by a straight line passing from the centre of the earth through his position. Now, if the sun were for ever on the equinoctial, the zenith distance would always be the latitude; for, whilst the zenith is the observer's position, referred to the heavens, the equator is there in like manner represented by the equinoctial; and we have already seen that latitude is the distance from the equator. But, as the sun is only twice a year upon the equinoctial, and as his distance from it at times increases to more than twenty degrees, it becomes necessary to take this distance (called his *declination*) into the estimate. The sun's declination is given, in the almanac, for the noon of each day; by correcting it for the time anticipated or elapsed, according as the sun comes first to him or to the first meridian, by his position east or west of it, the observer obtains the declination for noon at his own position. This declination applied to the zenith distance, by adding when the sun is on the same side of the equator, by subtracting when on the opposite side, gives the true latitude.

A daily and accurate knowledge of his latitude is, then, to the mariner of our day, a desideratum of easy attainment. By its aid, nothing is easier than to sail clear of any rock or shoal that crosses his track, either by a watchful look-out at the moment of passing its latitude, or else by avoiding its parallel entirely, until it be surely passed. Moreover, this is his best and surest guide in aiming at his destined port; for he has but to attain the exact latitude it lies in, and then sail directly upon it, east or west, to be sure of success. And here nature is again his friend: by a singular coincidence, discoverable in glancing at the map of the world, most coasts and continents lie in a northern and southern direction. Hence the value attached, by seamen, to an accurate knowledge of the latitude; and hence the nautical phrase of "Latitude, lead, and look-out." But, if it be possible to obtain the longitude with any thing like an equal ease and certainty, no one will dispute its advantage.

Various ways have been devised to find the longitude, in all of which the great element is time. Inasmuch as the earth performs her diurnal revolution in twenty-four hours from the time any given meridian is brought under the sun until it reaches it again, it follows that twenty-four hours and 360 degrees are both equal to a circle, and that the equator and other circles of longitude may be indifferently estimated by either of these divisions. Hence the difference of time between two places is no other than the difference between the sun's coming to their respective meridians, or, in a word, their difference of longitude; and hence it follows that if we, by any means, simultaneously ascertain the time at the first meridian and the time on board ship, we shall have ascertained the longitude. The easiest method of solving this problem is by means of the chronometer. This is a watch so nicely constructed as to go with perfect uniformity, either having no error whatever, or else losing or gaining a known quantity every day. This

watch is set to the time of the first meridian, and its rate is carefully ascertained, before leaving the land. To find the longitude by means of it, the mariner has merely to take an observation of the sun or other star, when rising or falling rapidly, and deduce the time of ship; this, compared with the time at the first meridian, simultaneously given by the chronometer, determines the longitude. Several chronometers concurring with each other may make the mariner sure of his position; but a single one, unchecked by other data, and liable, from its nicety of construction, to easy derangement, is a dangerous guide. The most expeditious and certain way of observing the longitude is by the eclipses of Jupiter's satellites. Their times of immersion and emersion at the first meridian are noted in the almanac, and these, compared with the times at which the telescope shows the observer the occurrence of the same phenomena, determine the longitude. But the unsteadiness of a ship at sea deprives the mariner of this expeditious method. Fortunately, there yet remains open to him one of sufficient accuracy: this is by observing the distance of the moon from the sun and other fixed stars, and comparing the time of observation with that time at which the almanac shows a similar distance for the first meridian. The only difficulty attending this beautiful method, which the rapid movement of the moon in her orbit, and her consequent change of distance from the stars, renders proportionably correct, consists in the first place in nicely observing the distance, and then in correcting it trigonometrically for the errors occasioned by parallax and refraction.

A single lunar observation, like a single chronometer, has been confided in to the loss of many a gallant ship; but a series of them, taken from day to day, with stars on different sides of the moon, and concurring to show the same longitude, are worthy of all confidence. Thus, aided by these heavenly guides, is the mariner at all times able to determine his position. He should not, however, be inattentive to any means of information; he should, by observing the difference between the magnetic bearing of some heavenly body, and what calculation shows to be its true bearing, daily inform himself of that wonderful phenomenon,—the magnetic variation; he should, in calm weather, ascertain the direction and force of the current, by lowering a boat and anchoring it to an iron vessel let down below the superficial strata of the ocean; in approaching the land, he should be attentive to the changing colour and temperature of the sea, which last is, especially on our coast, an admirable monitor; also to the floating of weeds, and the flight of birds, such as do not stray far from it. All these little cares, the watching of the barometer, and profiting by its friendly predictions, and the frequent inspection of the chart, whilst they take from the dangers of navigation, amuse the mariner, and beguile the tedium of the sea. Thus, then, is a ship conducted from port to port; thus are dangers avoided and difficulties overcome. Though they who traverse the vast ocean leave neither track nor waymark for the guidance of those who follow, it is thus converted into a plain and convenient highway, extending to the extremities of the earth. (See the article SHIP.)

NEAPED; the situation of a ship which is left aground on the height of a spring tide, so that she cannot be floated off till the return of the next spring.

NEAP TIDES are those which happen when the moon is nearly at the second and fourth quarters. The *neap* tides are low tides, in respect to their opposites, the *spring* tides.

NEBULA. The name of *nebulæ* is given to certain little spots, resembling white clouds, which are seen in the starry heavens, and which, as observed through the telescope, present three kinds of appearances. These appearances are either that of single stars enveloped in a nebulous veil, or of groups of little stars, or only of a glittering cloud. The last are the proper nebulæ, which astronomers consider as systems of fixed stars, of which there may be innumerable multitudes in infinite space. Herschel, who spent much time in observing them, and has described them in his *Catalogue of One Thousand new Nebulæ* (London, 1786, 4to.), does not consider them all as groups of stars. At present as many as 2000 are known.

NECK; that portion of the human frame which unites the head and the body. Several of the vertebræ of the spine belong to the neck; the first of them has the name of *atlas*, from its immediately supporting the head. Its upper side has two cavities, into which the apophyses of the os occipitis are received; but these two cavities together, unlike all other joints, are laterally portions of concentric circles, by which means they are but as one joint, and so suffer the head to move easily side-ways, which otherwise it could no more do than the knee, which also has two heads and two cavities. The under side of this bone has a very flat articulation with the next; by which means it is fitted for a rotary motion. The superior vertebræ of the neck being fixed behind the head's centre of gravity, the neck is so far bent forward as that the last of these vertebræ, which has a firm bearing upon those of the thorax, falls exactly under the centre of gravity.

NECROMANCY; the divination of the future by questioning the dead. This, like many superstitious rites, originated in the east, or the extreme north, and is of the highest antiquity. Some have, indeed, maintained that it was not brought from Egypt or Persia to Greece, but originated in the last-named country; but it is difficult to prove this. We find mention made of necromancy in the Old Testament; for instance, in the first book of Samuel (i. 18), and in Deuteronomy (xviii. 11), where it is forbidden. In the eleventh book of the Odyssey, Homer has made Ulysses raise the shade of Tiresias from the infernal regions. The rite as there described contains nothing magical, and consists merely in the performance of a sacrifice with peculiar solemnities. This description of Homer proves that necromancy was common in Greece before his time. In many parts of Greece there were oracles of the dead, the origin of which is lost in the obscurity of history. The fable of the descent of Orpheus to Hades is by some considered to refer to this species of necromancy. Indeed, it is very doubtful whether the expression used of many of the Greek heroes, that they descended to the infernal regions, means any thing more than that they consulted an oracle of the dead. While in the rest of Greece necromancy was practised in the temples by priests or other religious persons, individuals called ψυχαγωγοι (evokers of spirits) practised it in Thessaly, the native country of magic, and made use of magical practices. In later times, these practices became horrible; for magicians ascribing a

superior power to human blood, and every thing which came from the gibbet or the grave, were led to the most revolting and disgusting acts. They tore men, half burnt, from their funeral piles, buried others living, ripped out unborn babes from the wombs of their mothers, and committed other similar enormities. They frequently butchered men, in order to consult their spirits before they had time to hasten down to the regions of the dead. After the total downfall of paganism, men were satisfied with a kind of necromancy by which they merely caused the voices of the dead to be heard from their graves.

NECROSIS. This word, the strict meaning of which is simply mortification, is by the general consent of surgeons confined to the mortification of the bones. It was first used in this particular sense by the celebrated M. Louis, who restricted its application, however, to cases in which the whole thickness of the bone was destroyed. By the ancients, the death of parts of bones was not distinguished from caries. However, necrosis and caries are essentially different; for, in the former, the affected part of the bone is deprived of the vital principle; but this is not the case when it is simply carious. Caries is very analogous to ulceration, while necrosis closely resembles mortification of the soft parts.

Between caries and necrosis, says Weidmann, there is all that difference which exists between ulcers and gangrene, or sphacelus, of the soft parts. In caries, the nutrition of the bone is only impaired, and an irregular action disunites the elements of the bony structure, which consequently sustains a loss of substance; but every remaining part of it is yet alive. In necrosis, on the contrary, the vitality and nutritive functions cease altogether in a certain portion of the bone, the separation of which then becomes indispensable.

We have already mentioned that M. Louis confined the term necrosis to cases in which the whole thickness of a bone perished; but Weidmann judiciously criticises this limitation of the word, and maintains that the nature of the disorder is the same whether it affects a single scale, the whole, or a mere point, of the bone. He also objects to the definition of necrosis proposed by Chopart, and adopted by David. These two authors have defined necrosis to be a disorder in which a portion of bone perishes, and turns dry, in order to be soon separated from the living parts, and replaced by a new bony substance, which is to perform its functions. But, as Weidmann observes, it may happen that a piece of bone which dies and separates may not be replaced by any new formation of bone, though the disease is of the same character, and merely varies in some modifications. He therefore argues that a true necrosis must always be said to exist whenever a dead portion of bone has either separated or is about to separate.

The tibia, femur, lower jaw, clavicle, humerus, fibula, radius, and ulna, are the bones most frequently affected with necrosis. Excepting the lower jaw and scapula, the process of regeneration has been noticed only in the cylindrical bones. From twelve to eighteen years of age is the time of life most subject to necrosis. In some persons, two bones are affected at once, owing to constitutional causes.

In the treatment of necrosis, the first grand object of the surgeon should be to aid nature in her endeavours to effect a cure, and not to disturb her operations by any superfluous or unseasonable interference. The second should be to assist her, sometimes by the boldest proceedings, when she loses her way, and cannot by herself accomplish the end. But, in order not to attempt any thing wrong, the surgeon must understand correctly what nature does in this disease, what it is in her power to perform, what she either cannot accomplish at all or not with any degree of certainty, and lastly the circumstances in which she may err, and endanger the patient's life.

When a portion of bone dies, nature uses all her endeavours to bring about its separation from the part of the bone which still remains alive. Surgeons have denominated this process *exfoliation*, which resembles the separation that occurs between parts affected with gangrene and sphacelus, and the living flesh. An exfoliation of bone, however, happens much more slowly than the separation of a slough of the soft parts. Neither are all exfoliations completed at a regular period; for they proceed most quickly during youth, when the constitution is more full of energy, and the bones more vascular and less replete with solid inorganic earthy matter. On the other hand, the process is slower in old or debilitated subjects, whose vitality is less active.

When the disease presents itself with violent symptoms, the inflammation and fever being intense, the severity of the case is to be assuaged by low diet, antiphlogistic remedies, emollient applications, and venesection in moderation, the disease being one which is of long duration and apt to wear out the patient's strength. Here, perhaps, topical bleeding ought always to be preferred to venesection. When the necrosis has arisen from syphilis, scrofula, or scurvy, &c., the medicines calculated for the cure of these affections must be exhibited, ere any favourable changes can be expected in the state of the diseased bone.

Lastly, it is the duty of the practitioner to extract the fragments of dead bone, in order that the deficiencies produced by them may be filled up, and the ulcers of the soft parts healed. Nature, who succeeds by herself in detaching the dead pieces of bone, can do very little in promoting their passage outward. Frequently, indeed, she has no power at all in this process, and it is only from surgery that assistance can be derived. When a dead piece of bone is still adherent at some points, its extraction should be postponed until it has become completely loose. If it were forcibly pulled away, there would be danger of leaving a part of it behind, which must have time to separate ere the cure can be accomplished. But, when a fragment is entirely detached, and the orifices of the sores are sufficiently large, it is to be taken hold of with a pair of forceps, and extracted. When the ulcer has only a very narrow opening, suitable incisions must be made in order to facilitate the removal of the loose dead bone.

NEGATIVE SIGN. This sign implies that the real value of the quantity represented by the letter to which it is prefixed is to be subtracted; and it serves with the positive sign to keep in view what elements or parts enter into the composition of quantities. It serves to express a quantity of an opposite quality to the positive (as a line in a contrary position, a motion with an opposite direction, or a centrifugal force in opposition to gravity), and thus often saves the trouble of distinguishing and demonstrating separately the various cases of proportions, and preserves their analogy in view. But as the proportions

of lines depend on their magnitude only without regard to their position, and motions and forces are said to be equal or unequal in any given ratio without regard to their directions, and in general the proportion of quantity relates to their magnitude only, without determining whether they are to be considered as increments or decrements, so there is no ground to imagine any other proportion of $-b$ and $+a$ (or of -1 and $+1$) than of the real magnitudes of the quantities represented by b and a, whether these quantities are in any particular case to be added or subtracted. It is the same thing to subtract a decrement as to add an equal increment, or to subtract $-b$ from $a-b$, as to add $+b$ to it; and, because multiplying a quantity by a negative number implies only a repeated subtraction of it, the multiplying $-b$ by $-n$ is subtracting $-b$ as often as there are units in n, and is therefore equivalent to adding $+b$ so many times, or the same as adding $+nb$. But if we infer from this that 1 is to $-n$ as $-b$ to nb, according to the rule that unit is to one of the factors as the other factor is to the product, there is no ground to imagine that there is any mystery in this, or any other meaning than that the real magnitudes represented by 1, n, b, and nb are proportional; for that rule relates only to the magnitude of the factors and product, without determining whether any factor or the product is to be added or subtracted. But this likewise must be determined in algebraic computations: and this is the proper use of the rules concerning the signs, without which the operation could not proceed. As a quantity to be subtracted is never produced in composition by any repeated addition of a positive, or repeated subtraction of a negative, a negative square number is never produced by composition from the root. Hence $\sqrt{-1}$, or the square root of a negative, implies an imaginary quantity; and, in resolution, is a mark or character of the impossible cases of a problem, unless it is compensated by another imaginary symbol or supposition, when the whole expression may have a real signification. Thus $1+\sqrt{-1}$, and $1-\sqrt{-1}$ taken separately are imaginary, but their sum is 2; as the conditions that separately would render the solution of a problem impossible in some cases destroy each other's effect when conjoined. In the pursuit of general conclusions, and of simple forms representing them, expressions of this kind must sometimes arise where the imaginary symbol is compensated in a manner that is not always so obvious.

Nephriticum Lignum. This wood is brought from America in large compact pieces of a whitish or pale yellow colour without, and of a dark brownish or reddish colour within. If bruised and macerated in water, it imparts a deep tincture, appearing, when placed betwixt the eye and the light, of a golden colour, but in other situations of a fine blue, a property by which it differs from all other known woods. Other woods are often mixed with it, which only give a yellow tincture. With rectified spirit of wine the same blue tincture is procured, becoming yellow by adding an acid, but again blue by an alkali.

To the taste it is slightly bitter, and the raspings have a faint aromatic smell. A strong infusion in water is gently astringent, and is recommended in nephritic complaints and all disorders of the kidneys and urinary passages. It does not, like the warmer diuretics, increase inflammation.

Nerves. The nerves of the animal frame are composed of bundles of white parallel medullary threads. Every bundle is surrounded with a soft sheath full of blood-vessels, and whose finest branches terminate in the substance of the nerves. These nerves are spread through the whole animal frame, and variously connected with each other. Only the epidermis, the hair, and nails, are destitute of them. They are of various size, according as they are composed of more or fewer bundles of medullary threads. In the course of the nerves there are a number of knots; these are called *ganglions;* they are commonly of an oblong shape, and of a grayish colour, somewhat inclining to red, which is perhaps owing to their being extremely vascular. In particular parts of the body the nerves come in contact with each other, and the bundles composing them are mutually interwoven to such a degree that they cannot be disjoined without violence. These communications are called *plexuses*, and are found particularly in the abdomen, behind the stomach, and in the region of the pit of the stomach, near the liver, mesentery, heart, &c.

The final terminations of the nerves are various, particularly those which run to the organs of sense. In the auricular organ, for instance, the nerves terminate in a soft mass like pap, surrounded with moisture; the optic nerve terminates in a medullary skin; the nerves of taste terminate in little *papillæ;* those of feeling in the points of the fingers and the surface of the skin in general; those belonging to the muscles are lost in the texture of the same, so that their terminations cannot be accurately ascertained.

All the nerves are embraced under the general head of the *nervous system.* This is most intimately connected with the brain and the spinal marrow, which may be regarded as a prolongation of it. The brain is the centre, from which or to which proceed all impressions communicated to the nerves. The substance of the nerves is the same medullary matter which constitutes the brain, resembling the white of an egg, and appearing to the unassisted eye as if composed of little balls. The central termination of all the nerves is in the brain and spinal marrow, where they branch out into the skin or the interior of the organs. The various isolated, and in part heterogeneous, structures of which the body consists, which are mechanically joined by the cellular tissue, the membranes, and the ligaments, are united into one harmonious whole by means of the nerves. The vascular system connects them only so far as it furnishes the supply of blood required for their support and their operations; but it is properly the nervous system which imparts to all their life, governs their operations, and establishes their sympathy and mutual action. This is effected by means of that portion of the nervous system which is diffused through the abdomen, forming many nets and plexuses, and constituting what is called the *vegetative*, or *reproductive*, or *organic nervous system*, because the growth and support of the body are effected by it.

Another part of the nervous system affords the means of consciousness and voluntary action. This is the *brain* or *cerebral system*, which excites the nerves that put in action the muscles of voluntary motion, and those which supply sensibility to the organs of sense, and convey to the brain the impressions thence received. The nerves which communicate with the organs of sense run in pairs—the

first pair (olfactory nerve) to the nose, where it is spread over the surface of the nostrils, and forms the power of smell; the second (optic nerve) to the eyes; this is round, thick, and penetrates from behind the ball or globe of the eye (through a round plate of the firm coat of the ball, containing many little apertures), and is spread out on the inner and concave surface of the globe into a thin coat called the *retina*, on which the images of external objects are formed; the eighth pair (auditory nerves) are spread over the interior of the ear, and are sensible to the vibrations of the air.

From the numerous ramifications of the ninth pair come the nerves of the tongue, which give rise to the sense of taste. The general sense of feeling is situated particularly in the skin, and peculiarly in the points of the fingers. This sense is produced by a variety of nerves diffused over the skin, and those parts which are most sensitive are supplied with the greatest quantity of nerves, which form entire series of contiguous nervous *papillæ;* for instance, at the lips, the points of the fingers, &c. Thus the action of the nerves is reciprocal from without inwards, and from within outwards—the first, because the impressions on the organs of sense are communicated by the nerves to the brain, and there form perceptions and feelings; the second, because the voluntary motions are produced by communications from the brain to the nerves, while the reproductive part of the nervous system quietly supports the whole machine, and, in a sound state of the body, is recognized only by the operation of the appetites, and by a general feeling of ease throughout the system, but, in a diseased state, gives rise to general uneasiness and pain.

The power of the nervous system has no fixed point, but is variable, even in the same subject. In sleep, the activity of the cerebral system is impaired, that of the reproductive system heightened; therefore, in quiet sleep, the operations of the senses and the voluntary motions cease, while the activity of the organs of respiration and circulation, of digestion, secretion, and nourishment continues. From what has been said, it must be obvious that the whole action of the body depends upon the nervous system. (See PHYSIOLOGY and PHRENOLOGY.)

NERVOUS DISEASES (*neuroses*) are such as consist in disturbed affections of sense and motion, unattended by any chronic or acute inflammation, or hemorrhage, or by any disturbance of the circulation. Nervous pains are called *neuralgiæ; spasms* are involuntary contractions in organs which have muscular fibres, or which are merely susceptible of contraction; *convulsions* are involuntary and irregular contractions, alternating with relaxations, in one, or several, or all of the muscles, simultaneously or successively; *tetanus* is a permanent contraction of a certain class of muscles, ordinarily followed by death; *contraction* is a retraction of the flexor muscles of one member or of two parallel members; *paralysis* is the diminution or loss of the sensibility of an organ of sense, or the contractility of an organ of motion. The pains, spasms, paralysis, take different names, according to the parts affected. The most remarkable of all the *neuroses* is *apoplexy,* which is characterized by the suspension or successive loss of sense and understanding, as well as of motion. The affections of the mind, known under the names of *mental alienation, insanity, idiocy,* &c., are also *neuroses;* that is, disturbances in the action of the nervous system. It has been asserted that nervous diseases are rendered more common by the progress of civilization; and, in fact, the nerves become more irritable, and therefore more liable to be diseased, with the progress of intelligence. But the refinements of the moderns in their food and drinks, the use of fermented liquors, wine, coffee, and tea, are the most frequent causes of nervous maladies. The early and excessive use of these liquids provokes the nerves, diseases the stomach, and gives rise to cerebral fevers in children, to the vapours or hysterics in women, and to hypochondria, apoplexy, and paralysis in men. It is not always easy to distinguish the symptoms of *neurosis* from those of inflammation; but, as the treatment in the two cases must be entirely different, it is of the greatest importance to use every caution in this respect. Particular medicines, which were considered as specific remedies in nervous diseases, were formerly in use; but experience has proved that warm bathing, soothing drinks, vegetable diet, exercise, recreation, sometimes bleeding, at others rubefacients, opium in a few cases, when the pain is great, and Peruvian bark, are the best antagonists of *neurosis.* The treatment of nervous diseases, however, has not a little embarrassed the scientific practitioner, as they often resist the most skilful and sagacious applications.

NET, in *commerce;* that which remains of a weight, quantity, &c., after making certain deductions. Thus, in mercantile language, the *net weight* is the weight of any article after deducting tare and tret; *net profit, income,* &c., is the absolute profit or income after deducting expenses, interest, &c. It is opposed to *gross.*

NETHERLAND SCHOOL OF PAINTING includes all the painters in the Netherlands who, since the fourteenth and fifteenth centuries, have pursued their art in a style peculiar to that country. It is divided into the *Dutch* and the *Flemish* schools. The Flemish school was founded by John van Eyk, and is distinguished by a brilliant colouring; magical effect of the *chiaro-scuro;* carefully laboured, though often tasteless drawing; a strong, yet natural expression, and boldness in composition. To this school belong Francis Floris (born 1520, died 1570), called the *Flemish Raphael;* John Stradanus (de Straet), of Bruges (born 1536), who painted historical pieces and hunting scenes; Mart. de Vos (born 1520); Spranger (born 1546); Peter and Francis Porbus, father and son; Dionysius Calvart; the brothers Paul and Matthew Brill; Van Ort (born 1557); Peter Breughel and his son John; Roland Savery, of Courtray (born in 1576). After these came Peter Paul Rubens, the boldest painter of modern times; a man of inexhaustible industry, of gigantic imagination, and power of representation, to whom about 4000 paintings are ascribed. With him the Flemish school reached its acme. Several distinguished painters follow: Francis Snyders (born 1579), whose hunting pieces excel all others in boldness and truth; Jodocus Momper (born 1580), a landscape painter, esteemed for his valleys and the distant views which they present; Peter Neefs, the famous church painter; David Teniers, father and son, who, in representing companies of peasants, guard-rooms, tap-houses, and all kinds of low life, have hardly their equal; Gaspar de Crayer (born 1582), who approaches, in the expression and colouring of his historical paintings, to Rubens; Gerard Segers, distinguished as a historical painter; his brother Daniel, famous for flower and

insect pieces. James Jordaens (born 1594), however, excelled all those who made Rubens their model. Abraham Janssen, and his pupil Theodore Rombouts (greater than his teacher), equal Rubens in colouring, but not in conception. The industrious Luke van Uden executed the landscapes for Ruben's paintings; and his views of the sky at dawn are worthy the study of every artist.

Anthony van Dyk (born 1599) obtained the name of the *king of portrait painters*. He excelled Rubens in correctness and beauty of forms. Cornelius Schüt, for whom John Wildens often painted the landscapes, distinguished himself as a historical painter; Adrian Brouwer acquired fame by his excellent representations of scenes from common life; John van der Meer by his pastoral pieces; Anthony Francis van der Meulen by his battle pieces; Francis and John Milet, father and son, by their landscapes. Besides these, we might mention the names of John Bol, Wenceslaus Koeberger, Henry Goltzius, Henry van Balen, Francis Hals, William Nieuwland, James Fouquieres, Philip de Champagne, Erasmus Quellin, Abraham Diepenbeck, Theod. van Thulden, John Goeimar, James of Artois, Bonewent Peters, David Kickaert, Gonzalez Coques, Peter Boel, Samuel van Hoogstraaten, John Bapt. Monoyer, Abraham Genoels, Gerard Lairesse, Arnold von Vuez, John Francis van Bloemann, John van Cleef, Pet. Eykens, Richard van Orley, Louis Deyster, Nicholas Largillière, Verendael, Robert van Oudenaerde, John Anthony van der Leepe, Caspar Verbrügen, John van Breda.

The Dutch school is distinguished for a faithful copying of nature, great finish, good *chiaro-scuro* and skilful disposition of colours, and delicate pencilling; but it is reproached with choosing ignoble subjects, and with incorrectness of drawing. Its founder is Luke of Leyden (born 1494). Its most prominent artists are Octavius van Veen, of Leyden (born 1586, died 1634), who deserves mention also as the teacher of Rubens. Abraham Bloemart, of Gorcum (died 1647), painted historical subjects, landscapes, and animals, in good taste. Cornelius Poelenburg, of Utrecht (born 1586, died 1663), was peculiarly happy in painting small landscapes with figures.

John Weynants, of Haarlem (born 1600), is distinguished as a landscape painter; and John Daniel de Heem, of Utrecht (born 1604, died 1674), for his faithful imitation of flowers, fruits, carpets, vases, &c. The highest place belongs to Rembrandt, whose masterly colouring atones for all his defects, and Hermann Sachtleben, who painted fine landscapes. In the delineation of common life, the following are distinguished:—Gerard Terburg, of Zwoll (born 1608, died 1681); in landscapes, John Both, of Utrecht (born 1610, died 1650); Hermann Swaneveld, of Woerden (born 1620, died 1690). Asselyn (born 1610, died 1680) painted battles, landscapes, and pastoral pieces, with a brilliant colouring and a delicate pencil. But it will be difficult to find any painter who draws more correctly, colours more beautifully, and distributes light more truly, than Gerhard Dow, or Douw (born 1613, died 1680).

Peter van Laar was the inventor of the *Bambocciate;* John Fyt (born at Antwerp, 1625) was a good painter of beasts, birds, and fruits; Gabriel Metzu, who worked in the style of Terburg, excelled him in softness of pencilling. The landscapes of Benenberg of Utrecht are full of life and freshness. Phillip Wouvermann (born 1620, died 1668), the most famous painter of horses, produced battle and hunting pieces, horse-markets, travellers, and robbers; and his paintings, of all kinds, are highly esteemed. His pupil John Griffer painted the beautiful views on the Rhine. The landscapes of Anthony Waterloo, for which Weenix executed the figures, are sometimes cold, but please on account of the accuracy with which he represents light playing through foliage, and the reflection of objects in water.

Berghen acquired the name of the *Theocritus of painters;* and perhaps Paul Potter is the only one who can dispute the superiority with him. Whilst Ludolf Backhuysen painted storms at sea with an effect as true as it is terrible, Francis Mieris distinguished himself by fine and accurate representations of many domestic subjects, and John Peter Slingeland was hardly more accurate. Godfrey Schalken, of Dort, has not yet been excelled in the illumination of night scenes. Excellent market scenes, animals, and landscapes were painted by Charles du Jardin. Adrian van de Velde painted landscapes and animals with almost unequalled perfection. For the representation of the beautiful solitudes of nature, James Ruisdael is celebrated; and for quiet, lovely, moonlight scenes, Van der Neer: the former is one of the most successful painters that ever attempted to portray nature. No painter has painted more delicately, and with more finish, even in insignificant trifles, than Adrian van der Werf. The flower painter Peter van Hulst, of Dort, is not equal to James van Huysum, who is almost unrivalled in this department.

Among the modern painters, we should mention Van Os, Van Spaendonk, Scheffer, Pienemann, Hoges, Kuipers, Ommegang, Van Bree, Wonder, Schotels. Pienemann's picture, the Battle of Waterloo (eighteen feet wide, and twenty-five high), was bought by the king of Holland for 40,000 guilders, for the purpose of being presented to the duke of Wellington.

The reproach of an almost exclusive adherence to common reality has been often applied to the whole school of the Netherlands; but it is confined by some to the Dutch; whilst the Flemish school, they say, in its more elevated productions, has striven to represent a nobler nature. The chief question in painting, however, is not what the artist attempts, but what he accomplishes; and, if George Foster is right in saying that in the works of the Flemish painters we generally miss the spirit of the poet in the beauty of the manual execution, then the Dutch school would deserve the preference, because, though it takes most of its subjects from common reality, it often represents them with a poetic conception of their character. It would be better, however, to describe them both as deficient in ideal beauty, but as distinguished, in the highest degree, for faithful imitation of nature. There would still remain sufficient distinction between the two schools. That they both have great merit in respect to the technical part of the art has never been doubted; and that they have greater merits, to a much higher degree than is generally allowed them, will be evident from a careful study.

Neutralization, in *chemistry*, may be thus explained:—If we take a given quantity of sulphuric acid diluted with water, and add it slowly to the solution of soda by little at a time, and examine the mixture after every addition, we shall find that for a considerable time it will exhibit the properties of an acid,

reddening vegetable blues, and having a taste perceptibly sour; but these acid properties gradually diminish after every addition of the alkaline solution, and at last disappear altogether. If we still continue to add the soda, the mixture gradually acquires alkaline properties, converting vegetable blues to green, and manifesting a urinous taste. These properties become stronger and stronger the greater the quantity of the soda is which is added. Thus it appears that when sulphuric acid and soda are mixed together the properties either of the one or the other preponderate, according to the proportions of each; but there are certain proportions according to which, when they are combined, they mutually destroy or disguise the properties of each other, so that neither predominates, or rather so that both disappear. When substances thus mutually disguise each other's properties, they are said to *neutralize* one another. This property is common to a great number of bodies; but it manifests itself most strongly, and was first observed, in the acids, alkalies, and earths. Hence the salts which are combinations of these different bodies received long ago the name of *neutral salts*.

NEWTONIAN PHILOSOPHY. As the doctrines of our great English philosopher have long since acquired the stamp and impress of truth, it may be proper to furnish our readers with a condensed view of what has in this country been styled the *Doctrine of the Universe*.

The term *Newtonian philosophy* is applied very differently by different authors. Some view it as the corpuscular philosophy, corrected and reformed by the discoveries and improvements made by Sir Isaac Newton. In this sense it is that Gravesande calls his elements of physics *Introductio ad Philosophiam Newtonianam*. And in this sense the Newtonian is the same with the new philosophy, and stands contradistinguished from the Cartesian, the Peripatetic, and the ancient Corpuscular. Others, by Newtonian philosophy, mean the method or order which its great founder observed in philosophising; viz. the reasoning and drawing of conclusions directly from phenomena, exclusive of all previous hypotheses; the beginning from simple principles; deducing the first powers and laws of nature from a few select phenomena, and then applying those laws, &c., to account for other things. And in this sense the Newtonian philosophy is the same with the experimental philosophy, and stands opposed to the Corpuscular. Others, again, by Newtonian philosophy mean that in which physical bodies are considered mathematically, and where geometry and mechanics are applied to the solution of the appearances of nature, in which sense the Newtonian is the same with the mechanical and mathematical philosophy.

The whole of the *Newtonian philosophy*, as delivered by the author, is contained in his *Principia*, or *Mathematical Principles of Natural philosophy*. He founds his system on the following definitions:—1. The quantity of *matter* is the measure of the same arising from its density and bulk conjointly. Thus air of a double density, in a double space, is quadruple in quantity; in a triple space, sextuple in quantity, &c. 2. The quantity of *motion* is the measure of the same, arising from the velocity and quantity of matter conjointly. This is evident, because the motion of the whole is the motion of all its parts; and therefore in a body double in quantity, with equal velocity, the motion is double, &c. 3. The innate force of matter is a power of resistance, by which every body, as much as in it lies, endeavours to persevere in its present state, whether it be of rest or moving uniformly forward in a right line. 4. An *impressed force* is an action exerted upon a body, in order to change its state, either of rest or of moving uniformly forward in a right line. This force consists in the action only, and remains no longer in the body when the action is over; for a body maintains every new state it acquires by its *vis inertiæ* only. 5. A *centripetal* force is that by which bodies are drawn, impelled, or any way tend towards a point, or to a centre. The quantity of any centripetal force may be considered as of three kinds, absolute, accelerative, and motive. 6. The *absolute* quantity of a centrifugal force is a measure of the same proportional to the efficacy of the cause that propagates it from the centre through the spaces round about. 7. The accelerative quantity of a centripetal force is a measure of the same proportional to the velocity which it generates in a given time. 8. The motive quantity of a centripetal force is a measure of the same proportional to the motion which it generates in a given time. This is always known by the quantity of a force equal and contrary to it, that is, just sufficient to hinder the descent of the body.

SCHOLIUM I. Absolute, true, and mathematical *time*, of itself, and from its own nature, flows equably, without regard to any thing external, and, by another name, is called *duration*. Relative, apparent, and common time, is some sensible and external measure of duration, whether accurate or not, which is commonly used instead of true time; such as an hour, a day, a month, a year, &c.

II. Absolute *space*, in its own nature, without regard to any thing external, remains always similar and immovable. Relative space is some movable dimension or measure of the absolute spaces, and which is vulgarly taken for immovable space. Such is the dimension of a subterraneous, an aërial, or celestial space, determined by its position to bodies, and which is vulgarly taken for immovable space; as the distance of a subterraneous, an aërial, or celestial space, determined by its position in respect of the earth. Absolute and relative space are the same in figure and magnitude; but they do not remain always numerically the same. For if the earth, for instance, moves, a space of our air which, relatively and in respect of the earth, remains always the same, will at one time be one part of the absolute space into which the earth passes, at another time it will be another part of the same; and so, absolutely understood, it will be perpetually mutable.

III. A *place* is a part of space which a body takes up; and is, according to the space, either absolute or relative. Our author says it is *part* of space; not the situation nor the external surface of the body. For the places of equal solids are always equal; but their superficies, by reason of their dissimilar figures, are often unequal. Positions properly have no quantity, nor are they so much the places themselves as the properties of places. The motion of the whole is the same thing with the sum of the motions of the parts; that is, the translation of the whole out of its place is the same thing with the sum of the translations of the parts out of their places: and therefore the place of the whole is the same thing with the sum of the places of the parts;

and for that reason it is internal, and in the whole body.

IV. Absolute *motion* is the translation of a body from one absolute place into another; and relative motion the translation from one relative place into another. Thus, in a ship under sail, the relative place of a body is that part of a ship which the body possesses, or that part of its cavity which the body fills, and which therefore moves together with the ship; and relative rest is the continuance of the body in the same part of the ship, or of its cavity. But real absolute rest is the continuance of the body in the same part of that immovable space in which the ship itself, its cavity, and all that it contains, is moved. Wherefore, if the earth be really at rest, the body which relatively rests in the ship will really and absolutely move with the same velocity which the ship has on the earth. But, if the earth also move, the true and absolute motion of the body will arise partly from the true motion of the earth in immovable space, partly from the relative motion of the ship on the earth: and, if the body move also relatively in the ship, its true motion will arise partly from the true motion of the earth in immovable space, and partly from the relative motions as well of the ship on the earth as of the body in the ship; and from these relative motions will arise the relative motion of the body on the earth.

Absolute *time*, in astronomy, is distinguished from relative, by the equation or correction of the vulgar time. For the natural days are truly unequal, though they are commonly considered as equal, and used for a measure of time: astronomers correct this inequality for their more accurate deducing of the celestial motions. It may be that there is no such thing as an equable motion whereby time may be accurately measured. All motions may be accelerated or retarded; but the true or equable progress of absolute time is liable to no change.

As the order of the parts of time is immutable, so also is the order of the parts of space. Suppose those parts to be moved out of their places, and they will be moved (if we may be allowed the expression) out of themselves. For times and spaces are, as it were, the places of themselves as of all other things. All things are placed in time as to order of succession, and in space as to order of situation. It is from their essence or nature that they are places; and that the primary places of things should be movable is absurd. These are therefore the absolute places; and translations out of those places are the only absolute motions.

But, because the parts of space cannot be seen or distinguished from one another by the senses, therefore in their stead we use sensible measures of them. For, from the positions and distances of things from any body, considered as immovable, we define all places; and then, with respect to such places, we estimate all motions, considering bodies as transferred from some of those places into others. And so, instead of absolute places and motions, we use relative ones, and that without any inconvenience in common affairs: but in philosophical disquisitions we ought to abstract from our senses, and consider things themselves distinct from what are only sensible measures of them. For it may be that there is no body really at rest, to which the places and motions of others may be referred.

But we may distinguish rest and motion, absolute and relative, one from the other, by their properties, causes, and effects. It is a property of rest that bodies really at rest do rest in respect of each other. And therefore, as it is possible that in the remote regions of the fixed stars, or perhaps far beyond them, there may be some body absolutely at rest, though it be impossible to know from the position of bodies to one another in our regions whether any of these do keep the same position to that remote body, it follows that absolute rest cannot be determined from the position of bodies in our regions.

It is a property of motion that the parts which retain given positions to their wholes do partake of the motion of their wholes. For all parts of revolving bodies endeavour to recede from the axis of motion; and the impetus of bodies moving forwards arises from the joint impetus of all the parts. Therefore, if surrounding bodies be moved, those that are relatively at rest within them will partake of their motion, upon which account the true and absolute motion of a body cannot be determined by the translation of it from those only which seem to rest; for the external bodies ought not only to appear at rest, but to be really at rest, otherwise all included bodies, beside their translation from near the surrounding ones, partake likewise of their true motions; and, though that translation was not made, they would not really be at rest, but only seem to be so. For the surrounding bodies stand in the like relation to the surrounded as the exterior part of a whole does to the interior, or as the shell does to the kernel; but, if the shell move, the kernel will also move, as being part of the whole, without any removal from near the shell.

A property near akin to the preceding is that if a place is moved, whatever is placed therein moves along with it; and therefore a body which is moved from a place in motion partakes also of the motion of its place, upon which account all motions from places in motion are no other than parts of entire and absolute motions; and every entire motion is composed of the motion of the body out of its first place and the motion of this place out of its place; and so on, until we come to some immovable place, as in the previous example of the ship. Wherefore entire and absolute motions can be no otherwise determined than by immovable places. Now, no other places are immovable but those that from infinity to infinity do all retain the same given positions one to another, and upon this account must ever remain unmoved, and do thereby constitute what we call *immovable space*.

The causes by which true and relative motions are distinguished one from the other are the forces impressed upon bodies to generate motion. True motion is neither generated nor altered but by some force impressed upon the body moved: but relative motion may be generated or altered without any force impressed upon the body; for it is sufficient only to impress some force on other bodies with which the former is compared, that, by their giving way, that relation may be changed in which the relative rest or motion of the other body did consist. Again, true motion suffers always some change from any force impressed upon the moving body; but relative motion does not necessarily undergo any change by such force. For if the same forces are likewise impressed on those other bodies with which the comparison is made, that the relative position may be

preserved, then that condition will be preserved in which the relative motion consists. And therefore any relative motion may be changed when the true motion remains unaltered, and the relative may be preserved when the true motion suffers some change, upon which account true motion does by no means consist of such relations.

The powers which distinguish absolute from relative motion may be exemplified by the action of the centrifugal force. For there are no such forces in a circular motion purely relative: but, in a true and absolute circular motion, they are greater or less according to the quantity of the motion. If a vessel, hung by a long cord, be so often turned about that the cord is strongly twisted, then filled with water, and let go, it will be whirled about the contrary way; and, while the cord is untwisting itself, the surface of the water will at first be plain, as before the vessel began to move; but the vessel, by gradually communicating its motion to the water, will make it begin sensibly to revolve, and recede by little and little from the middle, and ascend to the sides of the vessel, forming itself into a concave figure; and the swifter the motion becomes the higher will the water rise, till at last, performing its revolution in the same times with the vessel, it becomes relatively at rest in it. This ascent of the water shows its endeavour to recede from the axis of its motion; and the true and absolute circular motion of the water, which is here directly contrary to the relative, discovers itself, and may be measured by this endeavour. At first, when the relative motion of the water was greatest, it produced no endeavour to recede from the axis; the water showed no tendency to the circumference, nor any ascent towards the sides of the vessel, but remained with a plain surface; and therefore its true circular motion had not yet begun. But afterwards, when the relative motion of the water had decreased, the ascent thereof towards the sides of the vessel proved its endeavour to recede from the axis; and this endeavour showed the real circular motion of the water perpetually increasing, till it had acquired its greatest amount, when the water rested relatively in the vessel. And therefore this endeavour does not depend upon any translation of the water in respect of the ambient bodies; nor can true circular motion be defined by such translations. (See Whirling Table.) There is only one real circular motion of any one revolving body, corresponding to only one power of endeavouring to recede from its axis of motion, as its proper and adequate effect; but relative motions in one and the same body are innumerable, according to the various relations it bears to external bodies; and, like other relations, are altogether destitute of any real effect, otherwise than they may perhaps participate of that only true motion. And therefore, in the system which supposes that our heavens, revolving below the sphere of the fixed stars, carry the planets along with them, the several parts of those heavens and the planets, which are indeed relatively at rest in their heavens, do yet really move, for they change their position one to another, which never happens to bodies truly at rest; and being carried together with the heavens participate of their motions, and, as parts of revolving wholes, endeavour to recede from the axis of their motion.

Wherefore relative quantities are not the quantities themselves whose names they bear, but those sensible measures of them, either accurate or inaccurate, which are commonly used instead of the measured quantities themselves. And then, if the meaning of words is to be determined by their use, by the names *time*, *space*, *place*, and *motion*, their measures are properly to be understood; and the expression will be purely mathematical if the measured quantities themselves be meant.

It is indeed a matter of great difficulty to discover, and effectually to distinguish, the true motions of particular bodies from those that are only apparent, because the parts of that immovable space in which those motions are performed do by no means come under the observation of our senses. Yet we have some things to direct us in this intricate affair, and these arise partly from the apparent motions which are the difference of the true motions, partly from the forces which are the causes and effects of the true motions. For instance, if two globes, kept at a given distance one from the other by means of a cord that connects them, were revolved about their common centre of gravity, we might, from the tension of the cord, discover the endeavour of the globes to recede from the axis of motion, and from thence we might compute the quantity of their circular motions. And then, if any equal forces should be impressed at once on the alternate faces of the globes to augment or diminish their circular motions, from the increase or decrease of the tension of the cord we might infer the increment or decrement of their motions; and thence would be found on what faces those forces ought to be impressed, that the motions of the globes might be most augmented; that is, we might discover their hindermost faces, or those which follow in the circular motion. But the faces which follow being known, and consequently the opposite ones that precede, we should likewise know the determination of their motions. And thus we might find both the quantity and determination of this circular motion, even in an immense vacuum where there was nothing external or sensible with which the globes might be compared. But now, if in that space some remote bodies were placed that kept always a given position one to another, as the fixed stars do in our regions, we could not indeed determine from the relative translation of the globes among those bodies whether the motion did belong to the globes or to the bodies. But if we observed the cord, and found that its tension was that very tension which the motion of the globes required, we might conclude the motion to be in the globes and the bodies to be at rest; and then, lastly, from the translation of the globes among the bodies we should find the determination of their motions.

Having thus explained himself, Sir Isaac proposes to show how we are to collect the true motions from their causes, effects, and apparent differences; and, *vice versâ*, how from the motions, either true or apparent, we may come to the knowledge of their causes and effects. In order to this, he lays down the following axioms or laws of motion :—

1. *Every body perseveres in its state of rest, or of uniform motion in a right line, unless it is compelled to change that state by forces impressed upon it.*—Sir Isaac's proof of this axiom is as follows: "Projectiles persevere in their motions so far as they are not retarded by the resistance of the air, or impelled downwards by the force of gravity. A top, whose parts, by their cohesion, are perpetually drawn aside from a rectilinear motion, does not cease its rotation other-

wise than as it is retarded by the air. The greater bodies of the planets and comets, meeting with less resistance in free space, preserve their motions, both progressive and circular, for a much longer time."

2. *The alteration of motion is ever proportional to the motive force impressed, and is made in the direction of the right line in which that force is impressed.*—Thus, if any force generates a certain quantity of motion, a double force will generate a double quantity, whether that force be impressed all at once or in successive moments. To this law no objection of consequence has ever been made. It is founded on this self-evident truth, that every effect must be proportional to its cause.

3. *To every action there always is opposed an equal re-action, or the mutual action of two bodies upon each other are always equal and directed to contrary parts.*—This axiom has been disputed by many. "When an action generates no motion," Mr. Young says, "it is certain that its effects have been destroyed by a contrary and equal action. When an action generates two contrary and equal motions it is also evident that mutual actions were exerted equal and contrary to each other. All cases where one of these conditions is not found are exceptions to the truth of the law. If a finger presses against a stone, the stone, if it does not yield to the pressure, presses as much upon the finger: but if the stone yields it re-acts less than the finger acts; and if it should yield with all the momentum that the force of the pressure ought to generate, which it would do if it were not impeded by friction or a medium, it would not re-act at all. So if the stone drawn by a horse follows after the horse, it does not re-act so much as the horse acts, but only so much as the velocity of the stone is diminished by friction, and it is the re-action of friction only, not of the stone. The stone does not re-act, because it does not act: it resists, but resistance is not action.

"In the loss of motion from a striking body, equal to the gain in the body struck, there is a plain solution without requiring any re-action. The motion *lost* is identically that which is *found* in the other body; this supposition accounts for the whole phenomenon in the most simple manner. If it be not admitted, but the solution by re-action is insisted upon, it will be incumbent on the party to account for the whole effect of communication of motion, otherwise he will lie under the imputation of rejecting a solution which is simple, obvious, and perfect, for one complex, unnatural, and incomplete. However this may be determined, it will be allowed that the circumstances mentioned afford no ground for the inference that action and re-action are equal, since appearances may be explained in another way."

Others grant that Sir Isaac's axiom is very true in respect to terrestrial substances, but they affirm that in these both action and re-action are the effects of gravity. Substances void of gravity would have no momentum, and without this they could not act; they would be moved by the least force, and therefore could not resist or re-act. "If therefore there is any fluid which is the cause of gravity, though such fluid could act upon terrestrial substances, yet these could not re-act upon it, because they have no force of their own, but depend entirely upon it for their momentum. In this manner, say they, we may conceive that the planets circulate, and all the operations of nature are carried on by means of a subtile fluid, which being perfectly active, and the rest of matter altogether passive, there is neither resistance nor loss of motion."

From the preceding axiom Sir Isaac draws the following corollaries:—

1. A body by two forces conjoined will describe the diagonal of a parallelogram in the same time that it would describe the sides by those forces apart.

2. Hence we may explain the composition of any one direct force out of any two oblique ones, viz. by making the two oblique forces the sides of a parallelogram, and the direct one the diagonal.

3. The quantity of motion which is collected by taking the sum of the motions directed towards the same parts, and the difference of those that are directed to contrary parts, suffers no change from the action of bodies among themselves, because the motion which one body loses is communicated to another; and, if we suppose friction and the resistance of the air to be absent, the motion of a number of bodies which mutually impelled one another would be perpetual and its quantity always equal.

4. The common centre of gravity of two or more bodies does not alter its state of motion or rest by the actions of the bodies among themselves, and therefore the common centre of gravity of all bodies acting upon each other (excluding outward actions and impediments) is either at rest or moves uniformly in a right line.

The motions of bodies included in a given space are the same among themselves, whether that space is at rest or moves uniformly forward in a right line without any circular motion. The truth of this is evidently shown by the experiment of a ship, where all motions happen after the same manner, whether the ship is at rest or proceeds uniformly forward in a straight line.

6. If bodies, any how moved among themselves, are urged in the direction of parallel lines by equal accelerative forces, they will all continue to move among themselves after the same manner as if they had been urged by no such forces.

The mathematical part of the Newtonian philosophy may be said to depend on the following lemmas, of which the first is the principal:—

LEM. I. Quantities and the ratios of quantities, which in any finite time converge continually to equality, and before that time approach nearer the one to the other than by any given difference become ultimately equal.

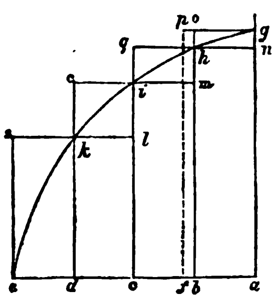
"These lemmas," observes Sir Issac Newton, "are premised, to avoid the tediousness of deducing perplexed demonstrations *ad absurdum*, according to the method of ancient geometers. For demonstrations are more contracted by the method of indivisibles: but because the hypothesis of indivisibles seems somewhat harsh, and therefore that method is reckoned less geometrical, I chose rather to reduce the demonstrations of the following propositions to the first and last sums and ratios of nascent and evanescent quantities, that is, to the limits of those sums and ratios; and so to premise, as short as I could, the demonstration of those limits. For thereby the same thing is performed as by the method of indivisibles; and now, those principles being demonstrated, we may use them with more safety. Therefore, if hereafter I should happen to consider quantities as made up of particles, or should use little curve lines for right ones, I would not be understood to mean indivisibles, but evanescent divisible quantities; not

the sums and ratios of determined parts, but always the limits of sums and ratios; and that the force of such demonstrations always depends on the method laid down in the foregoing lemmas.

"Perhaps it may be objected that there is no ultimate proportion of evanescent quantities, because the proportion, before the quantities have vanished, is not the ultimate, and, when they have vanished, is none. But by the same argument it may be alleged that a body arriving at a certain place, and there stopping, has no ultimate velocity; because the velocity before the body comes to the place is not its ultimate velocity; when it is arrived, it has none. But the answer is easy: for by the ultimate velocity is meant that with which the body is moved neither before it arrives at its place and the motion ceases, nor after, but at the very instant it arrives; that is, that velocity with which the body arrives at its last place, and with which the motion ceases. And in like manner, by the ultimate ratio of evanescent quantities is to be understood the ratio of the quantities, not before they vanish, nor afterwards, but with which they vanish. In like manner, the first ratio of nascent quantities is that with which they begin to be. And the first or last sum is that with which they begin and cease to be (or to be augmented and diminished). There is a limit which the velocity at the end of the motion may attain, but not exceed; and this is the ultimate velocity: and there is the like limit in all quantities and proportions that begin and cease to be. And, since such limits are certain and definite, to determine the same is a problem strictly geometrical. But whatever is geometrical we may be allowed to make use of in determining and demonstrating any other thing that is likewise geometrical.

"It may be also objected that, if the ultimate ratios of evanescent quantities be given, their ultimate magnitudes will be also given; and so all quantities will consist of indivisibles, which is contrary to what Euclid has demonstrated concerning incommensurables, in the tenth Book of his Elements. But this objection is founded on a false supposition; for those ultimate ratios with which quantities vanish are not truly the ratios of ultimate quantities, but limits towards which the ratios of quantities decreasing continually approach."

LEM. II. If in the figure *a g i e*, terminated by the right lines *a g*, *a e*, and the curve *g i e*, there be inscribed any number of parallelograms, *a h*, *b i*, *c k*, &c., comprehended under equal bases, *a b*, *b c*, *c d*, &c., and the sides *b h*, *c i*, *d k*, &c., parallel to one side, *a g*, of the figure; and the parallelograms *g n h o*, *h m i q*, *i l k c*, &c., are completed; then if the breadth of these parallelograms be supposed to be diminished, and their number augmented *in infinitum*, the ultimate ratios which the inscribed figure *a n h m i l k d*, the circumscribed figure *a g o b q i c k s e*, and curvilinear figure *a g h i k e*, will have to one another, are ratios of equality. For the difference

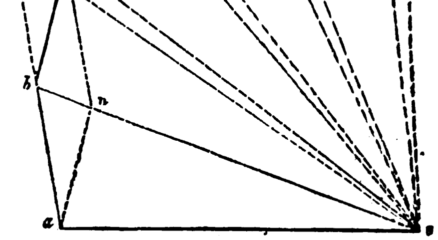


of the inscribed and circumscribed figures is the sum of the parallelograms *n o*, *m q*, *l c*, *d s*; that is (from the equality of all their bases), the rectangle under one of their bases *n h*, and the sum of their altitudes *a g*, that is, the rectangle *a b g o*. But the breadth of the rectangle in the direction *a b* is supposed to be diminished *ad infinitum*, so that, by lem. I., the figures inscribed and circumscribed become ultimately equal the one to the other; and much more will the intermediate curvilinear figure be ultimately equal to either.

LEM. III. The same ultimate ratios are also ratios of equality, when the breadths *a b*, *b c*, *c d*, &c, of the paralellograms are unequal, and are all diminished *ad infinitum*. The demonstration of this differs but little from that of the former.

In his succeeding lemmas, Sir Isaac goes on to prove, in a manner similar to the above, that the ultimate ratios of the sine, chord, and tangent of arcs infinitely diminished, are ratios of equality, and therefore that in all our reasonings about these we may safely use the one for the other: that the ultimate form of evanescent triangles made by the arc, chord, and tangent, is that of similitude, and their ultimate ratio is that of equality; and hence, in reasoning about ultimate ratios, we may safely use these triangles for each other, whether made with the sine, the arc, or the tangent. He then shows some properties of the ordinates of curvilinear figures; and proves that the spaces which a body describes by any finite force urging it, whether that force is determined and immutable, or is continually augmented or continually diminished, are, in the very beginning of the motion, one to the other in the duplicate ratio of the powers. And, lastly, having added some demonstrations concerning the evanescence of angles of contact, he proceeds to lay down the mathematical part of his system, and which depends on the following theorems:—

THEOR. I. The areas which revolving bodies describe by radii drawn to an immovable centre of force lie in the same immovable planes, and are proportioned to the times in which they are described.



For, suppose the time to be divided into equal parts, and in the first part of that time let the body by its innate force describe the right line *a b*; in the se-

cond part of that time the same would, by law 1, if not hindered, proceed directly to *g*, along the line *b c a b*; so that by the radii *a s b*, *s g s*, drawn to the centre, the equal areas *a s b*, *b s g*, would be described. But, when the body is arrived at *b*, suppose the centripetal force acts at once with a great impulse, and, turning aside the body from the right line *b g*, compels it afterwards to continue its motion along the right line *b c*. Draw *g c* parallel to *b s*, meeting *b c* in *c*; and at the end of the second part of the time the body, by cor. 1 of the laws, will be found in *c*, in the same plane with the triangle *a s b*. Join *s c*; and, because *s b* and *c i* are parallel, the triangle *s b c* will be equal to the triangle *s c d*, and therefore also to the triangle *s a b*. By the like argument, if the centripetal force act successively in *c d i*, &c., and make the body in each single particle of time to describe the right lines *c d*, *d e*, *e f*, &c., they will lie in the same plane, and the triangle *s c d* will be equal to the triangle *s b c*, and *s d e* to *s c d*, and *s e f* to *s d e*. And therefore, in equal times, equal areas are described in one immovable plane; and, by composition, any sums, *s a d*, *s a f*, of those areas are, one to the other, as the times in which they are described. Now let the numbers of those triangles be augmented, and their size diminished *in infinitum*; and then, by the preceding lemmas, their ultimate perimeter *a d f* will be a curve line; and therefore the centripetal force by which the body is perpetually drawn back from the tangent of this curve will act continually; and any described areas *s a d*, *s a f*, which are always proportional to the times of description, will, in this case also, be proportional to those times.

Cor. 1. The velocity of a body attracted towards an immovable centre, in spaces void of resistance, is reciprocally as the perpendicular let fall from that centre on the right line which touches the orbit. For the velocities in these places *a*, *b*, *c*, *d*, *e*, are the bases *a b*, *b c*, *d e*, *e f* of equal triangles; and these bases are reciprocally as the perpendiculars let fall upon them.

Cor. 2. If the chords *a b*, *b c*, of two arcs successively described in equal times by the same body, in spaces void of resistance, are completed into a parallelogram, *a b c n*, and the diagonal *b n* of this parallelogram, in the position which it ultimately acquires when those arcs are diminished *in infinitum*, is produced both ways, it will pass through the centre of force.

Cor. 3. If the chords *a b*, *b c*, and *d e*, *e f*, of arcs described in equal times, in spaces void of resistance, are completed into the parallelograms *a b c n*, *d e f m*, the forces in *b* and *e* are one to the other in the ultimate ratio of the diagonals *b n*, *e m*, when those arcs are diminished *in infinitum*. For the motions *b c* and *e f* of the body (by cor. 1 of the laws) are compounded of the motions *b c*, *b n*, and *e l*, *e m*; but *b n* and *e m*, which are equal to *c g* and *f l* in the demonstration of this proposition, were generated by the impulses of the centripetal force in *b* and *e*, and are therefore proportional to those impulses.

Cor. 4. The forces by which bodies, in spaces void of resistance, are drawn back from rectilinear motions, and turned into curvilinear orbits, are one to another as the versed sines of arcs described in equal times, which versed sines tend to the centre of force, and bisect the chords when these arcs are diminished to infinity. For such versed sines are the halfs of the diagonals mentioned in cor. 3.

Cor. 5. And therefore those forces are to the force of gravity as the said versed sines to the versed sines perpendicular to the horizon of those parabolic arcs which projectiles describe in the same time.

Cor. 6. And the same things do all hold good (by cor. 5 of the laws) when the planes in which the bodies are moved, together with the centres of force, which are placed in those planes, are not at rest, but move uniformly forward in right lines.

Theor. II. Every body that moves in any curve line described in a plane, and which, by a radius drawn to a point either immovable or moving forward with a uniform rectilinear motion, describes about that point areas proportional to the times, is urged by a centripetal force directed to that point.

Case I. For every body that moves in a curve line is (by law 1) turned aside from its rectilinear course by the action of some force that impels it; and that force by which the body is turned off from its rectilinear course, and made to describe in equal times the least equal triangles *s a b*, *s b c*, *s c d*, &c., about the immovable point *s* (by prop. 40, E. 1, and law 2), acts in the place *b* according to the direction of a line parallel to *c* (that is, in the direction of the line *b s*), and in the place *c* according to the direction of a line parallel to *h d* (that is, in the direction of the line *c s*), &c., and therefore acts always in the direction of lines tending to the immovable point *s*.

Case II. And (by cor. 5 of the laws) it is indifferent whether the superficies in which a body describes a curvilinear figure be quiescent or moves together with the body, the figure described, and its point *s*, uniformly forward in right lines.

Cor. 1. In nonresisting spaces or mediums, if the areas are not proportional to the times, the forces are not directed to the point in which the radii meet; but deviate therefrom *in consequentia*, or towards the parts to which the motion is directed, if the description of the areas is accelerated; but *in antecedentia* if retarded.

Cor. 2. And even in resisting mediums, if the description of the areas is accelerated, the direction of the forces deviates from the point in which the radii meet towards the parts to which the motion tends.

Scholium. A body may be urged by a centripetal force compounded of several forces; in which case the meaning of the proposition is that the force which results out of all tends to the point *s*. But, if any force act perpetually in the direction of lines perpendicular to the described surface, this force will make the body to deviate from the plane of its motion, but will neither augment nor diminish the quantity of the described surface, and is therefore not to be neglected in the composition of forces.

Theor. III. Every body that, by a radius drawn to the centre of another body, however moved, describes areas about that centre proportional to the times, is urged by a force compounded of the centripetal forces tending to that other body, and of all the accelerative force by which that other body is impelled. The demonstration of this is a natural consequence of the theorem immediately preceding.

Hence, if a body L, by a radius drawn to another body T, describes areas proportional to the times, and if from the whole force by which the first body L is urged (whether that force is simple, or, according to cor. 2 of the laws, compounded of several forces) we subduct that whole accelerative

force by which the other body is urged, the whole remaining force by which the first body is urged will tend to the other body T as its centre. And, *vice versâ*, if the remaining force tend nearly to the other body T, those areas will be nearly proportional to the times.

If the body L, by a radius drawn to the other body T, describe areas which, compared with the times, are very unequal, and that other body T is either at rest or moves uniformly forward in a right line, the action of the centripetal force tending to that other body T is either none at all or it is mixed and combined with very powerful actions of other forces, and the whole force compounded of them all, if they are many, is directed to another (immovable or movable) centre. The same thing obtains when the other body is actuated by any other motion whatever, provided that centripetal force is taken which remains after subducting that whole force acting upon that other body T.

Scholium. Because the equable description of areas indicates that a centre is respected by that force with which the body is most affected, and by which it is drawn back from its rectilinear motion and retained in its orbit, we may always be allowed to use the equable description of areas as an indication of a centre about which all circular motion is performed in free spaces.

Theor. IV. The centripetal forces of bodies which by equable motions describe different circles tend to the centres of the same circles, and are one to the other as the squares of the arcs described in equal times applied to the radii of circles.—For these forces tend to the centres of the circles (by theor. 2 and cor. 2 theor. 1), and are to one another as the versed sines of the least arcs described in equal times (by cor. 4 theor. 1), that is, as the squares of the same arcs applied to the diameters of the circles, by one of the lemmas; and therefore, since those arcs are as arcs described in any equal times, and the diameters are as the radii, the forces will be as the squares of any arcs described in the same time applied to the radii of the circles.

Cor. 1. Therefore, since those arcs are as the velocities of the bodies, the centripetal forces are in a ratio compounded of the duplicate ratio of the velocities directly, and of the simple ratio of the radii inversely.

Cor. 2. And, since the periodic times are in a ratio compounded of the ratio of the radii directly and the ratio of the velocities inversely, the centripetal forces are in a ratio compounded of the ratio of the radii directly and the duplicate ratio of the periodic times inversely.

Cor. 3. Whence, if the periodic times are equal, and the velocities therefore as the radii, the centripetal forces will be also as the radii; and the contrary.

Cor. 4. If the periodic times and the velocities are both in the subduplicate ratio of the radii, the centripetal forces will be equal among themselves; and the contrary.

Cor. 5. If the periodic times are as the radii, and therefore the velocities equal, the centripetal forces will be reciprocally as the radii; and the contrary.

Cor. 6. If the periodic times are in the sesquiplicate ratio of the radii, and therefore the velocities reciprocally in the subduplicate ratio of the radii, the centripetal forces will be in the duplicate ratio of the radii inversely; and the contrary.

Cor. 7. And universally, if the periodic time is as any power R^n of the radius R, and therefore the velocity reciprocally as the power R^{n-1} of the radius, the centripetal force will be reciprocally as the power R^{2n-1} of the radius; and the contrary.

Cor. 8. The same things all hold concerning the times, the velocities, and forces, by which bodies describe the similar parts of any similar figures, that have their centres in a similar position within those figures, as appears by applying the demonstrations of the preceding cases to those. And the application is easy, by only substituting the equable description of areas in the place of equable motion, and using the distances of the bodies from the centres instead of the radii.

Cor. 9. From the same demonstration it likewise follows that the arc which a body uniformly revolving in a circle by means of a given centripetal force describes in any time is a mean proportional between the diameter of the circle and the space which the same body, falling by the same given force, would descend through in the same given time.

By means of the preceding proposition, and its corollaries (says Sir Isaac), we may discover the proportion of a centripetal force to any other known force, such as that of gravity. For, if a body by means of its gravity revolves in a circle concentric to the earth, this gravity is the centripetal force of that body. But from the descent of heavy bodies the time of one entire revolution, as well as the arc described in any given time, is given (by cor. 9 of this theorem). And by such proposition Mr. Huygens, in his excellent book *De Horologio Oscillatorio*, has compared the force of gravity with the centrifugal forces of revolving bodies.

The preceding proposition may also be demonstrated in the following manner:—In any circle suppose a polygon to be inscribed of any number of sides. And if a body, moved with a given velocity along the sides of the polygon, is reflected from the circle at the several angular points, the force with which at every reflection it strikes the circle will be as its velocity; and therefore the sum of the forces, in a given time, will be as that velocity and the number of reflections conjointly; that is (if the species of the polygon be given), as the length described in that given time, and increased or diminished in the ratio of the same length to the radius of the circle (that is, as the square of that length applied to the radius); and therefore, if the polygon, by having its sides diminished *in infinitum*, coincides with the circle, as the square of the arc described in a given time applied to the radius. This is the centrifugal force, with which the body impels the circle, and to which the contrary force, wherewith the circle continually repels the body towards the centre, is equal.

Sir Isaac then shows how to find the centre to which the forces impelling any body are directed, having the velocity of the body given, and finds the centrifugal force to be always as the versed sine of the nascent arc directly, and as the square of the time inversely; or directly as the square of the velocity and inversely as the chord of the nascent arc. From these premises he deduces the method of finding the centripetal force directed to any given point when the body revolves in a circle, and this whether the central point is near or at an immense distance; so that all the lines drawn from it may be taken for parallels.

The same thing he shows with regard to bodies revolving in spirals, ellipses, hyperbolas, or parabolas. Having the figures of the orbits given, he shows also how to find the velocities and moving powers; and, in short, solves all the most difficult problems relating to the celestial bodies with an astonishing degree of mathematical skill. These problems and demonstrations are all contained in the first book of the *Principia:* but to give an account of them here would far exceed our limits; neither would many of them be intelligible, without lengthened mathematical demonstrations.

In the second book Sir Isaac treats of the properties of fluids and their powers of resistance; and here he lays down such principles as entirely overthrow the doctrine of Des Cartes's vortices. In the third book he particularly treats of the phenomena of the heavenly bodies, and applies them to the mathematical principles formerly demonstrated; and, as a necessary preliminary to this part, he lays down the following rules for reasoning in natural philosophy:—

1. We are to admit no more causes of natural things than such as are both true and sufficient to explain their natural appearances.

2. Therefore to the same natural effects we must always assign as far as possible the same causes.

3. The qualities of bodies which admit neither intension nor remission of degrees, and which are found to belong to all bodies within the reach of our experiments, are to be esteemed the universal qualities of all bodies whatsoever.

4. In experimental philosophy we are to look upon propositions collected by general induction from phenomena as accurately or very nearly true, notwithstanding any contrary hypotheses that may be imagined, till such time as other phenomena occur by which they may either be made more accurate or liable to exceptions.

The phenomena first considered are, 1. That the satellites of Jupiter, by radii drawn to the centre of their primary, describe equal areas in equal times; and that their periodic times, the fixed stars being at rest, are in the sesquiplicate ratio of their distances from its centre. 2. The same thing is likewise observed of the phenomena of Saturn. 3. The five primary planets, Mercury, Venus, Mars, Jupiter, and Saturn, with their several orbits, encompass the sun. 4. The fixed stars being supposed at rest, the periodic times of the five primary planets, and of the earth about the sun, are in the sesquiplicate proportion of their mean distances from the sun. 5. The primary planets, by radii drawn to the earth, describe areas no ways proportionable to the times; but the areas which they describe by radii drawn to the sun are proportional to the times of description. 6. The moon, by a radius drawn to the centre of the earth, describes an area proportional to the time of description. Sir Isaac Newton then proceeds to the following propositions:—

PROP. I. The forces by which the satellites of Jupiter are continually drawn off from rectilinear motions, and retained in their proper orbits, tend to the centre of that planet, and are reciprocally as the squares of the distances of those satellites from that centre.

PROP. II. The forces by which the primary planets are continually drawn off from rectilinear motions, and retained in their proper orbits, tend to the sun; and are reciprocally as the squares of the distances from the sun's centre. The former part of this proposition is manifest from phenom. 5 and from theor. 2; the latter from phenom. 4 and cor. 6 of theor. 4. But this part of the proposition is with great accuracy deducible from the quiescence of the aphelion points; for a very small aberration from the reciprocal duplicate proportion would produce a motion of the apsides, sensible in every single revolution, and in many of them enormously great.

PROP. III. The force by which the moon is retained in its orbit tends towards the earth, and is reciprocally as the square of the distance of its place from the centre of the earth. The former part of this proposition is evident from phenom. 5 and theor. 2; the latter from phenom. 6 and theor. 2 or 3. It is also evident from the very slow motion of the moon's apogee, which, in every single revolution amounting but to 3° 3′ *in consequentiu,* may be neglected: and this more fully appears from the next proposition.

PROP. IV. The moon gravitates towards the earth, and by the force of gravity is continually drawn off from a rectilinear motion, and retained in its orbit.— The mean distance of the moon from the earth in the syzigies in semi-diameters of the latter is about $60\frac{1}{2}$. Let us assume the mean distance of sixty semi diameters in the syzigies; and suppose one revolution of the moon in respect of the fixed stars to be completed in 27^d 7^h 43′, as astronomers have determined, and the circumference of the earth to amount to 123,249,600 Paris feet. Now, if we imagine the moon, deprived of all motion, to be let go, so as to descend towards the earth with the impulse of all that force by which it is retained in its orbit, it will, in the space of one minute of time, describe in its fall $15\frac{1}{4}$ Paris feet; for the versed sine of that arc which the moon, in the space of one minute of time, describes by its mean motion at the distance of sixty semi-diameters of the earth, is nearly $15\frac{1}{12}$ Paris feet —or, more accurately, 15 feet, 1 inch, 1 line $\frac{4}{9}$. Wherefore since that force, in approaching to the earth, increases in the reciprocal duplicate proportion of the distance, and upon that account at the surface of the earth is 60×60 times greater than at the moon, a body in our regions falling with that force ought, in the space of one minute of time, to describe $60 \times 60 \times 15\frac{1}{12}$ Paris feet; and in the space of one second of time to describe $15\frac{1}{12}$ of those feet— or, more accurately, 15 feet, 1 inch, 1 line $\frac{4}{9}$. And with this very force we actually find that bodies here on earth do really descend; for a pendulum oscillating seconds in the latitude of Paris will be three Paris feet and $8\frac{1}{2}$ lines in length, as Mr. Huygens has observed. And the space which a heavy body describes by falling one second of time is to half the length of the pendulum in the duplicate ratio of the circumference of the circle to its diameter, and is therefore 15 Paris feet, 1 inch, 1 line $\frac{4}{9}$. And therefore the force by which the moon is retained in its orbit becomes, at the very surface of the earth, equal to the force of gravity which we observe in heavy bodies there. And therefore (by rule 1 and 2) the force by which the moon is retained in its orbit is that very same force which we commonly call *gravity*. For, were gravity another force different from that, then bodies descending to the earth with the joint impulse of both forces would fall with a double velocity, and, in the space of one second of time, would describe $30\frac{1}{6}$ Paris feet, which is altogether against experience.

The demonstration of this proposition may be more diffusely explained after the following manner:—Suppose several moons to revolve about the earth, as in the system of Jupiter or Saturn, the periodic times of those moons would (by the argument of induction) observe the same law which Kepler found to obtain among the planets, and therefore their centripetal forces would be reciprocally as the squares of the distances from the centre of the earth by Prop. I. Now, if the lowest of these were very small, and were so near the earth as almost to touch the tops of the highest mountains, the centripetal force thereof, retaining it in its orbit, would be very nearly equal to the weights of any terrestrial bodies that should be found upon the tops of these mountains, as may be known from the foregoing calculation. Therefore, if the same little moon should be deserted by its centrifugal force that carries it through its orbit, it would descend to the earth, and that with the same velocity with which heavy bodies do actually descend upon the tops of those very mountains, because of the equality of forces that oblige them both to descend; and if the force by which that lowest moon would descend were different from that of gravity, and if that moon were to gravitate towards the earth as we find terrestrial bodies do on the tops of mountains, it would then descend with twice the velocity, as being impelled by both these forces conspiring together. Therefore, since both these forces (that is, the gravity of heavy bodies and the centripetal forces of the moons) respect the centre of the earth, and are similar and equal between themselves, they will (by rule 1 and 2) have the same cause; and therefore the force which retains the moon in its orbit is that very force which we commonly call *gravity*, because otherwise this little moon at the top of a mountain must either be without gravity or fall twice as swiftly as heavy bodies use to do.

Having thus demonstrated that the moon is retained in its orbit by its gravitation towards the earth, it is easy to apply the same demonstration to the motions of the other secondary planets, and of the primary planets round the sun, and thus to show that gravitation prevails throughout the whole creation, after which Sir Isaac proceeds to show from the same principles that the heavenly bodies gravitate towards each other, and contain different quantities of matter, or have different densities, in proportion to their bulks.

PROP. V. All bodies gravitate towards every planet; and the weights of bodies towards the same planet, at equal distances from its centre, are proportional to the quantities of matter they may contain.

COR. 1. Hence the weights of bodies do not depend upon their forms and textures. For, if the weights could be altered with the forms, they would be greater or less, according to the variety of forms in equal matter, which is altogether against experience.

COR. 2. Universally, all bodies about the earth gravitate towards the earth; and the weights of all, at equal distances from the earth's centre, are as the quantities of matter which they severally contain. This is the quality of all bodies within the reach of our experiments, and therefore (by rule 3) to be affirmed of all bodies whatsoever. If either, or any other body, were either altogether void of gravity or were to gravitate less in proportion to its quantity of matter, then, because (according to Aristotle, Des Cartes, and others) there is no difference betwixt that and other bodies, but in mere form of matter, by a successive change from form to form, it might be changed at last into a body of the same condition with those which gravitate most in proportion to their quantity of matter; and, on the other hand, the heaviest bodies, acquiring the first form of that body, might by degrees quite lose their gravity. And therefore the weights would depend upon the forms of bodies, and with those forms might be changed, contrary to what was proved in the preceding corollary.

COR. 3. All spaces are not equally full. For, if all spaces were equally full, then the specific gravity of the fluid which fills the region of the air, on account of the extreme density of the matter, would fall nothing short of the specific gravity of quicksilver or gold, or any other the most dense body; and therefore neither gold nor any other body could descend in air: for bodies do not descend in fluids unless they are specifically heavier than the fluids. And if the quantity of matter in a given space can by any rarefaction be diminished, what should hinder a diminution to infinity?

COR. 4. If all the solid particles of all bodies are of the same density, nor can be rarefied without pores, a void space or vacuum must be granted.

PROP. VI. That there is a power of gravity belonging to all bodies, proportional to the several quantities of matter which they contain.

That all the planets mutually gravitate one towards another has been proved before, as well as that the force of gravity towards every one of them, considered apart, is reciprocally as the square of the distance of places from the centre of the planet. And thence it follows that the gravity tending towards all the planets is proportional to the matter which they contain.

Moreover, since all the parts of a planet, *A*, gravitate towards another planet, *B*, and the gravity of every part is to the gravity of the whole as the matter of the part to the matter of the whole, and (by law 3) to every action corresponds an equal reaction, therefore the planet *B* will, on the other hand, gravitate towards all the parts of the planet *A*, and its gravity towards any one part will be to the gravity towards the whole as the matter of the part to the matter of the whole.

COR. 1. Therefore the force of gravity towards any whole planet arises from, and is compounded of, the forces of gravity towards all its parts. This may be easily understood in reference to gravity, if we consider a greater planet as formed of a number of smaller planets meeting together in one globe; for hence it would appear that the force of the whole must arise from the forces of the component parts. If it be objected that according to this law all bodies with us must mutually gravitate one towards another, whereas no such gravitation any where appears, it is answered that, since the gravitation towards these bodies is to the gravitation towards the whole earth as these bodies are to the whole earth, the gravitation towards them must be too small to fall under the observation of our senses.

COR. 2. The force of gravity towards the several equal particles of any body is reciprocally as the square of the distance of places from the particles.

PROP. VII. In two spheres, mutually gravitating each towards the other, if the matter, in places on all sides round about, and equidistant from the centres,

be similar, the weight of either sphere towards the other will be reciprocally as the square of the distance between their centres.

For the demonstration of this, see the *Principia*, book I., prop. 75 and 76.

Cor. 1., Hence we may find and compare together the weights with which bodies are drawn towards different planets. For the weights of bodies revolving in circles about planets are as the diameters of the circles directly and the squares of their periodic times reciprocally, and their weights at the surfaces of the planets, or at any other distances from their centres, are (by this prop.) greater or less in the reciprocal duplicate proportion of the distances. Thus from the periodic times of Venus, revolving about the sun in $224^d\ 16\frac{3}{4}^h$, of the utmost circumjovian satellite revolving about Jupiter in $16^d\ 16\frac{8}{13}^h$, of the Huygenian satellite about Saturn in $15^d\ 22\frac{2}{3}^h$, and of the moon about the earth in $27^d\ 7^h\ 43'$, compared with the mean distance of Venus from the sun and with the greatest heliocentric elongations of the outmost circumjovian satellite from Jupiter's centre (8′ 16″), of the Huygenian satellite from the centre of Saturn (3′ 4″), and of the moon from the earth (10′ 33″), by computation our author found that the weight of equal bodies, at equal distances from the centres of the sun, of Jupiter, of Saturn, and of the earth towards the sun, Jupiter, Saturn, and the earth, were one to another as $\frac{1}{1067}$, $\frac{1}{3021}$, and $\frac{1}{169282}$ respectively. Then, because as the distances are increased or diminished the weights are diminished or increased in a duplicate ratio, the weights of equal bodies towards the sun, Jupiter, Saturn, and the earth, at the distances 10,000, 997, 791, and 109 from their centres (that is, at their very superficies), will be as 10,000, 943, 529, and 435 respectively.

Cor. 2. Hence likewise we discover the quantity of matter in the several planets. For their quantities of matter are as the forces of gravity at equal distances from their centres, that is, in the sun, Jupiter, Saturn, and the earth, as 1, $\frac{1}{1067}$, $\frac{1}{3021}$, and $\frac{1}{169282}$, respectively. If the parallax of the sun be taken greater or less than 10″ 30‴, the quantity of matter in the earth must be augmented or diminished in the triplicate of that proportion.

Cor. 3. Hence also we find the densities of the planets. For (by prop. 72, book 1) the weights of equal and similar bodies towards similar spheres are, at the surfaces of those spheres, as the diameters of the spheres. And therefore the densities of dissimilar spheres are as those weights applied to the diameters of the spheres. But the true diameters of the sun, Jupiter, Saturn, and the earth, were one to another as 10,000, 997, 791, and 109; and the weights towards the same as 10,000, 943, 529, and 435 respectively; and therefore their densities are as 100, 94½, 67, and 400.

It is shown in the scholium of prop. 22 book 2 of the *Principia* that, at the height of 200 miles above the earth, the air is more rare than it is at the superficies of the earth in the ratio of 30 to 0.0000000000003998. And hence the planet Jupiter, revolving in a medium of the same density with that superior air, would not lose by the resistance of the medium the 1,000,000th part of its motion in 1,000,000 years.

In the above view of the Newtonian system of philosophising we have kept as close as possible both to the phraseology and mode of reasoning pursued by the illustrious author, and it forms a curious specimen of the style of argument adopted by the ancient schoolmen.

Nickel a metal whose distinct character was suspected by Cronstedt in 1751, and fully ascertained by Bergman in 1775. The ore in which it was first found, and from which it is principally obtained at present, is the *Kupfer nickel*, or sulphuret of nickel, mixed also with arsenic, iron, and cobalt. The pure metal and its preparations are obtained from this mineral, or from the artificial arseniuret called *speiss*, a metallurgic production derived from the roasted ores of cobalt. The most convenient method for obtaining the metal is that in which the speiss is employed, and was suggested by Dr. Wollaston. Sulphuric acid is added to the pulverized speiss, and nitric acid, also, at intervals, in the proportion of about one fourth part; a green solution is formed, and, after a subsidence of several hours, the green supernatant liquid is decanted and evaporated until crystals of sulphate of nickel are deposited: a further evaporation gives a crust of arseniate and sulphate, which is dissolved in water, and agitated by a current of sulphuretted hydrogen, until precipitation ceases. The fluid is filtered again, and more of the apple-green matter obtained by evaporation, which, when redissolved, becomes opaque, owing to the precipitation of arsenious acid. The fluid is again filtered, evaporated, and suffered to crystallize, when the sulphate of nickel may be relied upon as being entirely pure. This sulphate, being again dissolved, is decomposed by carbonate of soda, and the resulting carbonate made into balls with oil, and surrounded with charcoal in a crucible, and, being heated in a melting furnace for two hours, yields a pure button of nickel. Its colour, in this condition, is between that of silver and tin; and, when polished, its lustre is equal to that of platinum. Nickel is malleable, and can be forged into bars when hot, and hammered into plates when cold; its specific gravity, when cast, is 8.402, and when forged, 8.66. It is capable of being drawn into very fine wire. It is less fusible than iron. In a covered crucible, some of it is volatilized, and appears in drops on the cover of the crucible. It is attractable by the magnet nearly in the same degree as iron, and becomes itself a magnet by touching, hammering, &c. As nickel does not rust, it has a very great superiority over steel in the construction of a compass-needle. There are two oxides of nickle—the dark ash-gray and the black. If potash be added to the solution of the nitrate or sulphate, and the precipitate dried, we obtain the *protoxide*. It may be regarded as a compound of about 100 metal with twenty-eight oxygen.

The *peroxide* was formed by Thénard, by passing chlorine through the protoxide diffused in water: a black insoluble peroxide remains at the bottom. Its colour is a brilliant black. When heated, it loses oxygen, and becomes protoxide. *Sulphuret of nickel*, prepared directly from its elements, is of a yellow colour, like iron pyrites, and brittle. It consists of seventy nickel and thirty sulphur. *Chloride of nickel* is prepared by evaporating the muriate to dryness. It is of a yellow-green colour, and is a protochloride. When calcined in a retort, one portion of an olive-green colour remains in the bottom of the vessel, while another sublimes, and crystallizes in small, light, brilliant plates of a gold-yellow colour; these are the *deutochloride*. An *iodide of nickel* may be obtained by heating iodine and nickel in a tube. It

is a brown substance; fusible; soluble in water, to which it imparts a light-green colour.

The *salts of nickel* possess the following general properties:—They have usually a green colour, and yield a white precipitate with ferroprussiate of potash. Ammonia dissolves the oxide of nickel. Sulphureted hydrogen and infusion of galls occasion no precipitate. The hydrosulphuret of potash throws down a black precipitate. Their composition has been very imperfectly ascertained. The sulphuric and muriatic acids have little action upon nickel. Sulphate of nickel crystallizes very readily. Its primary form is a right-sided square prism. The nitric and nitromuriatic acids are the most appropriate solvents of nickel. The nitric solution is of a pure green colour. Carbonate of potash throws down from it a pale apple-green precipitate, which, when well washed and dried, is very light. When ammonia is added in excess to a nitric solution of nickel, a blue precipitate is formed, which changes to a purple red in a few hours, and is converted to an apple-green by an acid.

The *alloys* of nickel with other metals are unimportant. With gold, in the ratio of twenty grains to an ounce of nickel, a brass-coloured brittle compound is formed. With iron it unites in every proportion. If nickel prevails, the metal is white, and the ductility and magnetism are equal to that of iron. It does not amalgamate with mercury. Pure nickel being dear and rare, it is entirely unknown in common life, and almost so in the arts. It would undoubtedly be applied to useful purposes if it could be found in sufficient quantity. Dobreiner has observed that the metallic alloy, consisting chiefly of arsenic and nickel, which is obtained from the process of fabricating smalt, often crystallizes in four-sided tabular crystals, and is in every respect similar to arsenical nickel.

NICOTINE; a peculiar principle obtained from tobacco. The following process is adopted for obtaining it in a state of purity:—Boil twelve pounds of dry tobacco leaves in water acidulated with sulphuric acid; evaporate and treat the extract with alcohol diluted with a ninth part of water; add a little water to the solution, and distil; add hydrate of lime to the aqueous residuum, and redistil. The product being mixed and agitated with ether, the latter is to be poured off, and a fresh portion added. All the ethereous solutions are to be united, and mixed with muriate of lime, which will take away the water; and the concentrated ethereous solution, being evaporated or distilled, will leave 100 grains of reddish nicotine. It is liquid at 21° Fahrenheit; its odour resembles that of dry tobacco; its taste is very acrid, burning, and durable. It is denser than water, volatilizes in the air, and boils at 417° Fahrenheit. It dissolves in water in all proportions, and the solution has an alkaline reaction. When dissolved in alcohol or ether, and exposed to heat, it does not distil with their vapours. Acids take the nicotine from the ethereous solution, and form salts insoluble in either. It is eminently poisonous.

NICTITATING MEMBRANE, in comparative *anatomy;* a thin membrane, chiefly found in the bird and fish kinds, which covers the eyes of these animals, sheltering them from the dust, or from too much light, yet is so thin and pellucid that they can see pretty well through it.

NIELLO; a species of work used among the Romans and modern Italians, somewhat resembling Damascus work, and performed by enchasing a mixture of silver and lead into cavities and holes cut in all sorts of hard wood and metals. This art was denominated by the ancients *nigellum*, and was used by them to decorate a great variety of things, and more especially *candelabra*. It was practised by the jewellers and goldsmiths, and flourished chiefly in the fifteenth century.

NIGHT. (For the division of the twenty-four hours into day and night, see DAY.) As a telluric phenomenon, night is of the greatest interest, from the sleep which it brings to most organic creatures; the life to which others awake with it; the increase of feverish symptoms on its arrival, and many other phenomena. One of the most interesting of these is the greater clearness with which distant sounds are heard during night. This fact, which had been observed by the ancients, and in large cities, or their vicinity, was commonly ascribed to the repose of animated beings. When Humboldt first heard the noise of the great cataracts of the Orinoco, in the plain which surrounds the Mission of the Apures, his attention was particularly directed to this curious fact, and he was of opinion that the noise was three times louder at night than during the day. As the humming of insects was much greater at night than during the day, and as the breeze which agitated the leaves of the trees never rose till after sunset, this eminent traveller was compelled to seek for another cause of the phenomenon. In a hot day, when warm currents of air ascend from the heated ground, and mix with the cold air above, of a different density, the transparency of the air is so much affected that every object seen through it appears to be in motion, just as when we look at any object over a fire or the flame of a candle. The air is, therefore, during the day, a mixed medium in which the sounds are reflected and scattered in passing through streams of air of different densities, as in the experiment of mixing atmospheric air and hydrogen. At midnight, on the contrary, when the air is transparent, and of uniform density, as may be seen by the brilliancy and number of the stars, the slightest sound reaches the ear without interruption.

M. Chladni has illustrated the effect of a mixed medium by an elegant experiment of easy repetition. If we pour sparkling Champagne into a tall glass till it is half full, the glass cannot be made to ring by a stroke upon its edge, but admits a dull, disagreeable, and puffy sound. This effect continues as long as the effervescence lasts, and while the wine is filled with air-bubbles. But, as the effervescence subsides, the sound becomes clearer and clearer, till at last the glass rings as usual, when the air-bubbles have disappeared. By reproducing the effervescence, the sound is deadened as before. The same experiment may be made with effervescing malt liquors, and with still more effect by putting a piece of sponge, or a little wool or tow, into a tumbler of water. The cause of the result obtained by M. Chladni is that the glass and the contained liquid, in order to give a musical tone, must vibrate regularly in unison as a system; and, if any considerable part of a system is unsusceptible of regular vibration, the whole must be so. Baron Humboldt has employed this interesting experiment to illustrate and explain the phenomenon of distant sounds being more distinctly heard during the night,

NIGHT-MARE. Comfortable and undisturbed sleep is one of the greatest enjoyments of life; and, as the

brain sympathises more or less with every part of the body, it may be considered a strong proof of health. On the contrary, any interruption in this blessing, independent of mental perturbation, may be considered as a decisive proof of some deviation from health. The slightest disorder of the system may be frequently perceived by paying attention to the state of mind during sleep, particularly to the nature of dreams. This may be demonstrated by attending carefully to the state of the rest of persons on the approach of fever or any epidemic disease, when no sign of any disorder of the system is apparent. Frightful dreams, however, though sometimes the forerunners of dangerous and fatal diseases, not unfrequently occur when the disturbance of the system is comparatively trifling, as they accompany almost every derangement of the digestive organs. Children, whose digestive organs are particularly liable to derangement, are often the subjects of frightful dreams and night-mare. There are many people who frequently rise in the morning even more wearied and weak, both in mind and body, than when they retired to their couch; and, indeed, to whom sleep is an object of terror rather than comfort, and who in vain seek for relief from the ordinary means suggested by medical men. Mr. Waller, a surgeon in the royal navy, has written on the treatment of night-mare. He observes, "To those persons who are only occasionally subject to, and who are generally most alarmed at it, as the disease comes upon them unexpectedly, and without their being able to assign any cause for it, it appears difficult to apply a remedy, as the mischief is generally over before they are aware of its approach. A little attention, however, to the state of the digestive organs will generally point out to them that it was connected with indigestion, flatulence, or costiveness, or perhaps all these together; frequently it is the consequence of having eaten some particular kind of food, which experience shows always to disagree with the stomach. An old writer on medical subjects observes that 'he who wishes to know what night-mare is, let him eat chestnuts before going to sleep, and drink after them feculent wine.' I have found by experience in the West Indies that eating a particular fruit, called the Alligator pear, would at any time in the *day* produce *night*-mare. This is a pulpy fruit, which, when cut into, resembles a custard, and is frequently spread upon bread and eaten instead of butter, whence it has obtained among military men the name of *subaltern's butter*, and it is frequently no contemptible substitute for fresh butter. I used frequently to eat it beat up with the juice of Seville oranges and sugar, in which case its effects are almost instantaneous. So great a propensity to sleep came upon me that I could not resist the temptation, though well aware of the consequences, so that I generally kept some person by me to awake me as soon as the night-mare came on, which was always in the course of a few minutes. I have frequently shown this experiment to my medical friends. The articles most likely to produce night-mare I conceive to be cucumbers, nuts, apples, and all such things as produce flatulence. Whenever a person has discovered the offending article, it is certainly prudent to abstain from it, more especially in the evening. If, however, that state of stomach and bowels which gives rise to night-mare should be perceived, there will be just reason to apprehend that it will occur, and it will be advisable to have recourse to some preventive. The fit of night-mare does not always immediately follow the eating any improper food, but sometimes several days elapse before its attack. In this case it is easier to foresee and consequently to prevent it. The signs by which its approach may be known are unusual drowsiness, disagreeable dreams, and disturbed sleep, with wind in the stomach and bowels. In this case I would recommend immediate recourse to the carbonate of soda, of which ten grains may be taken mixed with three drachms of the compound tincture of cardamoms. The bowels should be opened by small doses of magnesia and rhubarb mixed in peppermint water. Intemperance of every kind is hurtful, but nothing is more productive of this disease than drinking *bad wine;* of eatables, those which are most prejudicial, are fat and greasy meats, most vegetables, fruits, and pastry. These ought to be avoided, or eaten with caution. The same thing may be said of salt meats, for which dyspeptic patients have frequently a predilection, but which are not on that account less noxious. Moderate exercise contributes in a superior degree to promote the digestion of the food, and prevent the formation of flatulence; to those, however, who are necessarily confined to a sedentary occupation, I would recommend particularly to avoid applying to study, or any other sedentary occupation, immediately after eating. If a strong propensity to sleep should occur after dinner, it will be certainly better to indulge it a little, as the process of digestion frequently goes on much better during sleep than when awake. What has been said with respect to night-mare will apply equally to all other kinds of disturbed sleep. They originate from the same cause, and will be removed by the same remedies."

NIGHTSHADE. This plant has been found of great use in the healing art. The deadly nightshade is a perennial plant, with a herbaceous stem, which is indigenous both in mountainous and woody situations in this country, and often cultivated in gardens. The whole plant is poisonous, and the berries, from their beautiful appearance, have sometimes proved fatal to children. The symptoms excited are, dryness of the mouth, trembling of the tongue, very distressing thirst, difficulty of swallowing, fruitless efforts to vomit, and great anxiety about the præcordia. Delirium then comes on, with gnashing of the teeth, and convulsions. The pupil remains dilated, and is not sensible even to the stimulus of light. The face becomes tumid, and of a dark red colour. The jaws are frequently locked. Inflammation attacks the œsophagus, stomach, and intestines, sometimes extending to the mesentery, lungs, and liver, accompanied with violent pains in the abdomen. The stomach is very insensible to stimulus, and the peristaltic motion of the intestines is destroyed. General relaxation, palsy, especially of the lower extremities, convulsions, vertigo, blindness, coma, and death succeed. The body soon putrefies, swells, and becomes marked with livid spots; blood flows from the nose, mouth, and ears, and the stench is insufferable. On dissection the blood is found to be fluid, the intestines are inflated and inflamed, or eroded and gangrenous. The best method of cure is to excite vomiting as soon as possible, by emetics, and tickling the fauces; to evacuate the bowels by purgatives and glysters; and to give largely vinegar, honey, milk, and oil. In some children who recovered by this

treatment, the delirium was succeeded by a profound stupor, accompanied with subsultus tendinum; the face and hands became pale and cold, and the pulse small, hard, and quick. Their recovery was slow, and the blindness continued a considerable time, but at last went off. Yet this virulent poison, under proper management, may become an excellent remedy. Besides its narcotic power, it promotes all the excretions: but its exhibition requires the greatest caution; for it is apt, when continued for any length of time, even in small doses, to cause dryness and tension of the throat and neighbouring parts, vertigo, dimness of sight, and even temporary blindness. When any of these symptoms occur, its use must be suspended for some time, and afterwards resumed in smaller doses.

Deadly nightshade has been employed; 1. In several febrile diseases: in obstinate intermittents, and in the plague. 2. In inflammations: the gout. 3. In comatose diseases: in palsy, and loss of speech from apoplexy. 4. In spasmodic diseases: in epilepsy, chincough, hydrophobia, melancholy, and mania. 5. In cachectic affections: in dropsies, and obstinate jaundice. 6. In local diseases: in amaurosis, ophthalmia, and cancer.

Deadly nightshade is best employed in substance, beginning with a very small dose of the powdered leaves or root, such as the fourth or eighth part of a grain for children, and one grain for adults, to be repeated daily, and gradually increased. In hydrophobia, Dr. Munch gave the powdered root every second morning, to the extent of from one to five grains to children, and fourteen or fifteen grains to adults.

The watery infusion is also a powerful remedy. One scruple of the dried leaves is infused in ten ounces of warm water, and strained after cooling. At first two ounces of this may be given daily to adults, and gradually increased, until the tension of the throat shows that it would be imprudent to go further.

The watery extract is not a judicious preparation.

Externally, the powdered leaves are applied as a narcotic to diminish pain, and to cancerous and ill-conditioned sores.

Nilometer, an instrument used amongst the ancients to measure the height of the water of the river Nile, at the period of its overflowing. The nilometer is said, by several Arabian writers, to have been first erected for this purpose by Joseph, during his reign in Egypt. It was sixteen cubits in height. As all the riches and prosperity of Egypt depended on the overflowing of this river, the inhabitants were in the habit of supplicating Serapis when they examined the nilometer.

The most rational and consistent account, however, which we have of the nilometer, is given by the celebrated traveller Bruce. "On the point of the island of Rhode, between Geyah and Cairo, near the middle of the river, is a round tower enclosing a neat well or cistern lined with marble. The bottom of this well is on the same level with the bottom of the Nile, which has free access to it through a large opening like an embrasure. In the middle of the well rises a thin column of eight faces of blue and white marble, of which the foot is on the same plane with the bottom of the river. This pillar is divided into twenty divisions called pecks, of twenty-two inches each. Of these pecks the two lowermost are left without any division, to stand for the quantity of sludge which the water deposits there. Two pecks are then divided, on the right-hand, into twenty-four digits each; then on the left four pecks are divided into twenty-four digits; then on the right, four; and on the left another four: again, four on the right, which completes the number of eighteen pecks from the first division marked on the pillar, each peck being twenty-two inches. Thus the whole, marked and unmarked, amounts to something more than thirty-six feet English.

"On the night of St. John, when, by the falling of the dew, they perceive the rain-water from Ethiopia mixed with the Nile at Cairo, they begin to announce the elevation of the river, having then five pecks of water marked on the nilometer and two unmarked for the sludge, of which they take no notice. Their first proclamation, supposing the Nile to have risen twelve digits, is twelve from six, or it wants twelve digits to be six pecks. When it has risen three more, it is nine from six; and so on, till the whole eighteen be filled, when all the land of Egypt is fit for cultivation. Several canals are then opened, which convey the water into the desert, and prevent any further overflowing of the fields; for, were the inundation suffered to go on, it would not drain soon enough to fit the land for tillage: and to guard against this mischief is the principal use of the nilometer, though the Turkish government makes it an engine of taxation. From time immemorial the Egyptians paid, as tribute, a certain proportion of the fruit of the ground; and this was anciently ascertained by the elevation of the water on the nilometer, and by the mensuration of the land actually overflowed. But the Saracen government, and afterwards the Turkish, taxed the people by the elevation alone of the water, without attending to its course over the country or the extent of the land actually overflowed."

Nitre. This salt is, under certain circumstances, formed spontaneously at the surface of the soil; it is thus procured in India, whence the nitre we use is imported. In some countries of Europe, the production of it is favoured by artificial arrangements. Vegetable and animal substances, with an intermixture of old plaster, mortar, or other forms of carbonate of lime, are put into ditches lined with clay, and covered with sheds to protect them from the rain, while the air is admitted. They are turned up occasionally, and at the end of a few months, when washed with water, afford nitrates of potash and lime. A quantity of wood-ashes is added to the solution, the potash of which decomposes the nitrate of lime, and increases the product of nitrate of potash; this salt is obtained in crystals by evaporation, and is purified from a portion of muriate of soda and other saline matter which adheres to it, by repeated solutions and crystallizations.

The nitre does not pre-exist in these materials, and is therefore obviously formed in the process. As an intermixture of animal and vegetable matter, the presence of carbonate of lime, and the admission of the atmospheric air, are all necessary, it is probable that the nitrogen of the animal matter combines with the oxygen of the air, and perhaps with a portion of the oxygen of the vegetable matter, and forms the acid, the carbonate of lime favouring this combination by the resulting affinity exerted by the lime, and attracting the acid as it is formed: the vegetable matter moderates the decomposition of the animal substances, and prevents them from running into that

putrefaction by which the nitrogen is spent in the formation of ammonia; it may further afford the potash, which is the base of the nitre, though it has also been supposed that a part of this is formed in the process. A certain degree of humidity favours the mutual actions whence these combinations arise, and diffuses more equally through the materials the nitrous salts.

Nitre crystallizes in six-sided prisms, bevelled at the extremities; its taste is cool; it is soluble in seven parts of water at 60°, a production of cold attending its solution, and in an equal quantity of boiling water. It melts easily: if the heat be raised, a partial decomposition of the acid takes place, and oxygen gas is expelled; and at the temperature of ignition the decomposition is more complete, and oxygen and nitrogen gases are disengaged.

From its facility of decomposition by heat, nitre produces deflagration, when heated with inflammable bodies. It is from this property that it is employed as the principal ingredient in the composition of gunpowder, which consists of seventy-five parts of it by weight with sixteen of charcoal and nine of sulphur. These ingredients are thoroughly mixed by continued trituration, a small quantity of water being added to favour this; the paste into which the composition is at length brought is granulated by pressing it through a sieve, and the grains, after they are dry, are rounded and glazed by friction from agitation. The deflagration of the gunpowder, when an ignited spark falls on it, is owing to the rapid communication of the oxygen to the sulphur and the charcoal, the sulphur in particular being easily inflamed; and its great expansive force depends on the sudden extrication of the aërial products. Sulphurous acid and carbonic acid are formed by the oxygenation of the sulphur and charcoal, and nitrogen by the decomposition of the acid, probably with watery vapour, the elasticity of these being much increased by the caloric rendered sensible.

Nitric Acid.—This acid, which can be extracted without much difficulty from common nitre and sulphuric acid, has been long known to chemists, and in a diluted state has been used in the chemical arts under the name of aquafortis. Priestley observed its partial decomposition, and its reproduction from the union of nitric oxide (the product of that decomposition) with oxygen. Cavendish discovered its ultimate composition, and proved that nitrogen is its base. This was done by a very simple experiment,—taking the electric spark for a considerable time in atmospheric air, confined in a tube. The volume was diminished, an acid was produced, and this acid was found to be nitric. When a portion of oxygen gas was added to the air, and the electric spark continued sufficiently long, the disappearance of the whole was nearly complete; and a similar result was obtained from submitting to experiment a mixture of oxygen and nitrogen gases. In all these cases, the electric spark establishes the combination of the gravitating matter of the two gases; and the principal peculiarities which attend this combination are the slowness with which it takes place, and its not being accompanied by any sensible extrication of heat and light.

Analysis likewise establishes the composition of nitric acid. If it be passed through an ignited glass or earthen tube, it is resolved into oxygen and nitrogen gases; its saline compounds exposed to a red heat afford the same elements; and its oxygen can be abstracted by inflammable substances, its nitrogen being evolved, either pure or retaining a portion of oxygen combined with it, which by further operations may be abstracted.

It has been found difficult to determine with accuracy the proportions in which its elements combine, and in particular to reconcile them with those of the other nitrous compounds, conformably to the usual laws of definite proportions. Those assigned by Cavendish were 72.2 of oxygen and 27.8 of nitrogen by weight. Davy stated them not far different from these, at 70.5 of oxygen and 29.5 of nitrogen. The latter are not far from the proportions of 100 of nitrogen and 200 of oxygen by measure. Gay-Lussac, judging from the composition of nitric oxide and the quantity of oxygen with which he found it to combine to form nitric acid, states the proportions at 100 of nitrogen and 250 of oxygen by measure.

Nitric acid is obtained from the decomposition of nitre, a salt in which it exists combined with potash, and the process usually followed is that by the medium of sulphuric acid. Two parts of nitre in coarse powder are put into a retort, and rather more than one part of sulphuric acid is poured upon it, the retort being placed in a sand-bath, and connected with a large receiver. A moderate heat is applied to produce distillation; towards the end it is gradually raised, and is continued as long as any acid is produced. The sulphuric acid combines with the potash of the nitre, and disengages the nitric acid, this decomposition being aided by the greater volatility of the nitric acid. The nitric acid, however, when disengaged, is also partially decomposed; losing a little of its oxygen, a portion of it passes to the state of nitric oxide, and this being absorbed by the acid which distils over gives it a yellow colour, more or less deep, or converts it into nitrous acid. This decomposition appears to arise in a great measure from the action of the high temperature, and hence it takes place principally towards the end of the distillation. The addition of more sulphuric acid than is strictly necessary to neutralize the potash of the nitre is useful, partly from the quantity aiding its affinity, and partly by affording water to preserve the constitution of the nitric acid.

In consequence of this partial decomposition, an additional process is requisite to obtain nitric acid. The coloured acid is exposed to a gentle heat, applied by a water-bath; the nitric oxide holding a portion of nitric acid combined with it is expelled, and the acid becomes nearly colourless; or, what succeeds more completely, the nitrous acid is distilled from a little oxide of manganese, which, imparting to it oxygen, converts it into nitric.

Nitric acid is colourless and transparent; it emits white vapours having a peculiar odour. It has all the acid properties, tastes sour even when much diluted, reddens the vegetable colours, and neutralizes the properties of the alkalies and earths. Its specific gravity is 1.55 at 60°. In this state it contains a quantity of combined water, equal, according to Kirwan and Dalton, to 26, according to Dr. Wollaston to 25.1 in 100 parts. The presence of water is essential to the acid in its insulated state, as it can neither be formed nor can it be disengaged from its saline combinations without water be supplied to it.

This acid freezes by cold, the facility of congelation varying considerably, according to its state of

concentration: if it is highly concentrated, or if, on the other hand, it is much diluted, it freezes with more difficulty than when of intermediate strength. It is volatilized by heat; but its volatility is also much influenced by its state of concentration; the highest boiling point is that of the acid at the specific gravity of 1.42; it boils at 248°; if either stronger or weaker than this, it boils at a lower temperature. This, too, is the only acid which rises unchanged by boiling, a weaker acid becoming stronger, and a stronger acid than this becoming weaker, as it boils. At a higher heat the acid is partially decomposed. A partial decomposition of it is also effected by light; oxygen is expelled, and it passes to the state of nitrous acid.

Nitric acid has a considerable affinity to water: it attracts it from the atmosphere, and it combines with it in every proportion. In consequence of this affinity, too, it acts with energy on ice and snow, liquefying them rapidly, and producing intense cold.

The affinity between the elements of this acid not being strong, it is decomposed by metallic and inflammable bodies, which attract its oxygen partially or completely; and, in consequence of this facility with which it yields oxygen, it acts with much energy on these substances.

It combines with the alkalies, earths, and metallic oxides, forming salts, denominated nitrates. The generic characters of these are a cool penetrating taste, affording oxygen gas at a high temperature, and deflagrating with inflammable bodies at the temperature of ignition. They are all soluble in water, and crystallizable. The individual nitrates will be considered under their respective bases. (See Oxide, Nitric.)

Nitrogen.—This gas has already been examined under the name of Azote, and we must now confine ourselves to a few facts connected with its combination with *iodine* and *chlorine*. Nitrogen combines with chlorine and iodine to form two very remarkable compounds. The first of these, the *chlorine of nitrogen*, is formed by the action of chlorine on some salt of ammonia. Its formation is owing to the decomposition of ammonia (a compound of nitrogen and hydrogen) by chlorine: the hydrogen of the ammonia unites with chlorine and forms muriatic acid, while the nitrogen of the ammonia, being presented in its nascent state to chlorine dissolved in the solution, enters into combination with it. The chloride of nitrogen is formed gradually, when a glass receiver filled with chlorine gas is inverted over a bowl containing a solution of muriate of ammonia, and falls in little globules through the fluid to the bottom of the dish, whence it is withdrawn with the utmost care by means of a glass syringe. On being ejected into a metallic mortar, or leaden dish, containing a little volatile oil, or phosphorus in small pieces, it detonates with extreme violence. Its specific gravity is 1.653: it is not congealed by the intense cold produced by a mixture of snow and salt, may be distilled at 160° Fahr., but explodes at a temperature between 200° and 212°. It consists of chlorine 144, or four proportions; nitrogen fourteen, or one proportion.

Iodide of nitrogen. From the weak affinity that exists between iodine and nitrogen, these substances cannot be made to unite directly; but, when iodine is put into a solution of ammonia, the alkali is decomposed, its elements unite with different portions of iodine, and thus cause the formation of hydriodic acid and iodide of nitrogen. The latter subsides in the form of a dark powder, which is characterized, like chloride of nitrogen, by its explosive property. It detonates violently as soon as it is dried, and slight pressure while it is moist produces a similar effect. Heat and light are emitted during the explosion, and iodine and nitrogen are set free. It consists of one proportional of nitrogen to three of iodine.

With regard to the nature of nitrogen there has been, and still exists, a considerable diversity of opinion. Berzelius has inferred, from speculations connected with the doctrine of definite proportions, that it is a compound of oxygen with an unknown base, to which he has given the name of *nitricum*, and has fixed the proportions at 44.32 of base and 55.68 of oxygen; others, on the contrary, have affirmed, as a consequence of this doctrine, that nitrogen can contain no oxygen—a proof of the little value to be attached to such speculations. The strongest arguments for the compound nature of nitrogen are derived from its slight tendency to combination, and from its being found abundantly in the organs of animals which feed on substances that do not contain it. Its uses in the economy of the globe are little understood. One thing however is certain, that it serves to dilute the oxygen of the atmosphere, and without it we could not employ the ordinary materials of combustion.

Nitro-Muriatic Acid is formed by mixing muriatic acid and nitric acid. This compound has some peculiar properties, among which is that of dissolving gold with facility, from which it received from the alchemists the name of *aqua regia*. One part of muriatic acid is mixed with two parts of nitric; during their combination the formation of oxymuriatic acid is indicated by its odour, nitric oxide gas is disengaged, and a portion of it is retained in the liquid, giving it a dark orange colour. It is concluded, therefore, that in the mutual action of these acids part of the nitric acid is decomposed, its oxygen is transferred to the muriatic, and to the oxymuriatic acid thus formed the peculiar chemical powers of the compound have been ascribed. It appears, however, to be chiefly a compound of nitric and muriatic acids; and its energetic action on the metals seems to be owing to the latter acid by a disposing or resulting affinity promoting the decomposition of the former, favouring therefore the communication from it of oxygen to the metal, with which in its oxidated state it then combines. It is employed in some of the processes of assaying.

Nitrous Acid.—This name is given to the yellow acid obtained by the usual process of decomposing nitre by sulphuric acid; and it owes its yellow colour to the presence of a portion of nitric oxide. When this is disengaged by a moderate heat, it becomes colourless: and, if nitric oxide is transmitted through it in this state, it regains its colour.

It appears to follow from these facts that there is no acid of determinate composition to which the name nitrous can be properly applied. What is called such is nitric acid holding nitric oxide dissolved: and the quantity of this may be variable, and even indefinite, between the minimum and maximum. According to the quantity communicated, the colour is deeper. From a portion not exceeding 1.2 of nitric oxide by weight in 100 parts, a pale yellow colour is communicated; this, as the quantity is increased, passes through shades of bright yel-

low to dark orange, in which the proportion amounts to about 5.5; beyond this an olive colour, and then a bright green, verging into blue, are obtained; and, if the transmission of the nitric oxide gas be continued longer, it communicates its elasticity to the liquid acid, and the whole rises in very dense. red, suffocating vapours.

Some chemists have, however, assumed the existence of an acid of determinate composition, and have in particular given this name to the compound in which the largest proportion of nitric oxide gas is condensed by oxygen gas. It is obtained by admitting oxygen gas to nitric oxide gas, when the latter is kept in excess: a dense red-coloured vapour is formed.

Nitrous acid vapour, formed by the combination of nitric oxide and oxygen gases, is of a deep red colour, extremely suffocating; its specific gravity is 1.457, air being 1000; it is rapidly absorbed by water, forming a solution of a green colour. It acts on inflammables, and, in particular, sustains the combustion of phosphorus.

The common liquid nitrous acid must, if these views be correct, be a mixture of these acids of a specific composition in various proportions with probably more or less water. It is more or less coloured according to the quantity of nitric oxide; its specific gravity is also diminished, a pale acid of 1.52, when converted into yellow acid, becoming nearly of the specific gravity of 1.51. The acid obtained by distillation from nitre and sulphuric acid is usually of a pale yellow colour: but, if the heat has been raised very high towards the end of the process, it is of a deeper colour; and, if any inflammable matter has been contained in the materials, it is of a dark orange red. The colours which the acid assumes from this impregnation of nitric oxide are likewise dependent on its state with regard to dilution. If the dark orange-coloured acid be mixed with water, the different shades are produced; with a large quantity of water, blue; with more acid, olive, and bright green. These colours are not permanent, the oxygen loosely dissolved in the water, or imbibed from the atmosphere, oxygenating the nitric oxide, and bringing the whole to the state of nitric acid.

Nitrous acid in its relations to other chemical agents is similar to nitric acid. It oxidizes in the same manner and with the same phenomena, in inflammable bodies and metals, and combines with the metallic oxides. These combinations are indeed merely those of the nitric acid, as the nitrous oxide is disengaged during the process.

The compounds of nitrous acid with the alkalies or earths can scarcely be obtained by direct combination; for, when it is added, the greater part of the nitric oxide is expelled. They are usually obtained by an indirect mode, pointed out by Scheele, that of exposing a nitrate to such a heat as partially decomposes the nitric acid, and expels part of its oxygen. The remaining acid with a portion of nitric oxide exists in combination with the alkaline base, forming the salts which have been named nitrites. They are easily decomposed, and give out nitrous acid vapour on the affusion of an acid. On exposure to the atmosphere, they absorb oxygen, and return to the state of nitrates. (See OXIDE, NITROUS.)

NODES, in *astronomy;* the two points where the orbit of a planet intersects the ecliptic. These nodes are constantly changing their places.

NORIA, a hydraulic machine used in Spain. It consists of a vertical wheel of twenty feet diameter, on the circumference of which are fixed a number of little boxes or square buckets, for the purpose of raising the water out of the well, communicating with the canal below, and emptying it in a reservoir above, placed by the side of the wheel. The buckets have a lateral orifice to receive and to discharge the water. The axis of this wheel is embraced by four small beams, crossing each other at right angles, tapering at the extremities, and forming eight small arms. This wheel is near the centre of the horse-walk, contiguous to the vertical axis, into the top of which the horse-beam is fixed; but near the bottom it is embraced by four small beams, forming eight arms, similar to those above described, on the axis of the water-wheel. As the mule which they use goes round, these horizontal arms, supplying the place of cogs, take hold, each in succession, of those arms which are fixed on the axis of the water-wheel, and keep it in rotation.

This machine raises a great quantity of water; but it has two defects: the first is, that part of the water runs out of the buckets and falls back into the well after it has been raised nearly to the level of the reservoir: the second is, that a considerable proportion of the water to be discharged is raised higher than the reservoir, and falls into it only at the moment when the bucket is at the highest point of the circle, and ready to descend.

Both these defects are occasionally remedied by leaving the square buckets open at one end, making them swing on a pivot fixed a little above their centre of gravity, and placing the trough of the reservoir in such a position as to stop their progress whilst perpendicular, make them turn upon their pivot, and so discharge their contents.

From the reservoir the water is conveyed by channels to every part of the garden; these have divisions and subdivisions or beds, some large, others very small, separated from each other by little channels, into which a boy, with his shovel or his hoe, directs the water, first into the most distant trenches, and successively to all the rest, till all. the beds and trenches have been either covered or filled with water.

Mr. Townsend, from whom we take the above account, states that by the aid of this machine the inhabitants every morning draw as much water from the well as will serve through the day, and in the evening distribute it to every quarter according to the nature of their crops. The reservoirs into which they raise the water are about twenty, thirty, or even forty feet square, and three feet high above the surface of the ground, with a stone cope on the wall, declining to the water, for the women to wash and beat their clothes upon.

Our limits preclude us from following Mr. Townsend further in the description of a particular noria used at Barcelona, which he conceives to be the original chain-pump, or at least its parent. He compares it with similar instruments, and shows its advantages and disadvantages.

NORTH; one of the four cardinal points of the world, being that point of the horizon which is directly opposite to the sun at its meridian. The north wind is generally accompanied with a considerable decrease of temperature. It sometimes blows with almost irresistible fury; and is often mentioned by the classic authors under the name of *Boreas.*

Nose; that prominence on the face which is the organ of scent. The ancients seem to have had an aversion to small noses, and the Romans esteemed above all the aquiline nose, which Pliny termed, by way of distinction, *royal*. It is thus that Ælian has described that of Aspasia, and Philostratus those of Achilles and of Paris. According to Plutarch, Cyrus had the same; and on this account the Persians are said to have admired noses of this shape. But aquiline noses were reckoned beautiful only when the curve was gentle and almost insensible, in contradistinction to such as were decidedly crooked, resembling the beak of a parrot. The Grecians, indeed, generally speaking, seem to have held a straight line from the forehead, or rather slightly inclined, to be the *beau idéal* with respect to this feature; and accordingly we find it in their best statues, &c.

Nosology, in *medicine;* that science which treats of the systematic arrangement and classification of diseases.

Notation, in *arithmetic*, is the method of expressing, by means of certain signs, any proposed number or quantity. In the modern analysis, *notation* implies a method of representing any operation belonging to this science; and the judicious and ingenious selection of proper symbols forms not the least important part of it. The success of a great mathematical operation depends much upon this point, and the science itself has sometimes made a new advance by the invention of new and more manageable symbols. In the common scale of notation, every number is expressed by the ten characters 1, 2, 3, 4, 5, 6, 7, 8, 9, 0, the first nine of which represent different numbers of units, and denote various values according to the place which they occupy.

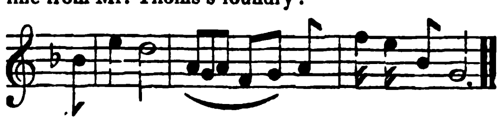
Notes, in *music;* the signs for tones. Even in the most remote antiquity, certain letters of the alphabet were used as signs for musical tones. According to some, the Hebrews made use of accents for this purpose, as the modern Greeks still do. The Greeks used different signs for vocal and instrumental music; and, as they had not yet conceived the idea of using the octave to express, by means of a prefixed key, a number of the most diversified tones in a similar manner, they must have required a great number of notes (said to have amounted to 990; half for vocal tones, half for instruments). As they used the alphabetical signs for notes, it became necessary to employ the same letter in different positions (inclining, inverted, &c.); thus F signified, in different positions, seven different tones. Accents, also, were used, partly by themselves, partly added to letters.

If a poem was to be sung, the letters which signified the instrumental tone were placed first; under these the letters for the voice; and under these the words. As the syllables of the Greek language have mostly a natural and distinct quantity (i. e. duration of time), the Greek notes were not required to show the time, and generally could be restricted to height, depth, and nature of tone. In the case of the syllables called common (short and long), there was a liability to mistake, and they were therefore marked with A if long and with B if short. The fifteen chief tones of the Greek system were first reduced to seven by pope Gregory I. towards the end of the sixth century, and marked with the first seven letters of the Roman alphabet; so that the capitals were used for the first voice, the small letters for the higher octave, and the double letters for the highest octave.

Parallel lines were soon invented, on which the letters were written. These were used until the happy idea was conceived of substituting for letters points with five lines, the points and rhombuses being placed as well between the lines as on them. This invention is generally ascribed to Guido of Arezzo. According to some, it was known even in the tenth century. The letters which had been formerly used as notes now became clefs. Still the sign for the duration of a tone was wanting. The way of marking it was invented, according to some, by a German of Cologne, of the name of Franco, who lived towards the end of the eleventh century. Others ascribe the invention, or at least the improvement, to John de Murs (Jean de Moeurs, or Meurs.) The *diminutio*, or division of one note into others of less value (for instance, the division of a fourth into two eighths), and the use of running notes, were invented first by Jean Mouton, chapel-master to king Francis I., in the sixteenth century. Since Rousseau, the designating of notes by ciphers has been repeatedly proposed, and adopted with great success in elementary schools; but, in other respects, the old way of writing notes—one of the most ingenious contrivances ever produced, which seems to have given to Leibnitz even the idea of a *pasigraphy*, or system of universal writing—has kept its ground.

As to printing notes, two periods are distinguished—the first when notes were printed by plates, the second by movable types. The first plates used for this purpose were of wood, and the oldest known are of 1473. Then the printing of notes by copper-plates was invented. The cheaper way of printing from tin plates, in which the notes are punched with steel punches, did not become common till the middle of the last century.

As to the second period, the inventor is uncertain. Some consider Ottavio Pistrucci, in the beginning of the sixteenth century, as such. James Panlecque (born at Chaulne, in Picardy, 1573), a celebrated type-founder at Paris, where he died 1648, probably introduced the printing of notes from types into France. Yet the art of printing with them remained very imperfect, until the well-known typographer Breitkopf, at Leipsic, carried the process, in 1755, to such perfection that he may fairly be called the second inventor. The printing of music with movable types has now attained so high a degree of excellence as to equal that which is printed from tin or pewter plates, in proof of which we give a line from Mr. Thoms's foundry:



Tauchnitz, of Leipsic, first stereotyped notes. The process of lithography is used at present.

Great musicians can sometimes compose with the pen in their hand, and without the aid of the piano. They hear all the music in their soul, as a picture stands, with all its hues and proportions, before the mental eye of an artist, prior to his touching the canvass. Many persons, however, who play well extempore, are by no means able to compose on paper; and for them a machine would be convenient which could accompany the player's motions, and write the notes with a rapidity equal to that of his performance. The first idea of such a machine was given in

the *Philosophical Transactions,* in 1747 (No. 483), as the invention of an English clergyman of the name of Creed; yet the practicability of this idea was not sufficiently shown. In 1748, a Mr. Unger, burgomaster of Eimbeck, had the same idea without knowing of Creed's communication; and, in 1752, the academy of sciences at Berlin approved of his suggestions; but nothing was done until a member of the academy, M. Selzer, induced a mechanic, Hohlfeld, to construct such a machine from an imperfect description of Unger's plan. In the *Nouveaux Mémoires de l'Académie royale des Sciences et des Belles-lettres à Berlin,* of 1771, is a description of this machine. It consists of two cylinders, from one of which paper rolls off, while it is rolled round the other, during which time the keys move corresponding pencils, which write the note on the paper. Not much use, however, has been made of the machine.

November; the ninth month of the Roman year. In our calendar it forms the eleventh.

Noyau; a cordial. The word is French, and is derived from the use of the kernels of apricots, nectarines, and peaches, in flavouring the liqueur of which it is the name. The use of them in too large quantities has sometimes made the liqueur poisonous, as prussic acid may be extracted from them. The other ingredients are French brandy, prunes, celery, bitter almonds, a little essence of orange-peel, essence of lemon-peel, and rose-water. It is used like the other liqueurs.

Number.—Number is either abstract or applicate: abstract when referred to things in general, without attending to their particular properties; and applicate when considered as the number of a particular sort of things, as yards, trees, &c. When particular things are mentioned, there is always something more considered than barely their numbers; so that what is true of number in the abstract, or when nothing but the number of things is considered, will not be true when the question is limited to particular things: for instance, the number two is less than three; yet two yards is a greater quantity than three inches, because regard must be had to their different natures as well as number, whenever things of a different species are considered; for, though we can compare the number of such things abstractedly, yet we cannot compare them in any applicate sense. And this difference is necessary to be considered, because upon it the true sense, and the possibility or impossibility, of some questions depend. Number is unlimited in respect of increase; because we can never conceive a number so great but still there is a greater. However, in respect of decrease, it is limited; unity being the first and least number, below which therefore it cannot descend, except by subdivision into decimal or other parts, which may also be extended infinitely, at least in idea, if not in fact; for we cannot conceive any particle of matter so small but that it may be supposed capable of being rendered still smaller by division and subdivision.

Numerator of a Fraction; that number which stands above the line, and shows how many parts the fraction consists of, as the *denominator* represents the number of parts into which the unit is supposed to be divided.

Numismatics is the name of the science which has for its object the study of coins and medals, principally those struck by the ancient Greeks and Romans. The name of *coins* is given to the pieces of metal on which the public authority has impressed different marks to indicate their weight and value, to make them a convenient medium of exchange. By the word *medals*, when used in reference to modern times, is understood pieces of metal similar to coins, not intended as means of exchange, but struck and distributed in memory of some important event. The name of *medals*, however, is sometimes given to all pieces of money which have remained from ancient times.

The parts of a coin or medal are the two sides; 1. the obverse side, face, or head, which contains a portrait of the person at whose command or in whose honour it was struck, or other figures relating to him. This portrait consists either of the head alone, or the bust, or of a half or full-length figure. 2. The reverse contains mythological, allegorical, or other figures. The words around the border form the legend; those in the middle the inscription. Neither of these was originally placed on coins: the latter is frequently merely a monogram. The lower part of the coin, which is separated by a line from the figures, or the inscription, is the basis, or *exergue*, and contains subsidiary matter, as the date, the place where the piece was struck, &c.

Numismatics has the same divisions as history. Ancient numismatics extends to the extinction of the empire of the West; the numismatics of the middle ages commence with Charlemagne; modern numismatics with the revival of learning. The pieces of metal used first as money were rude and shapeless, with some mark to indicate at once their weight and value. Ancient writers even mention money of leather among the Carthaginians, Spartans, and Romans. Money of wood is also mentioned among the Romans; as also of shells, which are still used by some African tribes. But gold, silver, and copper, have been and are the ordinary materials of money. The form of money is round, oval, square, triangular, or long, as were at first the *oboli*. The study of medals is indispensable to archæology, and to a thorough acquaintance with the fine arts. They indicate the names of provinces and cities, determine their position, and present pictures of many celebrated places. They fix the period of events, determine, sometimes, their character, and enable us to trace the series of kings. They enable us to learn the different metallurgical processes, the different alloys, the mode of gilding and plating practised by the ancients, the metals which they used, their weights and measures, their different modes of reckoning, the names and titles of the various magistrates and princes, and also their portraits, the different divinities, with their attributes and titles, the utensils and the ceremonies of their worship, the costume of the priests—in fine, every thing which relates to usages, civil, military, and religious. Medals also serve to acquaint us with the history of art. They contain representations of several celebrated works of antiquity, as the Hercules Farnese, and the Venus of Cnidus. Like gems and statues, they enable us to trace the epochs of different styles of art, to ascertain its progress among the most civilized nations, and its condition among the rude. Medals are of great assistance to philology, and the explanation of the ancient classics. The ancient medals were struck or cast. Some were first cast, and then struck.

The first coins of Rome, and the other cities of Italy, must have been cast: the hammer could not

have produced so bold a relief. The copper coins of Egypt were cast. The right of coining money has always been one of the privileges which rulers have confined to themselves. The free cities possessed the right of inscribing their names on coins. The cities subject to kings sometimes obtained permission to strike money in their own name, but most frequently were required to add the name or image of the king to whom they were subject. The medals of the Parthians and Phœnicians offer many examples of this sort. Rome, under the republic, allowed no individual the right to coin money; no magistrate was to put his image thereon, though, sometimes, this honour was allowed by a particular decree of the senate.

We can count among the numismatic countries only those into which the Greeks and the Romans carried the use of money. The people in the most northern part of Europe had no money, nor had those of Asia, which extended most to the east, and those of Africa, at a distance from the Mediterranean. Weight should be the standard of the value of money; and many volumes have been written on the value of coins and their weight. The difficulties, however, have not been entirely cleared up, because the same terms have always been employed without regard to difference of time. In the code of Justinian complaints are made of the indefiniteness of these expressions in donations. The difficulty is increased by the difference of weight in the coins of different cities, and by our ignorance of the value of gold and silver compared with that of bronze at different periods. The coins preserved from antiquity are much more numerous than those which we possess from the period of the middle ages, in the proportion of 100 to one.

Medals are sometimes dug up singly, or in small numbers, where they appear to have been thrown by accident; but the principal stores are found in tombs, or in places where fear, avarice, or superstition had deposited them. Millin thinks that the number of extant medals from ancient times may amount to 70,000. Till the third century, the faces on medals were represented in profile. In the coins of the lower empire, on the contrary, we see Gothic front faces filling the whole field of medals. The moderns have employed both modes. The ancients gave more relief to the figure. The art of coining has flourished much in Spain. That country was deprived of the privilege of coining in the time of Caligula. The most ancient Spanish medals are of silver; their form is rude, the style of the design barbarous. The numerous cities which existed in ancient Gaul, before its conquest by the Romans, fabricated money of gold, silver, and copper. The execution of some of them is excellent, but the greatest part are barbarous. No medals are known of Britain, with the exception of some struck by some of the Augustuses, towards the decline of the Roman empire; and the same may be said of Germany. The medals of some of the Italian cities bear the character of Greek art, and are excellent. The medals of these cities are numerous, as the Romans permitted their inhabitants to coin money long after having subjected them. Greece and Asia Minor present many fine and curious medals. The coins of the kings of Macedon are the most ancient of any yet discovered bearing portraits; and Alexander I., who commenced his reign about 500 years B. C., is the earliest monarch whose medals have yet been found. Then succeed the sovereigns who reigned in Sicily, Caria, Cyprus, Heraclea, and Pontus. Afterwards comes the series of kings of Egypt, Syria, the Cimmerian Bosphorus, Thrace, Parthia, Armenia, Damascus, Cappadocia, Paphlagonia, Pergamos, Galatia, Cilicia, Sparta, Pæonia, Epirus, Illyricum, Gaul, and the Alps. This series reaches from the era of Alexander the Great to the Christian era, comprising a period of about 330 years. This must be accounted the third medallic series of ancient monarchs; and the fourth and last descends to the fourth century, including some of the kings of Thrace, of Bosphorus, and Parthia, with those of Comagene, Edessa, or Osrhoene, Mauritania, and Judea. A perfect and distinct series is formed by the Roman emperors, from Julius Cæsar to the Gothic destruction of the empire, and, indeed, still later. The Grecian medals claim that place in a cabinet, from their antiquity, which their workmanship might ensure to them independently of that adventitious consideration.

It is observed by Pinkerton that an immense number of the medals of cities, which, from their character, we must judge to be of the highest antiquity, have a surprising strength, beauty, and relief, in their impressions. About the time of Alexander the Great, however, this art appears to have attained its highest perfection. The coins of Alexander and his father exceed all that were ever executed, if we except those of Sicily, Magna Græcia, and the ancient ones of Asia Minor. Sicilian medals are famous for their workmanship, even from Gelo's time. The coins of the Syrian kings, successors to Alexander, almost equal his own in beauty. But adequate judges are constrained to confine their high praises of the Greek mint to those coins struck before the subjection of Greece to the Roman empire. The Roman coins, considered as medals in a cabinet, may be resolved into two great divisions, the consular and imperial. The consular coins seldom or never bore the names or titles of consuls till towards the close of the republic; nevertheless they are not improperly called *consular*, because they were struck in the consular times of Rome. These have also been denominated "coins of families," and are arranged according to the names inscribed on them. The brass consular coins are rather uninteresting, consisting chiefly of large, unwieldy pieces, with types of great similarity. Few of them have any imagery or symbol.

Gold was first coined at Rome, sixty-two years after the application of the mint to silver. The general gold coin is the *aureus*. The consular coins, whose number is estimated at 200 in brass and 2000 in silver, extend not to above 100 in gold, most of which are curious. The name of *imperial* medals is applied specifically to those struck after the conclusion of the republican era of Rome down to the fall of the Roman empire. Caius Julius Cæsar was the first Roman who obtained permission to put his figure upon medals. The triumvirs had each his set of medals. The medals struck after the death and apotheosis of Augustus bear the title *Divus Augustus*. With Constantine commences the series of medals of the emperors of the East or of Constantinople. The series of imperial medals concludes with those of Michael IX. The colonial medals had sometimes Greek, sometimes even Punic, legends; but those with Latin only are far more numerous. Some of these coins are elegant; but they are for the most part rude and uninteresting. They begin with Julius and

Antony, and occur only in brass. Most of the gold consular coins are of great beauty and high value. They are also very rare.

The coins of the middle ages embrace the *bracteates*, &c., which after the dissolution of the Roman empire were circulated in the newly-formed European states.

The science of numismatics seems to have been entirely unknown to the ancients. It does not appear from any ancient works that any value was set upon coins as curiosities by the collectors of works of art in the times of Augustus and the Antonines, though there were at that time series of coins of cities, some of which have come down to us, and attract attention on account of their antiquity and the beauty of their execution. Such are the coins of Sybaris and the cities of Magna Græcia, which, with their independence, lost the right of coinage. This disregard is more remarkable because gems, which are so nearly allied to them, were in high esteem; but in the fifteenth, and particularly in the middle of the sixteenth century, princes, and private individuals, in Italy, France, and Germany, rivalled each other in zeal for collecting these remains of antiquity, at first principally with a view of obtaining portraits of the chief characters of Roman history. Learned treatises soon succeeded these first collections, in which the chief attention had been paid to striking impressions.

The earliest treatise upon numismatics was published by a Spaniard, Antonio Agostino, in 1577, in his dialogues, which have been translated into all languages. Jac. and Octav. Strada, by works illustrated with plates, drew the attention of the great and the rich to this subject. Wolfgang Lazius, physician to Ferdinand I., made use of coins for the illustration of history. Fulvio Orsini, and Ad. Occo, a physician at Augsburg, applied themselves to the study of the Roman family and imperial coins: and it is to be regretted that the latter restricted himself so much in his enquiries; for his process, with respect to chronological arrangement, was confessedly good. Hub. Goltz, the son of a painter of Wurtzburg, is particularly worthy of mention, as the first who paid much attention to Grecian coins; but there is a want of accuracy in the writers of that period which renders a great part of their labours useless. Goltz was at once a draughtsman and an engraver, but suffered himself to introduce so much of his own invention into his engravings of coins that they are liable to suspicion in many cases where they may have been correct. Meanwhile the art of imitating the genuine antique coins began to be practised. At first, without any intention of deceiving, but merely to facilitate the study, the skilful die-cutters, Cavino, Belli, &c., at Padua, Parma, and Vicenza, made imitations of ancient coins; but these imitations were afterwards passed off for genuine, and soon became an article of trade, which has continued to this day.

The great number of counterfeit coins deterred many, during the period which now commenced, from the study of numismatics; at least it lessened the taste for this study, always difficult on account of the learned apparatus necessary; but the researches into separate departments of the science became more extensive, and the works of Vaillant, Spanheim, J. J. Gessner, Pellerin, not to mention numerous others, who have applied immense stores of learning to the illustration and explanation of numismatics, are well worthy of attention, though they are not to be implicitly trusted. The materials had now so much increased, by the accumulation of newly-discovered pieces (Vaillant visited the east several times; Pellerin added to the Parisian cabinet alone 33,000 ancient coins), that a critical selection and arrangement of the genuine became doubly necessary, in order to facilitate a general survey of them. Joseph Eckhel undertook this task with success, and, by a strict geographical and chronological method, introduced so much order into this science that great light was shed upon many obscure points of history and archæology. His system was first practically applied by himself to the arrangement of the cabinet at Vienna, and afterwards presented in an improved form in his great work, *Doctrina Numorum Veterum* (Vienna, 1792—98, 8 vols., 4to.), to which all later researches can only be considered as additions or improvements.

The coins of the middle ages, which have from time to time been brought to light, are now sought for with zeal. By pursuing the same method with the modern as with the ancient coins, arranging them in a strictly chronological order, they have been made to shed light upon subjects which manuscripts had left unexplained.

NUTATION of the axis of the earth. By a slight study of the *precession* of the *equinoxes* the reasons will be seen why the axis of the globe undergoes annually a change of position of about 50″, on account of the irregularity in the attractions of the sun and moon, occasioned by the spheroidal form of the earth. Of these 50″, 30″ are, on an average, referrible to the attraction of the moon. But she cannot produce this effect regularly, on account of her own change of position; and there result from these changes not only inequalities in the quantity of the precession of the equinoxes, but also a small motion or *nutation* in the axis of the earth, or in the plane of the equator, in consequence of which the stars appear sometimes to approach the equator, at other times to recede from it, varying from their mean place about 9½ seconds. This apparent change in the declination of the stars was first discovered by observation by Bradley, and the physical causes of it were explained by D'Alembert and others. It is obvious that a change in the position of the moon towards the earth must produce a change in the attraction of the moon upon the spheroidal part of the earth. Now this position is affected considerably by the change in the situation of the moon's nodes, which are subjected to an annual motion of about 18°, completing a revolution round the heavens in about eighteen or nineteen years. In consequence of this the position of the moon's orbit to the equator can vary 10°, and the change in the attraction of the moon on the spheroidal part of the earth, arising from this change of inclination, produces the nutation of 9½ seconds, the period of which is about eighteen or nineteen years. The precession and nutation alter the right ascensions, declinations, and longitudes of the heavenly bodies; the latitudes remain unchanged. D'Alembert (in his *Recherches sur la Précession des Equinoxes et sur la Nutation* (Paris, 1749, 4to.), and Laplace (*Mécanique Celeste*), have succeeded, by analysis, in reducing all these intricate phenomena to the law of gravity with the most complete success, and the corrections calculated thereupon, and contained in the astronomical tables, agree most perfectly with observations.

NUTMEG. The use of this fruit for culinary purposes is well known, as it has become an article of commerce in every part of the civilized world. With the East Indians it is likewise employed as a masticatory. It does not, however, appear to have been very anciently known, at least among Europeans; for the Greeks and Romans have left no account of it, and it is first mentioned by the early Arabian writers. The tree that produces it is a native of the Molucca islands, and is remarkable for the beauty of its foliage. It attains the height of about thirty feet, and the branches are disposed four or five together, almost in circles, forming a rounded and very dense summit. The fruit is a drupe, about as large as a peach, smooth externally, and yellow when it arrives at maturity: the outer envelope is fleshy, and opens at the summit into two valves, disclosing the scarlet mace, which forms the second envelope: the mace is a fleshy fibrous membrane, having a reticulated appearance, which turns yellow with age, and becomes brittle when dry; the third envelope is thin, hard, and blackish-brown; the nut, or, more properly, kernel, consists of a very firm, white, oily substance, penetrated with numerous irregular branching veins. The tree constantly bears flowers and fruits of all ages, and its leaves fall so insensibly that the loss is not perceived. About nine months are required to bring the fruit to maturity. Mace is very commonly employed as a culinary spice, and resembles the nutmeg in taste and odour, but is more pungent and bitter.

For a long time, the Dutch had the monopoly of the commerce in nutmegs; but, about the year 1770, it was introduced into the Isle of France, and thence passed into Surinam, the West Indies, and other parts of tropical America. During the last year, rather more than 250,000 lbs. of nutmegs were imported into this country, of which only 160,000 lbs. were retained for home consumption, and the rest exported.

NUTRITION; the process by which living creatures repair the loss which attrition and other causes are continually making in the animal frame. In young persons the nutritive juices not only serve to repair the waste, but also to supply the new materials essential to the growth of the individual.

Buffon, in order to account for nutrition, supposes the body of an animal or vegetable to be a kind of mould, in which the matter necessary to its nutrition is modelled and assimilated to the whole. But (continues he) of what nature is this matter which an animal or vegetable assimilates to its own substance? What power is it that communicates to this matter the activity and motion necessary to penetrate this mould? and, if such a force exist, must it not be by the same force that the internal mould itself is reproduced?

As to the first question, he supposes that there exists in nature an infinite number of living organical parts, and that all organized bodies consist of such organical parts; that their production costs nature nothing, since their existence is constant and invariable; so that the matter which the animal or vegetable assimilates to its substance is an organical matter of the same nature with that of the animal or vegetable, which consequently may augment its volume without changing its form or altering the quality of the substance in the mould.

As to the second question, "there exist," says he, "in nature certain powers, as that of gravity, that have no affinity with the external qualities of the body, but act upon the most intimate parts, and penetrate them throughout, and which can never fall under the observation of our senses."

And, as to the third question, he answers that "the internal mould itself is reproduced, not only by a similar power, but it is plain that it is the very same power that causes the unfolding and reproduction thereof; for it is sufficient," proceeds he, "that in an organized body that unfolds itself there be some part similar to the whole, in order that this part may one day become itself an organized body, altogether like that of which it is actually a part."

We may next examine the practical part of this subject, and show the comparative nutritive properties of different species of food, and the effects of cookery in increasing or diminishing its power of sustaining animal life.

Dr. Paris thus compares the relative advantages of an *animal* and *vegetable* diet with reference to nutrition. "As every description of food," says he, "whether derived from the animal or vegetable kingdom, is converted into blood, it may be inferred that the ultimate effects of all aliments must be the same, and that the several species can differ from each other only in the quantity of nutriment they afford, in the comparative degree of stimulus they impart to the organs through which they pass, and in the proportion of vital energy they require for their assimilation. Were the degree of excitement which attends the digestion of a meal commensurate with the labour imposed upon the organs which perform it, less irritation and heat would attend the digestion of animal than of vegetable food; for, in the one case, the aliment already possesses a composition analogous to that of the structure which it is designed to supply, and requires little more than division and depuration; whereas, in the other, a complicated series of decompositions and recompositions must be effected before the matter can be animalized or assimilated to the body. But the digestive fever, if we may be allowed the use of that expression, and the complexity of the alimentary changes, would appear in every case to bear an inverse relation to each other. This must depend upon the fact of animal food affording a more highly animalized chyle, or a greater proportion of that principle which is essentially nutritive, as well as upon the immediate stimulus which the alimentary nerves receive from its contact. In hot countries therefore, or during the heats of summer, we are instinctively led to prefer vegetable food, and we accordingly find that the inhabitants of tropical climates select a diet of this description. The Brahmins in India, and the people of the Canary Islands, Brasils, &c., live almost entirely on herbage, grains, and roots; while those of the north use little besides animal food.' On account of the superior nutritive powers of animal matter, it is equally evident that the degree of bodily exertion or exercise sustained by a person should not be overlooked in an attempt to adjust the proportion in which animal and vegetable food should be mixed. Persons of sedentary habits are oppressed and ultimately become diseased from the excess of nutriment which a full diet of animal food occasions: such a condition, by some process not understood, is best corrected by acescent vegetables. It is well known that artisans and labourers in the confined manufactories of large towns suffer considerably in their health whenever a

failure occurs in the crops of common fruits; this fact was remarkably striking in the years 1804 and 1805. Young children and growing youths generally thrive upon a generous diet of animal food; the excess of nutritive matter is consumed in the developement of the body, and, if properly digested, imparts strength without repletion. Adults and old persons comparatively require but a small proportion of aliment, unless the nutritive movement be accelerated by violent exercise and hard labour.

Those who advocate the exclusive value of animal food, and deny the utility of its admixture with vegetable matter, adduce in proof of their system the rude health and Herculean strength of our hardy ancestors. The British aborigines, when first visited by the Romans, certainly do not appear to have been conversant with the cultivation of the ground; and according to the early writers, Cæsar, Strabo, Diodorus Siculus, and others, their principal subsistence was on flesh and milk; but, before any valid conclusion can be deduced from this circumstance, the habits of the people must be compared with those of their descendants. The history of later times will furnish us with a satisfactory answer to those who deny the necessity of vegetable aliment. We learn from the *London Bills of Mortality* that scurvy raged to such an excess in the sixteenth century as to have occasioned considerable ravages; at this period the art of gardening had not long been introduced. It appears that the most common articles of the kitchen garden, such as cabbages, were not cultivated in England until the reign of Henry VIII.; indeed, we are told that his queen, Catherine of Arragon, could not procure a salad until a gardener was sent for from the Netherlands to raise it. Since the change thus happily introduced into our diet, the ravages of the scurvy are unknown. It follows, then, that in our climate a diet of animal food cannot, with safety, be exclusively employed. It is too highly stimulant; the springs of life are urged on too fast; and disease necessarily follows. There may, nevertheless, exist certain states of the system which require such a preternatural stimulus; and the physician may, therefore, confine his patient to an animal regimen with as much propriety as he would prescribe opium, or any other remedy. By a parity of reasoning, the exclusive use of vegetable food may be shown to be inconsistent with the acknowledged principles of dietetics, and to be incapable of conveying a nourishment sufficiently stimulating for the active exertions which belong to our present civilized condition. At the same time it must be allowed that an adherence to vegetable diet is usually productive of far less evil than that which follows the use of an exclusively animal regimen.

Dr. Paris quotes some curious experiments made by M. Majendie to ascertain the relative quantities of azote (nitrogen) yielded by animal and vegetable food. He took a small dog of three year's old, fat, and in good health, and put it to feed upon sugar alone, and gave it distilled water to drink: it had as much as it chose of both. It appeared very well in this way of living for the first seven or eight days; it was brisk, active, ate eagerly, and drank in its usual manner. In the second week it began to get thin, although its appetite continued good, and it took about six or eight ounces of sugar in twenty-four hours. Its alvine excretions were neither frequent nor copious; that of the urine was very abundant. In the third week its leanness increased, its strength diminished, the animal lost its liveliness, and its appetite declined. At this period there was developed upon one eye, and then on the other, as mall ulceration on the centre of the transparent cornea; it increased very quickly, and in a few days it was more than a line in diameter; its depth increased in the same proportion; the cornea was very soon entirely perforated, and the humours of the eye ran out. This singular phenomenon was accompanied with an abundant secretion of the glands of the eyelids. It, however, became weaker and weaker, was unable to stand, and, though the animal ate from three to four ounces of sugar per day, it became so weak that it could neither chew nor swallow: for the same reason every other motion was impossible. It expired the thirty-second day of the experiment. M. Majendie opened the animal with every possible precaution. He found a total want of fat; the muscles were reduced more than five-sixths of their ordinary size; the stomach and intestines were also much diminished in volume, and strongly contracted. The gall and urinary bladders were distended by their proper fluids, which M. Chevreul was called upon to examine. That distinguished chemist found in them nearly all the characters which belong to the urine and bile of herbivorous animals; that is, that the urine instead of being acid, as it is in carnivorous animals, was sensibly alkaline, and did not present any trace of uric acid, nor of phosphate. The bile contained a considerable portion of picromel, a character considered as peculiar to the bile of the ox, and, in general, to that of herbivorous animals. The excrements were also examined by M. Chevreul, and were found to contain very little azote, whereas they usually furnish a considerable quantity.

M. Majendie considered that such results required to be verified by new experiments: he accordingly repeated them on other dogs, but always with the same conclusions. He therefore considered it proved that sugar, by itself, is incapable of supporting dogs. He afterwards proceeded to enquire whether other substances, nonazotised, but generally considered as nutritive, would be attended with the same consequences, which was found to be the fact.

The character and amount of cookery which food undergoes materially affects its nutritive properties, and we cannot do better than quote Dr. Paris's observations on this branch of our subject. "By *cookery*," he says, "alimentary substances undergo a two-fold change; their principles are chemically modified, and their textures mechanically changed. The extent and nature, however, of these changes, will greatly depend on the manner in which heat has been applied to them; and, if we enquire into the culinary history of different countries, we shall trace its connexion with the fuel most accessible to them. This fact readily explains the prevalence of the peculiar species of cookery which distinguishes the French table, and which has no reference, as some have imagined, to the dietetic theory, or superior refinement, of the inhabitants."

By boiling, according to this author, the principles not properly soluble are rendered softer, more pulpy, and consequently easier of digestion; but the meat, at the same time, is deprived of some of its nutritive properties by the removal of a portion of its soluble constituents. The albumen and

gelatine are also acted upon, the former being solidified and the latter converted into a gelatinous substance. If, therefore, our meat be boiled too long or too fast, we shall obtain, where the albumen predominates (as in beef), a hard and indigestible mass, like an over-boiled egg; or where the gelatine predominates, as in young meats, such as veal, a gelatinous substance equally injurious to the digestive organs.

Young and viscid food, therefore, as veal, chickens, &c., is more wholesome when roasted than when boiled, and is easily digested. Dr. Prout has very justly remarked that the boiling temperature is too high for a great many of the processes of cookery, and that a lower temperature and a greater time, or a species of infusion, are better adapted for most of them. This is notorious with substances intended to be stewed, which, even in the cookery books, are directed to be boiled slowly (that is, not at all), and for a considerable time. The ignorance and prejudice existing on these points is very great, and combated with great difficulty; yet, when we take into account their importance, and how intimately they are connected with health, they will be found to deserve no small share of our attention. The loss occasioned by boiling partly depends upon the melting of the fat, but chiefly on the solution of the gelatine and osmazone: mutton generally loses about one-fifth, and beef about one-fourth, of its original weight. Boiling is particularly applicable to vegetables, rendering them more soluble in the stomach, and depriving them of a considerable quantity of air, so injurious to weak stomachs. But, even in this case, the operation may be carried to an injurious extent; thus, potatoes are frequently boiled to a dry insipid powder, instead of being preserved in that state in which the parts of which they are composed are rendered soft and gelatinous, so as to retain their shape, yet be very easily separated. On the other hand, the cabbage tribe, and carrots, are frequently not boiled long enough, in which state they are highly indigestible. In conducting this process, it is necessary to pay some attention to the quality of the water employed; thus, mutton boiled in hard water is more tender and juicy than when soft water is used; while vegetables, on the contrary, are rendered harder and less digestible when boiled in hard water.

By *roasting*, the fibrin is corrugated, the albumen coagulated, and the fat liquefied. As the operation proceeds, the surface becomes first brown and then scorched; and the tendinous parts are rendered soft and gluey. Care should always be taken that the meat be not overdone: nor ought it to be under-dressed; for, although in such a state it may contain more nutriment, yet it will be less digestible, on account of the density of its texture. This fact has been satisfactorily proved by the experiments of Spallanzani; and Mr. Hunter observes "that boiled, and roasted, and even putrid meat, are easier of digestion than raw." Animal matter loses more by roasting than by boiling: it has been stated above that in this latter process mutton loses one-fifth, and beef one-fourth; but, by roasting, these meats lose about one-third of their weight. In roasting, the loss arises from the melting out of the fat, and the evaporating of the water; but the nutritious matter remains condensed in the cooked solid; whereas, in boiling, the gelatine is partly abstracted. Roast meats are, therefore, more nutritive than boiled.

A memoir presented to the French Academy, by M. Donné, having thrown some doubts upon the wholesomeness of gelatine, M. Darcet made the following summary:—Butchers' meat contains per 100 lbs. at a medium:

Dry meat	24
Water	64
Bones	15
Total	103

Bones contain per 100:

Earthy matter	60
Gelatine	30
Fat	10
	100

Thus the fifteen parts of bones in butchers' meat may furnish six parts of pure animal substance, and therefore 100 lbs of meat, which commonly yield but twenty-four of alimentary matter, may furnish thirty pounds, if care be taken to extract the whole. It is obvious, therefore, that four head of cattle may supply as much nutriment as is now obtained by five. (See PAPIN'S DIGESTER.)

NUX VOMICA, a flat, compressed, round, and poisonous fruit, about the breadth of a shilling, brought from the East Indies. Its surface is not much corrugated; and its texture is firm like horn, and of a pale greyish-brown colour. It is said to be used as a specific against the bite of a species of water-snake. It is considerably bitter, and has been used in doses from five to ten grains twice a day or so, in intermittents, particularly quartans, and in contagious dysentery. The *strychnus Ignatii* is a tree of the same kind, producing a guard-like fruit, the seeds of which are improperly called St. Ignatius's beans. These, as also the woods or roots of some such trees, called *lignum colubrinum*, or snakewood, are very narcotic bitters, like the *nux vomica*.

NYCTALOPIA; an affection of the sight, in which the patient is blind in the daylight, but sees very well at night.

With respect to the causes of the complaint, Dr. Hillary observes that it proceeds from too great a tenderness and sensibility of the iris and retina. M. Lassus thinks the causes may be of different kinds. For instance, he says that if there were a small opacity, like a point, exactly opposite the pupil or centre of the crystalline lens, the pupil, contracting in the open daylight, would stop the entrance of the rays of light into the eye, and a day blindness arise, which would be diminished by the expansion of the pupil in the shade. Here, the cure would depend upon the removal of the opacity.

Persons whose pupils do not move freely, but remain much dilated, and do not sufficiently contract in light situations, are also affected with nyctalopia; for so large a quantity of the rays of light pass into their eyes that it serves rather to destroy than assist vision. Such persons see tolerably well, and better than the preceding class of patients, in a darkish place, and they ought to wear green spectacles in the day-time, in order to weaken the impression of the rays of light. When a person is shut up a long while in a dark place, the pupils become habitually dilated, and, if he expose himself suddenly and incautiously to a strong light, the eyesight may be destroyed. This is more particularly the case when experiments with the oxy-hydrogen blow-pipe are made.

OAK.—This tree is valuable both for its timber and the application of its bark to the useful arts. The oak grows wild in Britain, and flowers in April. The superior excellence of its wood for ship-building has rendered its cultivation an object of national concern. Duhamel made a series of experiments to ascertain the strength of oak wood. He placed a piece of oak, 9.6 inches deep, 10.6 inches in breadth, upon two supports 24½ inches apart; when a weight of 8193 lbs. was suspended to the middle, it was bent in the middle 3.7 inches. The piece broke with a weight of 9613 lbs., when it was found to have been faulty.

Another piece of oak, but sound, 12.2 inches deep, 10.6 inches thick, and placed on supports at the same distance apart as at the first trial, with a weight of 8193 lbs., bent 2.6 inches, and broke with a weight of 19,666 lbs. which was placed in the middle.

A piece of sound oak, 13.8 inches deep, 12.8 inches thick, and placed on supports 24½ feet apart, was bent one inch in the middle with a weight of 8198 lbs.

A piece of English oak 7 feet long, 2 inches broad, and 2 inches deep, bent 1.27 inches with a weight of 200 lbs.

A piece of Canadian oak of the same dimensions bent 1.07 inch with a weight of 225 lbs.

A piece of old ship timber, 2½ feet long, 1 inch broad, and 1 inch deep, bent ½ inch with a weight of 127 lbs.

The oak bark is a material much used in tanning. It was formerly thought to be extremely useful in vegetation. One load of oak bark, laid in a heap and rotted, after the tanners have used it for dressing of leather, will do more service to stiffen cold land (says Mr. Mills, in his treatise on husbandry) than two loads of the richest dung; but this has been controverted.

M. Vauquelin discovered a remarkable chemical difference between the bark and nut-galls, the latter precipitating tartrate of antimony and infusion of cinchona, which are not acted on by the former. Oak bark is a strong astringent, and is recommended in hæmorrhages, alvine fluxes, and other preternatural or immoderate secretions. In these it is sometimes attended with good effects. But it is by no means capable of being employed as a substitute, in every instance, for Peruvian bark, as some have asserted; and, indeed, it is so difficultly reduced to a sufficiently fine powder, that it can scarcely be given internally, in substance.

Olivier has, in his *Travels in the Ottoman Empire*, given us an accurate botanical description of the oak which produces the gall-nut, and which, he says, was till then unknown to botanists. It is scattered through all Asia Minor, from the Bosphorus to Syria, and from the shore of the Archipelago to the frontiers of Persia. It has a crooked stem, and seldom reaches the height of six feet. It oftener has the appearance of a shrub than of a small tree. The gall-nuts come at the shoots of the young bough, and are produced by the puncture of *diplolepis gallæ tinctoriæ* to deposit an egg. They acquire from four to twelve lines in diameter, and are generally round and covered with tuberosities. They are in perfection when they have acquired their full size and weight, but before the insect has pierced them, after which they get a brighter colour and lose some of their weight. The galls first picked are laid apart, and are known under the name of *yorli*, and in commerce are called black and green galls. Those gathered later are called white galls, and are very inferior in value. In commerce they occur of different sizes, smooth or knotty on the surface, of a whitish, reddish, or blackish colour, and generally penetrated with a small hole. Internally they consist of a spongy, but hard, more or less brown substance, and they have a very rough astringent taste. The best galls are of a blackish-grey, or yellow colour, heavy, and tuberculated on the surface. Neumann got from 960 grains of coarsely powdered galls 840 watery extract, and afterwards only 4 alcoholic; and, inversely, 760 alcoholic, and 80 watery. But the most minute analysis is that of Sir H. Davy, who found that 500 grains of good Aleppo galls gave, by lixiviating them until their soluble matters were taken up, and evaporating the solution slowly, 185 grains of solid matter, which, when examined by analysis, appeared to consist of,

Tannin	130
Mucilage, and matter rendered insoluble by evaporation	12
Gallic acid, and a little extractive matter	31
Remainder, calcareous earth and saline matter	12

From some experiments by Dr. Duncan, he is disposed to think that Sir H. Davy has under-rated the tannin of nut-galls; for, by simple repeated infusions in hot water, the residuum of 500 grains in one experiment amounted only to 158, and in another only to 136 grains. The quantity of tannin estimated in Sir H. Davy's way amounted in the first to 220 grains, and in the second to 256. The great difference in these results from Sir H. Davy's must be ascribed to some differences in the galls themselves, or in the mode of operation. A saturated decoction of galls, on cooling, deposits a copious pale yellow precipitate, which seems to be purer tannin than what can be got by any other process; but it still requires and deserves a more minute examination. In Dr. Duncan's experiments, a very weak infusion of nut-galls was precipitated by sulphuric acid, lime-water, sub-carbonate of potass, acetate of lead, sulphate of copper, nitrate of silver, sulphate of iron, tartrate of antimony, nitrate of mercury, infusion of officinal cinchona, and solution of gelatine; it was not precipitated by nitrous acid, ammonia, sulphate of zinc, muriate of mercury, infusion of quassia, or infusion of saffron. To what principles these precipitates are owing remains still to be ascertained. Vauquelin justly observes that the infusion of nut-galls and of cinchona agree in precipitating both gelatine and tartrate of antimony, but that they precipitate each other. Another fact, equally curious, occurred: a mutually saturated mixture of the infusions of nut-galls and cinchona still precipitates gelatine; but these infusions, separately saturated by gelatine, do not act on each other. Hence it appears that the action of these infusions on each other depends on principles contained in each, compatible with the presence of tannin, but re-acting on each other, and that gelatine precipitates these principles along with the tannin. Sir H. Davy has concluded that tannin and gelatine unite in fixed proportions, viz. 46 of tannin with 54 gelatine: were this correct, it would very much facilitate the analysis of astringents. A twelve hours' infusion of 500

grains of nut-galls in twelve ounces of water, precipitated successively with equal quantities of solution of gelatine, containing each twenty-four grains, gave precipitates weighing 98, 64, 48, and 36 grains: hence, if we suppose the whole gelatine used to be contained in each precipitate, these consisted of 24 grains of gelatine, and 74, 40, 24, and 12 grains of tannin: so that, from the weight of the precipitate alone, we cannot estimate the tannin. Dr. Bostock drew the same conclusions from a set of experiments which he made. It has been generally asserted that the precipitate of tannin and gelatine is insoluble in water, either cold or hot; but Dr. Duncan found that in boiling water it not only became soft and viscid, but a certain portion was dissolved, which separated again when the solution cooled.

Oakum; the substance into which old ropes are reduced when they are untwisted, loosened, and drawn asunder. It is principally used in calking the seams, tree-nails and bends of a ship, for stopping or preventing leaks.

Oar; a long piece of timber, flat at one end, and round or square at the other, used to make a vessel advance upon the water. The flat part, which is dipped into the water, is called the *blade*, and that which is within the board is termed the *loom*, whose extremity, being small enough to be grasped by the rowers, is called the *handle*. To push the boat or vessel forwards by means of this instrument, the rowers turn their backs forwards, and, dipping the blade of the oar in the water, pull the handle forward, so that the blade, at the same time, may move aft in the water. But, since the blade cannot be so moved without striking the water, this impulsion is the same as if the water were to strike the blade from the stern towards the head: the vessel is therefore necessarily moved according to the direction. Hence it follows that she will advance with the greater rapidity, by as much as the oar strikes the water more forcibly; consequently, an oar acts upon the side of a boat or vessel like a lever of the second class, whose fulcrum is the station upon which the oar rests on the boat's gunwale.

Oat.—The meal of this grain is nutritious, and in some countries forms an important article of food; but the bread made of it is rather indifferent in quality, and somewhat bitter. Beer is made from this grain in Poland; and it is, besides, distilled to procure ardent spirits. Oats are the best food for horses, and for this purpose are principally cultivated. They are also recommended as a good winter fodder for sheep, a handful to be given daily.

Obelisk, in *architecture*; a truncated, quadrangular, and slender pyramid. Obelisks are of very great antiquity, and appear to have been first raised to transmit to posterity precepts of philosophy, which were cut in hieroglyphical characters; afterwards they were used to immortalise the great actions of heroes, and the memory of eminent persons. The first obelisk mentioned in history was that of Ramasus king of Egypt, in the time of the Trojan war, which was forty cubits high. Phius, another king of Egypt, raised one of fifty-five cubits; and Ptolemy Philadelphus another of eighty-eight cubits, in memory of Arsinoë. Augustus erected one at Rome in the Campus Martius, which served to mark the hours of an horizontal dial drawn on the pavement. They were called by the Egyptian priests the fingers of the sun, because they were made in Egypt also to serve as styles or gnomons to mark the hours on the ground. The Arabs still call them Pharaoh's needles; whence the Italian *agvglia*, and the French *aiguilles*. One of the most common and frequent situations in which obelisks were erected was the space before a temple. At Luxor are still to be found two very fine obelisks: they are shown in the accompanying view.

These obelisks are about 100 feet in height, and are each composed of a single block of granite, from the quarries of Elephantine.

The Romans, in the plenitude of their power and splendour, removed many of these relics from their original situations into Italy. When that majestic empire was over-run by the barbarians most of these noble monuments were thrown down, defaced, or demolished. The exhumations made by the decree of pope Sextus V. brought to light four of them, which were repaired by his architect, Fontana. Since that period several others have been dug up. Several obelisks have likewise been preserved at Constantinople, the most celebrated of which stood in that part of the hippodrome denominated Media Spina. On the four sides of the base of this noble monument were sculptured a variety of subjects; the bassi-relievi of the northern side have been published by Spon. At Catana, in Sicily, fragments have been discovered of two Egyptian obelisks, most probably conveyed thither by the Romans. One has been set up again, presenting a curious appearance, from its having eight faces.

On the north side of Penrith, in Cumberland, in the church-yard, are two square obelisks of a single stone each, eleven or twelve feet high, about twelve inches diameter, and twelve by eight at the sides; the highest about eighteen inches diameter, with something like a transverse piece, and mortised into a round base. They are fourteen feet asunder, and between them is a grave enclosed between four semicircular stones of the unequal lengths of five, six, four and a half, and two feet high, having on the outsides rude carving, and the tops notched. This is called the Giant's Grave, and ascribed to Sir Ewan

Cæsarius, who is said to have been as tall as one of the columns, and capable of stretching his arms from one to the other.

Object-Glass. See Telescope.

Oblate (flattened or shortened); having its axis shorter than its middle diameter, being formed by the rotation of an ellipse about the shorter axis. The earth is an oblate spheroid, the polar diameter being shorter than the equatorial diameter in the proportion of 331 to 332; i. e. the polar diameter is 7898 miles, and the equatorial diameter 7924 miles.

Obligato, in *music*, is used of those voices or instruments which are indispensable to the just performance of a piece. An instrument may be *obligato* throughout a piece, in which case the piece is called a *concerto* for such an instrument; or an instrument may become now and then *obligato*, when these passages are called *obligato* or *solo* passages. All instruments can be used *obligato*, except, perhaps, the double bass: this is excepted partly because solo players are very rare on this instrument, partly because the solo voice would be too deep for being duly supported by other instruments; it is therefore used more properly for the basis of harmony. There are some musicians, however, who play solos on the double bass.

Obolus; a Grecian coin of silver or copper, the sixth part of a drachm, about 10⅓ pence in value. In early times, instead of money, were used little pointed pieces of iron or of copper. Six of these filled the hand, and made a drachm. The same name was afterwards given to a small silver coin. The Greeks placed an obolus in the mouth of the dead, to pay Charon for their passage over the Styx. In weight, the obolus is likewise the sixth part of a drachm; the latter coin, however, is not always of the same value.

Observatory; a place destined for observing the heavenly bodies, being generally a building erected on some eminence, covered with a terrace for making astronomical observations. The more celebrated observatories are—

The *Greenwich* observatory, built in 1676, by order of Charles II., at the solicitation of Sir Jonas Moore and Sir Christopher Wren; and furnished with the most accurate instruments.

Tycho Brahe's observatory, in the little island Ween, or Scarlet Island, between the coasts of Schonen and Zealand in the Baltic. It was erected and furnished with instruments at his own expense, and called by him *Uraniburg*. Here he spent twenty years in observing the stars: the result is his catalogue.

Father Le Compte describes a very magnificent observatory, erected and furnished by the emperor of *China*, in his capital, at the intercession of some Jesuit missionaries, principally father Verbeist, whom he made his chief observer. The instruments are exceedingly large; but the mode of division is less accurate, and the contrivance in some respects less commodious, than that of the Europeans. The chief are, an armillary zodiacal sphere of six feet diameter; an equinoctial sphere of six feet diameter; an azimuthal horizon of six feet diameter; a large quadrant six feet radius; a sextant eight feet radius; and a celestial globe six feet diameter.

The following interesting account of the observatory at *Benares* is taken from a paper in the sixty-seventh volume of the Philosophical Transactions by Sir Robert Barker. "We entered this building," says Sir Robert Barker, "and went up a staircase to the top of a part of it, near the river Ganges, that led to a large terrace, where, to my surprise and satisfaction, I saw a number of instruments yet remaining in the best preservation, stupendously large, immovable from the spot, and built of stone, some of them being upwards of twenty feet in height; and, though they are said to have been erected 200 years before, the gradations and divisions on the several arcs appeared as well cut, and as accurately divided, as if they had been the performance of a modern artist. The execution in the construction of these instruments exhibited a mathematical exactness in the fixing, bearing, and fitting of the several parts, in the necessary and sufficient supports to the very large stones that compose them, and in joining and fastening them into each other by means of lead and iron cramps. The situation of the two large quadrants, whose radius is nine feet two inches, by being at right angles with a gnomon at 25° elevation, are thrown into such an oblique situation as to render them the most difficult, not only to construct of such a magnitude, but to secure in the position for so long a period, and affords a striking instance of the ability of the architect in their construction; for, by the shadow of the gnomon thrown on the quadrants, they do not appear to have altered in the least from their original position; and so true is the line of the gnomon that by applying the eye to a small iron ring, of an inch diameter, at one end, the sight is carried through three others of the same dimensions to the extremity at the other end, distant thirty-eight feet eight inches, without obstruction; such is the firmness and art with which this instrument has been executed. This performance is the more extraordinary when compared with the works of the artificers of Hindostan of this day who are not under the immediate direction of a European mechanic; but arts appear to have declined equally with science in the east.

"Lieutenant Colonel Archibald Campbell, at that time (1777) chief engineer in the East India Company's service at Bengal, a gentleman whose abilities do honour to his profession, made a perspective drawing of the whole apparatus that could be brought within his eye at one view; but I lament he could not represent some very large quadrants, whose radii were about twenty feet, being on the side whence he took his drawing. Their description, however, is that they are exact quarters of circles of different radii, the largest of which I judged to be twenty feet, constructed very exactly on the sides of stone walls built perpendicular, and situated, I suppose, in the meridian of the place: a brass pin is fixed at the centre or angle of the quadrant, from which the brahmin informed me they stretched a wire to the circumference when an observation was to be made; from which it occurred to me that the observer must have moved his eye up or down the circumference by means of a ladder or some such contrivance to raise or lower himself, till he had discovered the altitude of any of the heavenly bodies in their passage over the meridian, so expressed on the arcs of these quadrants; these arcs were very exactly divided into nine large sections; each of these again into ten, making ninety divisions or degrees; and those also into twenty, expressing three minutes each, of about two-tenths of an inch asunder; so that it is probable they had some method of dividing even these into more minute divisions at the time of observation.

"My time would only permit me to take down

the particular dimensions of the most capital instrument, or the greater equinoctial sun-dial, which appears to be an instrument to express solar time by the shadow of a gnomon on two quadrants, one situated to the east and the other to the west of it; and indeed the chief part of their instruments at this place appear to be constructed for the same purpose, except the quadrants, and a brass instrument described hereafter. There is another instrument for the purpose of determining the exact hour of the day by the shadow of a gnomon, which stands perpendicular to, and in the centre of, a flat circular stone, supported in an oblique situation by means of four upright stones and a cross-piece; so that the shadow of the gnomon, which is a perpendicular iron rod, is thrown on the divisions of the circle described on the face of the flat circular stone. There is also a brass circle, about two feet diameter, moving vertically on two pivots between two stone pillars, having an index or hand turning round horizontally on the centre of this circle. This instrument appears to be made for taking the angle of a star at setting or rising, or for taking the azimuth or amplitude of the sun at rising or setting. The use of another instrument I was at a loss to guess. It consists of two circular walls, the outer of which is about forty feet in diameter and eight feet high; the wall within is about half that height, and appears intended for a place to stand in to observe the divisions on the upper circle of the outer wall, rather than for any other purpose; it is divided into 360 degrees, each degree being subdivided into twenty small divisions, the same as the quadrants. There is a door-way to pass into the inner circle, and a pillar in the centre of the same height with the lower circle, having a hole in it, in the centre of both circles, which seems to be a socket for an iron rod to be placed perpendicularly in it. The divisions on these, as well as all the other instruments, will bear a nice examination with a pair of compasses. There is also a smaller equinoctial sun-dial, constructed on the same principle as the large one. This observatory at Benares is said to have been built by the order of the emperor Ackbar; for, as this wise prince endeavoured to improve the arts, so he wished also to recover the sciences of Hindostan, and therefore directed that three such places should be erected, one at Delhi, another at Agra, and the third at Benares. Some doubts have arisen with regard to the certainty of the ancient Brahmins having a knowledge in astronomy, and whether the Persians might not have introduced it into Hindostan when conquered by that people; but these doubts, I think, must vanish when we know that the present Brahmins pronounce, from the records and tables which have been handed to them by their forefathers, the approach of the eclipses of the sun and moon, and regularly as they advance give timely information to the emperor and the princes in whose dominions they reside."

The *Paris* royal observatory was begun in 1667, and finished in 1672. It is 160 feet in front length, 120 broad, and ninety feet high, having a terrace at top, and cellars underneath ninety feet deep. There is said to be neither iron nor wood employed in its construction. Here was not long since an old thermometer of M. de la Hire, which stood always at the same height. The mural quadrant used by La Lande here has been, in imitation of that of Tycho Brahe, transferred to the heavens as a constellation situated between Hercules, Bootes, and the Serpent, as the quadrans muralis, containing forty stars. New rooms and vaults have been added to this building since 1788, as well as a large transit instrument and circle by Ramsden; and three observers were established here by the unfortunate Louis XVI. On the first floor of the west tower is a geographical chart, twenty-seven feet in diameter, traced under the direction of Cassini. The difference in longitude between this and the Greenwich observatory is 2°, 20′, 15″. There are now two fine observatories in Paris.

The *St. Petersburg* observatory, which is one of the most magnificent and well-furnished in Europe, was an erection of the czar Peter I. shortly after his visit to England. It has three stories, and is 130 feet high. M. de l'Isle, according to La Lande, has made a number of excellent observations here. The celebrated observatory at Dublin is described in our article ASTRONOMY.

OCEAN; the great mass of waters which surrounds the land, and which probably extends from pole to pole, covering nearly three quarters of the globe. For the sake of convenience we distinguish different parts of it under the names of *seas, bays, gulfs, sounds*, and even give the name of *ocean* to large portions which are partially divided from each other by the continents; but these divisions are arbitrary. The following classification, adopted by Malte-Brun in his *System of Geopraphy*, has at least the advantage of showing in a striking manner the connection which exists between the great masses of water :—

A. Great Austro-Oriental or South-Eastern Basin.	1. Austral Ocean, or Southern Frozen Ocean (Antarctic Ocean).	Its limits are a line drawn from Cape Horn to the Cape of Good Hope, by Van Diemen's Land, and the south of New Zealand, back to Cape Horn.
	2. Oriental or Pacific Ocean.	*a.* The Great Archipelago (*Oceanica*), comprised between the Austral Ocean, the Marquesas, the Straits of Malacca, and the latitude of Formosa. *b.* The Northern Oriental Ocean, between Asia and North America. *c.* Southern Oriental Ocean, between the Great Archipelago and South America.
	3. Indian Ocean.	
B. The Western Basin, forming a sort of channel between the two continents.	4. Western Ocean.	*a.* Northern Ocean or Frozen Ocean (Arctic Ocean). *b.* Atlantic Ocean, lying between Europe and North America, and extending south to the nearest points of Brazil and Guinea. *c.* The Ethiopic Ocean, between the Atlantic and Austral Oceans.

For a more particular description of the different geographical divisions of the ocean, see the SECOND DIVISION of this work.

It has been calculated that the land of the northern hemisphere is to the sea of the same as 419 to 1000; in the southern hemisphere the proportion is as 129 to 1000. To account for this great disproportion, it has been conjectured that there is a great southern continent surrounding the south pole, but the voyages of navigators have not revealed the existence of such an extent of land. The bed of the ocean presents the same irregularities of aspect as the surface of the land. It is diversified by rocks, mountains, plains, and deep valleys. In some places it has been found impossible to reach the bottom, but the notion that it is any where without a bottom is incompatible with the spherical figure of the earth. The mean depth of the ocean has been shown by Laplace to be about the same as the mean height of the continents and islands above its surface, which does not much exceed 3000 feet. This distance is but a small fraction of the excess of the equatorial over the polar radius, which is about 60,000 feet. The greatest depth that has ever been sounded is 7200 feet (by Scoresby, in 1819). But it is probable that there are deep cavities or valleys in the bed of the ocean corresponding to the elevation of the mountains on the surface of the earth.

A variety of contrivances have been resorted to for the purpose of ascertaining the depth of the sea at a distance from land, and in those situations in which the common lead-line cannot be employed.

The ingenious Dr. Hales, in his *Vegetable Statics* proposed a method of measuring what he termed the *unfathomable depths* of the sea, on the principles by which Dr. Desaguliers contrived an instrument called a sea-gauge, which was tried before the Royal Society, and is described in the *Philosophical Transactions*, No. 405. A more particular description of this instrument by Dr. Hales himself is as follows :—

Suppose an iron tube, or musket barrel, of any length, as fifty inches, having its upper end well closed; if this tube be let down in this position about thirty-three feet into the sea, a column of water of that height is nearly equal to the mean weight of our atmosphere, and consequently, from a known property of the air's elasticity, it will be compressed into half the space it took up before, so that the water will ascend half-way up the tube: and, if the tube be let down thirty-three feet deeper, the air will be compressed into one-third of its first dimensions, and so on one-fourth, one-fifth, one-sixth, &c., the air being constantly compressible in proportion to the incumbent weight; whence, by knowing to what height the water has ascended in the tube, we may readily know to what depth the tube has descended into the sea.

Now to measure the depth of one of these columns of sea-water: the iron tube should be attached by a line, with a weight at its bottom, and allowed to sink about thirty-three feet, which depth in salt water will nearly answer to the weight of the air at the mean height of the barometer; then draw up the tube, and observe how far the water rose. If thirty-three feet of water be equal to one atmosphere, then will the water rise so high as to fill exactly one-half of the tube: but, if the water rise higher or lower than half-way, then, by the rule of three, say, as the number to which the water rises is to one, so is thirty-three to the number of feet measuring the depth of the column required.

But since, when the instrument has descended to the depth of ninety-nine columns, or ninety-nine times thirty-three feet, the air will be compressed into the one-hundredth part of fifty inches, that is, into half an inch, the division both for some space below and also above that will be so very small that the difference in depth of several columns of water will not be sensible; so that an instrument of no greater length than this would scarcely give an accurate estimate of half a mile's depth, that is, 2640 feet, or 80 columns' depth of water. The lengthening of this instrument to four, five, or ten times this length would obviate this defect, and make the difference of the degrees of descent much more sensible. But since it is impracticable to make a metalline tube of so great a length, and if it were made it would be so unwieldy as to be easily broken, the difficulty may be obviated by having a large globe and tube like those employed in the common thermometer.

It was afterwards thought more desirable to employ an apparatus which, when it reached the bottom, should discharge a ball, so that the latter, having a less specific gravity than the water, should at once rise to the surface. Having, by a simple experiment,once ascertained the time of descent in a given quantity of water, it only became necesssary to keep an exact account of the time the machine remained under water, which might be done by a watch, or by a pendulum vibrating seconds. Dr. Hook found upon trial that a leaden ball which weighed two pounds, fixed to a wooden ball of the same weight, and both let down in fourteen fathoms' water, reached the bottom in seventeen seconds, and the detached wooden ball ascended to the surface in seventeen more. Consequently, if this machine descended and ascended greater depths with the same velocity, it would reach to the depth of a mile in seventeen minutes, and re-ascend in the like time. This, however, could be but a vague estimate until experience had furnished a rule.

This machine was tried in various depths in the Thames, and answered very well, always returning in the calculated time.

The general colour of the sea in the open ocean is a deep greenish-blue; the blue tint, which is predominant, seems to proceed from the same cause as the colour of the sky, the blue rays being reflected in the greatest quantity on account of their superior refrangibility. The other shades which have sometimes been observed in different seas seem to be owing to local causes, and often, perhaps, to optical illusions. In approaching soundings the water assumes a lighter shade. The luminous appearance of the sea by night is an imposing and magnificent phenomenon. It has been ascribed by some to animals of the zoöphyte and mollusca classes, which are said to possess phosphorescent qualities; some attribute it to the phosphorescence of decaying animal and vegetable substances; others to the spawn of fish. Some have explained it to be the effect of friction, but the appearances are extremely different at different times, and all these causes probably operate to produce them.

Observations made on the temperature of the sea show that the sun's rays rarely penetrate below the depth of forty-five, or, according to some, of 113

fathoms, below which the sea receives no light, and consequently little or no direct heat from the sun; and that the temperature increases with the depth to a certain degree, but never to freezing. The constant motion of the sea contributes in some measure to render its temperature equable. "We must distinguish," says Humboldt, "four different phenomena with respect to the ocean—the temperature of the water at the surface in different latitudes, the decrease of temperature in the lower strata, the effect of waves on the temperature of the surface, and the temperature of currents. The region of warmest water is between 5° 45′ N. and 6° 15′ S lat., and different observations give from 82 to 84 as the maximum. In the parallel of warmest waters the temperature of the surface of the sea is from 3° to 5° higher than that of the superincumbent air." The observations of Humboldt also show that both in the Atlantic and Pacific in changing the latitude and longitude the waters often retain nearly the same temperature over a great extent, and that between 27° N. and 27° S. lat. the temperature of the sea is entirely independent of the changes in the atmosphere. From the equator to 25° or 28 N. there is a remarkable constancy of temperature, but in higher latitudes there is more change. The great periodical oscillations of the sea, caused by the attraction of the sun and moon, are treated of in the article TIDES. In some places springs of fresh water are observed to issue from the sea entirely unaffected by the salt water. The most remarkable of these phenomena are in the Gulf of Spezia, in the Persian Gulf, and in the bay of Xagua, on the south coast of Cuba. It is probable that these are subterraneous streams, which find their way under the bed of the ocean until they encounter a fissure, into which they are impelled in the same manner as spouting springs on land.

The great divisions of the sea appear to be inhabited by their peculiar fish, mollusca, zoöphytes, &c., and to be frequented by peculiar species of birds. The level of the sea is, generally speaking, every where the same. This arises from the equal pressure in every direction which the particles of a fluid exercise upon each other. The ocean therefore considered as a whole has a spherical or a spheroidal surface, which may be considered as the true surface of our planet.

Different statements have been given of the quantity of saline matter in the waters of the ocean, some chemists asserting that the waters taken in different situations do not differ materially: others stating that the waters of different latitudes, and at different depths, contain different quantities of saline matter.

According to Glauber, the sea-water which he examined contained 3.01 per cent. of saline matter. Bouillon, Lagrange, and Vogel, in their experiments on the waters of the English Channel, of the Bay of Biscay, and of the Mediterranean, found that the saline ingredients amounted to 3.47 per cent. Bergman states that the water from the latitudes of the Canaries contained 3.59 per cent.; while, according to Dr Murray, the saline matter in the water of the Frith of Forth is only 3.03 per cent. From the experiments of Pages, it appears that sea-water, procured in south latitude 1° 16′, contained 3.5 per cent. of saline ingredients; in south latitude 20°, the quantity was 3.9 per cent; in south latitude 40°, it was 4 per cent; and in 46°, it was 4.5 per cent.; the quantity of saline matter gradually becoming greater on receding from the equator.

In the waters collected in the northen latitudes by the same gentleman, the proportion of saline ingredients did not differ from each other, being in the different trials 4 per cent.

From experiments made by Dr. Fyfe on sea-water, procured in different degrees of *north* latitude, and from different depths, there does not seem to be any material difference in the quality of saline matter. The specimens examined were collected by Captain Scoresby in his voyages to the Greenland Seas, and also by Captain Ross of his Majesty's ship Isabella, during the northern expedition.

The experiments to ascertain the quantity of saline ingredients in the different specimens of sea-water were performed on a large scale, that there might be as little chance of error as possible. For this purpose, ten ounces of each were slowly evaporated; the residue of the evaporation was then subjected to a heat sufficient to render it dry, and weighed in the vessel before being allowed to cool, as it very quickly attracted moisture. The results are given in the following table:—

	N. Latitude.	Longitude.	Remarks	Specific gravity at 45° F.	Saline matter per cent.
A	61° 52′	0° 7′ W.	Blue sea; water from surface; transparent and colourless.	10274	3.70
B	64° 26′	0° 38′ E.	Ditto, ditto.	10274	3 54
C	66° 45′	1° 0′ E.	Ditto. ditto. Smell of sulphuretted hydrogen, gave a black precipitate with the acetate of lead.	10272	3.79
D	69° 14′	3° 0′ E.	Blue sea; water from the surface, transparent and colourless.	10272	3.75
E	67° 50′	1° 30′ W.	Sea greenish-blue; water from surface; turbid; after filtration slightly opaque. N. B. This water was exposed to the air after being collected, by which part of it had evaporated.	10276	3.77
F	71° 10′	5° 30′ E.	Blue sea: water from the surface, transparent and colourless.	10272	3.75
G	74° 34′	10° 0′ E.	Ditto, ditto.	10276	3.77
H	74° 50′	59° 15′ W.	Water from the surface, transparent and colourless.	10263	3.33
I	74° 50′	59° 15′ W.	Water transparent and colourless, taken at the depth of eighty fathoms, by Sir H. Davy's bottle; its temperature at the moment that it was drawn was 30½°. H. M. S. Isabella, July 18, 1818.	10265	3.30
K	75°	65° 32′ W.	Water transparent and colourless, from eighty fathoms deep. August 12, 1818.	10256	3.62
L	76° 33′	10° 20′ E.	Blue sea: water from the surface, transparent and colourless.	10274	3.60

	N. Latitude.	Longitude.	Remarks.	Specific gravity at 45° F.	Saline matter per cent.
M	77° 30′	6° 10′ E.	Sea deep olive-green. Some ice; water when taken very thick. After standing, transparent and colourless,	10267	3.42
N	77° 34′	8° 0′ E.	Blue sea. Among ice-streams. Water from the surface, transparent and colourless,	10267	3.70
O	78° 25′	8° 20′ E.	Sea greenish-blue. Middle Hook of Charles Island. Spitzbergen E. 6 N. 7 leagues. Water from the surface, transparent and colourless,	10276	3.91
P	78° 30′	6° 30′ E.	Sea olive-green. Middle Hook of Charles Island E½. S. 9 leagues. Water from surface, transparent and colourless,	10276	3.88
Q	78° 35′	6° 0′ E.	Sea deep olive-green. Some ice; water from the surface. When taken very thick, after standing transparent and colourless,	10256	3.27

The results of the above experiments show that the water of the ocean, from north latitude 61° 52′ to north latitude 78° 35′ does not differ essentially in the quantity of saline matter which it contains, the smallest quantity being 3.27 per cent., the greatest 3.91 per cent. The average quantity of saline ingredients in the water within these latitudes is 3.50 per cent.

If the experiments of Pages be correct, the saline substance contained in the water of southern latitudes is greater than that in the water north of the equator. At south latitude 20° the saline ingredients amount to 3.9, and at south latitude 46° to 4.5 per cent.; while the greatest quantity in the water of the north seas, according to Dr. Fyfe's experiments, is only 3.91 per cent. in water procured at north latitude 78° 25′, upwards of 30 degrees further distant from the equator than the southernmost latitude at which Pages collected the water on which his experiments were performed.

We pass from the experimental investigations of Dr. Fyfe, to a very important paper published by Dr. Marcet. His attention appears to have been directed at a very early period to the analysis of water; and when the late celebrated Mr. Tenant received from Sir Joseph Banks some phials of the water of the Dead Sea and of the River Jordan, brought home by Mr. Gordon of Clunie, he entrusted them to Dr. Marcet, whom he knew to have been engaged in similar researches. These emiment chemists embraced every opportunity of collecting sea-water from different parts of the world; and, though the melancholy death of Mr. Tennant interrupted for a considerable time the researches of his friend, he was induced to resume his labours after the return of the Arctic Expedition, which furnished him with numerous specimens of water from the Polar Seas.

Having procured above seventy different kinds of sea-water from different parts of the world, a great number of which were raised by an ingenious apparatus invented by himself, Dr. Marcet began his investigation of their physical properties, and their chemical composition. The specific gravities were measured in the usual manner, by comparison with equal bulks of distilled water of the same temperature. As the results would occupy too much room, we have arranged them in the following table in groups, and given the extremes, as well as the mean, of the different results.

Places where the water was obtained.	Number of Specimens.	Intervals of Latitude.	Intervals of Longitude.	Extremes of Specific Gravity.	Mean of all the Results.
Arctic Ocean.	12.	66° 50′ to 80 29	11° 15′ E. to 76 46 W.	1.02555 to 1.02727	1.02664

Lake of Ourmia.	1.	——	——	1.16507	——

From the preceding facts Dr. Marcet concludes,

1. That the Southern Ocean contains more salt than the Northern Ocean, in the ratio of 1.02919 to 1.02757.

2. That the mean specific gravity of sea-water near the equator is 1.02777, intermediate between that of the northern and southern hemispheres.

3. That there is no considerable difference in sea-water under different meridians.

4. That there is no satisfactory evidence that the sea at great depths is more salt than at the surface.*

5. That the sea in general contains more salt where it is deepest and most remote from land, and that its saltness is always diminished in the vicinity of large masses of ice.

6. That small inland seas, though communicating with the ocean, are much less salt than the open ocean.

7. The Mediterranean contains rather larger proportions of salt than the ocean.

The singularity of this last result has been explained upon the supposition that the Mediterranean is not supplied by the rivers which flow into it with a quantity of fresh water sufficient to replace what it loses by evaporation under a burning sun, aided by a powerful radiation from the African shores, and the parching winds blowing from the adjacent deserts. Philosophers have, therefore, attempted to explain why this sea does not gradually increase in saltness, and indeed be ultimately converted into saturated brine. This has been ascribed to an under current of water, salter than the ocean, which runs out at the Straits of Gibraltar, and unloads its waters of their excess of salt. This idea of a submarine current is countenanced by the fact, communicated to Dr. Marcet by Dr. Macmichael, on the authority of the British consul at Valentia, that some years ago a vessel was lost at Ceuta, on the African coast, and its wreck afterwards thrown up at Tariffa, on the European shore, fully two miles west of Ceuta.*

The results obtained by Dr. Marcet from twelve specimens of water from the Arctic Seas agree wonderfully with those previously obtained by Dr. Fyfe, the intervals of latitude and longitude being nearly the same, and also with those of Mr. Scoresby, published in his work on the Arctic Regions.

	Number of Specimens.	Intervals of Latitude.	Intervals of Longitude.	Specific Gravity.
Dr. Fyfe's result,	16.	61° 52′ N. 78 25 N.	10° 20′ E. 65 32 W.	1.02697
Dr. Marcet's result,	12.	66 50 N. 80 29 N.	11 15 E. 76 46 W.	1.02664
Mr. Scoresby's result,	14.	76 16 N. 80 0 N.	90 0 E. 0 10 W.	1.02653

Dr. Marcet next proceeds to give an account of the general results respecting the temperature of the Polar Seas, as obtained by the officers of the late expedition to those regions.

In Baffin's Bay, the Mediterranean Sea, and the tropical seas, *the temperature of the sea diminishes* with the depth, according to the observations of Phipps, Ross, Parry, Sabine, Saussure, Ellis, and Peron; but it is a remarkable fact that in the Arctic or Greenland Seas *the temperature of the sea increases* with the depth. This singular result was first obtained by Mr. Scoresby, in a series of well-conducted experiments, and has been confirmed by the later observations of Lieutenants Franklin, Beechy, and Mr. Fisher.

The following is an abstract of Mr. Scoresby's results:—

Lat.	Long.	Depth in Feet.	Temperature.	Temper. of Air.
76° 16′	9° 0′ E.	Surface	28.8°	12°
	——	300	31.8	
	——	738	33.8	
76 16	10 50	Surface	28.3	16
	——	738	30.0	
76 34	10 0	Surface	30.0	25
	——	600	34.7	
77 15	8 10	Surface	29.3	16
	——	600	30.0	
77 40	5 40	Surface	29.0	34
	——	2400	30.0	
79 4	5 38	Surface	29.0	38
	——	4380	37.0	
80 0	5 0	Surface	29.7	40
	——	720	36.3	
78 2	0 10 W.	Surface	32.0	36
	——	4566	38.0	

The following are some of the results obtained by Lieutenant Beechy on board the Trent:—

Lat.	Long.	Depth in Fath.	Temper. at Bottom.	Temper. of Surface.
79° 44′	9° 34′ E.	15	34.0°	33.0°
79 58	11 14	30	31.0	30.0
79 52	9 57	60	34.0	32.0
80 23	9 50	120	36.0	30.3
80 21	11 11	140	36.5	30.5
80 27	11 5	200	35.5	32.5
80 23	11 3	237	27.0	32.0
76 48	12 26	700	43.0	33.0

The following are some of Mr. Fisher's results, obtained on board the Dorothea:—

Latitude.	Longitude.	Depth in Fath.	Temp. at Bottom.	Temp. of Surface.
Between 79° 51′ and 80 14	11° 30′ E.	40	35.5°	31.8°
		60	36.0	32.0
		100	36.3	32.0
		124	36.7	33.5
		140	36.5	32.0
		188	42.5	33.0
		304	39.0	31.0

The greatest difference found by Lieutenant Parry was 6°, at a depth of 246 fathoms; and the greatest obtained by Captain Sabine was 7½°, at a depth of 680 fathoms.

The following table contains the results obtained by Dr. Marcet:—

* A similar conclusion was deduced by Mr. Scoresby, who obtained the following results. See his *Account of the Arctic Regions*.

	Depth in feet.	Spec. Grav.		Depth in feet.	Spec. Grav.		Depth in feet.	Spec. Grav.

Sea of Marmora. Bottom. Spec. 52.	1028.19	21.	40.4	3.55	0.9	3.2	48.05	From bottom. Carbon of lime deposited during evap. but none from the water at surface. Operated on 500 grains.
Middle of North Atlantic. Spec. 27.	1028.86	21.3	42.	3.85	0.8	2.7	49.35	Operated on 250 grains for evap. of water and mur. of silver. 500 for other salts.
Yellow Sea Spec. 48.	1022.91	16.1	32.9	1.35	0.75	2.2	37.2	During concentration deposited carbon. of lime. The water was yellowish and had a strong hepatic smell. Operated on 500 grains.
Mediterranean. Spec. 51.	1027.3	97.7	38.5	3.6	0.8	3.0	45.9	From Marseilles, and rather weak, from vicinity of rivers. Opd. on 100 grains for evap. and mur. of silver; and 250 for other salts.
Dead Sea.	1211.	192.5	326.4	0.5	9.78	55.5	584.68	*Phil. Trans.* 1807.
Lake Ourmia, in Persia.	1165.07	111.5	237.5	66.0	0.	10.5	425.5	Spec. brought by Brown. Operated on 100 and 50 grains.

By cooling sea-water with freezing mixtures, and ascertaining its specific gravity at each degree of temperature, as it approached congelation, Dr. Marcet found that the law of maximum density at 40° did not prevail in the case of sea-water; but, on the contrary, sea-water gradually increased in weight down to the freezing point. This able chemist confirmed this result by means of an ingenious instrument, with which he measured the bulk of the water under various temperatures. The water was always found to contract in bulk down to 22° of Fahrenheit, when the water appeared to expand a little, and con-

tinued to do so till its temperature descended to between 19° and 18°, when the fluid suddenly expanded to a very considerable degree, shooting up with great rapidity, and forcing itself out of the open end of the tube. At the same moment the thermometer rises to 28°, and remains at that point. The liquid is now found frozen, and in a few minutes the maximum of expansion is obtained.

Dr. Marcet next proceeded to ascertain the saline contents of the different seas; and in this investigation he employed a method which he had previously used and explained in his analysis of the Dead Sea, published in the *Phil. Trans.* for 1807. "It is satisfactory to observe," says Dr. Marcet, "that Dr. Murray adopted, several years afterwards, a mode of proceeding precisely similar, and indeed that he proposed, in a subsequent paper (*Edin. Trans.* 1816, vol. viii.), a general formula for the analysis of mineral waters, in which this method is pointed out as likely to lead to the most accurate results. And this coincidence is the more remarkable as it would appear, from Dr. Murray not mentioning my labours, that they had not at that time come to his knowledge." All the results which Dr. Marcet obtained by this mode of investigation, prove that sea-water contains the same ingredients all over the world, and that these bear very nearly the same proportion to each other, differing only in the total amount of their saline contents. See *Edinburgh Philosophical Journal.*

Octagon, in *geometry*, is a figure of eight sides and angles, which, when the sides and angles are all equal, is called a *regular octagon*, and when they are not equal, an *irregular octagon.*

Octahedron or Octaedron; a body consisting of eight equal and equilateral triangles.

Octant, an astronomical instrument, is the eighth part of a circle divided into degrees, for the purpose of calculating the amplitude of the stars, but it is now little used.

Octave, in the diatonic system of musical sounds; the eighth sound from an assumed fundamental tone. It belongs to the perfect concordant intervals, so that when it is sounded with the fundamental, the ear scarcely perceives more than one sound, and is hardly able to distinguish the one from the other. For this reason, the octave must, in our musical scale, be perfect; whereas the other intervals may be tuned somewhat higher or lower than their true pitch. The upper octave (that is, the one which is eight notes above the fundamental) is obtained when the string which sounds it is only half as long, and the lower octave when this string is twice as long, as that of the fundamental. The string which sounds the upper octave in each makes two vibrations while the string of the fundamental makes one. Therefore on the eighth diatonic string the tone of the first, or lowest, recurs. The ninth string repeats the second tone, called the *second*, the tenth string the third tone, or the *third*, &c.

According to the arrangement of our new or diatonic system of tones, the octave is the limit within which the seven essential tones are kept distinct from each other: and all tones without the limit of the octave are only repetitions, in an augmented or diminished degree, of the tones already contained in the compass of the octave. For this reason we call the octave the whole extent of the tones of the diatonic system. The number of upper and lower octaves, or the manner in which several octaves of different heights are to be chiefly distinguished, is not absolutely determined, on account of the continually increasing compass of instruments, particularly stringed instruments, and especially the piano-forte, which, within a short period, has been considerably increased.

The octave, considered as an interval, has of all intervals the least harmonic effect. On this account composers, when there is only one principal voice, forbid rising to the octave except at the beginning or close. But a succession of octaves following each other, when a melody is to be raised in that manner, has a very good effect. False or disallowed octaves are, in musical compositions for many voices, progressions of two voices in exact movement by octaves, which offend the ear. The reason why such progressions by octaves are disallowed in a musical piece for many voices is evident, because, when two voices proceed by octaves, no difference can be perceived between these two; and, for example, a piece for four voices becomes one for two. There are also those which are called *covered octaves*, that is, such as become for the first time distinguishable when the interval of the two voices, proceeding in an exact movement by octaves, is filled up with unimportant notes. Of the compositions for two voices, or in the two upper parts of composition for three or four voices, those alone are free from fault in which the upper part rises or falls a second, but the fundamental a fourth or fifth. The use of the others is allowed only under the middle part, or between an upper and a middle part.

Octave, also, in an organ, signifies the open flute stop, which is one or two octaves higher than the principal.

October; originally the eighth month in the Roman calendar, whence its name, which it still retained after the beginning of the year had been changed from March to January.

Odontalgic, in *medicine;* a term applied to all remedies for the tooth-ache. When the affection is rheumatic, blistering behind the ear, or applying flannel dipped in spirits and covered with ginger or pepper, will generally cure; but, when it proceeds entirely from the injury of a carious tooth, the pain is much more obstinate. In this case it has been recommended to touch the pained carious part of the tooth with a hot iron, or with oil of vitriol, in order to destroy the aching nerve, to hold spirits in the mouth, to put a drop of oil of cloves into the hollow of the tooth, or a pill made of camphor, opium, oleum caryophylli. But one of the most useful applications of this kind is strong nitrous acid, diluted with three or four times its weight of alcohol, and introduced into the hollow of the tooth either by means of a hair pencil or a little cotton. When the constitution has had some share in the disease, the Peruvian bark has been recommended, and perhaps with much justice, on account of its tonic and antiseptic powers. When the pain is not fixed to one tooth, leeches applied to the gum are of great service. But very often all the foregoing remedies will fail; and the only infallible cure is to draw the tooth.

Odour, that quality of certain bodies which excites the sensation of smell. In the *Annales de Chimie*, we have a detailed account of a series of experiments made by M. Prevost, with a view to render the emanations of odorant bodies perceptible to sight. We have space only for a few passages illustrative of the author's views.

1. A concrete odorant substance, laid upon a wet glass or broad saucer, covered with a thin stratum of water, immediately causes the water to recede, so as to form a space of several inches around it.

2. Fragments of concrete odorant matter, or small morsels of paper or cork impregnated with an odorant liquor, and wiped, being placed on the surface of water, are immediately moved by a very swift rotation. Romieu had made this observation on camphor, and erroneously attributed the effect to electricity. The motion was perceptible even in pieces of camphor of seven or eight gros.

3. An odorant liquor being poured on the water stops the motion till it is dissipated by evaporation. Fixed oils arrest the motion for a much longer time, and until the pellicle it forms on the water is taken off.

4. When the surface of the water is cleaned by a leaf of metal, of paper, or of glass, plunged in and withdrawn successively until the pellicle is removed, the gyratory motion is renewed. If a piece of red wax or of paper be dipped in water, and the drops shaken off into a glass of water containing odorant bodies in motion, the movement will be stopped. The same effect is not produced by metal.

5. A small piece of camphor, plunged to the depth of three or four lines in water, without floating, excites a movement of trepidation in the surrounding water, which repels small bodies in its vicinity, and carries them again to the camphor by starts. The author concludes that an elastic fluid escapes from the odorant body in the manner of the fire of a fusee, or the discharge of fire-arms.

6. When there is a certain proportion between the height of the water and that of the small fragment of camphor, the water is briskly driven off, returns again to the camphor, and again retires, as if by an explosion, the recoil of which often causes the camphor to make part of a revolution on its axis.

7. Camphor evaporates thirty or forty times more speedily when placed upon water, than when entirely surrounded with air.

8. Camphor, during the act of dissipation in the air, preserves its form and its opaque whiteness; upon water it is rounded, and becomes transparent as if it had undergone a kind of fusion. It may be inferred that this arises from the acquired motion which causes it to present a greater surface to the air.

9. When small pieces of camphor are plunged in water, the camphor becomes rounded and transparent, does not acquire any motion, and its dissipation is less perceptible than in the air. The concurrence of air and water is therefore necessary to disengage the fluid, which is the cause of the motion and total dissipation of odorant bodies.

10. The motion of odorant bodies upon water decays and ceases spontaneously at the end of a certain time; because, the water having then contracted a similar character with the body, the volatilization takes place in all the points of its surface; and the small mass being thus surrounded by the odorant fluid, which is no longer air, dissolves, as in the ordinary odorant fluids, without forming the gaseous jet which is the cause of the motion. The author compares the volatilization of the aromatic substance to a combustion excited by water.

Professor Ventury of Modena, who heard Prevost's memoir read in the National Institute, had himself made some experiments with camphor kept separately in the air, in the water, and at the surface of the water; whence he deduces that the most active virtue for dissolving camphor resides at that part where both the air and the water touch the camphor at the same time. Hence he explains why, in like circumstances, camphor evaporates more quickly in a moist than in a dry air; and why the natives of Holland use water in their process for subliming this substance.

It might be thought that the camphor was decomposed at the surface of the water; that the water might seize the acidifying part, which renders the camphor concrete; and that the volatile part is dissipated in the atmosphere. The author rejects this notion. He thinks that water with camphor floating on its surface becomes charged with no more than a very small portion: 1. Because in these circumstances the water acquires the same taste and smell of camphor as it obtains when a small quantity of this substance is kept plunged in the same fluid. This water, by exposure to the air, loses the qualities with which it had been charged, and becomes insipid and without smell. 2. Because, when the water is saturated with all it can take up, the dissipation of the camphor continues at its surface as before. 3. Because the aërial emanations of camphor made at the surface of water do themselves crystallize into camphor.

Œsophagus.—The gullet is a contracted continuation of the pharynx, the last part of the fauces. Its anterior part is connected with the root of the tongue, the os hyoides, and the larynx; it closely adheres behind to the vertebræ of the neck, and is moved by various muscles, which elevate or dilate the pharynx, and by others which shut it. One pair of these muscles, arising by three origins from the os hyoides, the cartilago cricoides, and the cartilago thyroides, totally surrounds the pharynx. The *œsophagus* first runs straight between the aspera arteria and the vertebræ of the neck and back, but turns to the right about the fifth vertebra, and to the left about the ninth; then proceeding through the middle of the thorax and the muscular part of the diaphragm, behind the little lobe of the liver, it terminates in the superior orifice of the stomach. The œsophagus consists of four coats: the outermost coat is a thin, vascular, cellular membrane, originating from the pleura, uniting the gullet to the adjacent parts. The next coat is muscular, furnished with orbicular fibres, and above these with longitudinal ones. The third is nervous, common to the mouth and fauces, and extending a little way within the stomach; it is glandular, and the glands secrete a mucous. The innermost coat is covered with mucous, is villous, and the orifices of the glands are numerous. The cuticle lines the œsophagus, but is too thin to be demonstrated. Besides the glands mentioned, the dorsal gland about the fifth vertebra of the back, adhering to the gullet, and the thyroid gland, situated between the thyrocricoid cartilage and the œsophagus, are enumerated as belonging to this organ. Its upper part receives arteries from the internal carotids, its middle from the aorta and intercostal, and its inferior from the gastric arteries. Veins from the jugulars, from the vena sine pari, and from the caronary veins of the stomach, return the blood in the respective portions. The nerves proceed from the par vagum.

There are few situations in which foreign bodies lodge more frequently than in the œsophagus. The

function of this tube explains the reason of this occurrence, and its nearness to the wind-pipe accounts for the danger of suffocation, whenever a foreign body above a certain size is lodged in it. Foreign bodies, liable to stick in the œsophagus, are not only food, such as pieces of crust, or meat imperfectly chewed, but also various substances which are accidentally swallowed alone, or with the food, such as small bones, stones, pins, pieces of money, &c. These latter articles, by lodging in the pharynx or œsophagus, may occasion very bad symptoms; and, if forced down into the stomach, may produce still worse effects. Hence we should immediately try to extract them. For this purpose, the fingers are to be used, and, if they cannot reach them, forceps must be employed. Some have recommended hooks, for the accomplishment of the object in view; others, various instruments, adapted to particular circumstances. The excitement of vomiting has been tried, and occasionally with success; but it is not free from danger, and the most distressing symptoms have been brought on by it.

When such extraneous substances cannot be extracted, they must be pushed down into the stomach, with some such instrument as a large bougie, or a whalebone probang, fifteen or sixteen inches long, and on the end of which a piece of fine sponge is firmly fastened. But when such bodies are, from their sharp-pointed, angular shape, or hurtful nature, likely to occasion perilous consequences, by being pushed down into the stomach, the plan must not be attempted. Sharp substances not unfrequently make their way to the surface of the body, and give rise to an abcess, out of which they are discharged.

Œnanthe (water hemlock); a plant employed in medicine. An infusion of the leaves are said to be of the greatest service in cutaneous diseases. It must, however, be employed with great care, as it is a virulent poison. It grows in great plenty all over Pembrokeshire, and is called by the inhabitants *five-fingered root:* it is much used by them in cataplasms, for the worst kind of whitlow. They eat some parts of it, but carefully avoid the roots and stalk. These indeed are of a most pernicious nature, and never fail to prove instantly fatal, unless a proper remedy is applied. The following instance of the effects of this plant on man may be relied on:—

"Three French prisoners, being in the fields near the town of Pembroke, dug up a large quantity of a plant with its roots (which they took to be wild celery), to eat with their bread and butter for dinner. After washing it, while yet in the fields, they all three ate, or rather only tasted, of the roots. As they were entering the town one of them was seized with convulsions. The other two ran and sent a surgeon, who endeavoured first to bleed, and then vomit him; but in vain, and he died presently. Ignorant of the cause of their comrade's death, and of their own danger, they gave some of these roots to eight other prisoners, who all ate of them with their dinner. A few minutes after, the two who gathered the plants were seized in the same manner as the first, of which one died: the other was bled, and an emetic with great difficulty forced down, on account of his jaws being set. This operating, he recovered; but was for some time much affected with a dizziness in his head, though not sick, or in the least disordered in his stomach. The other eight being bled and vomited immediately were soon well."

Offing, or Offin; that part of the sea a good distance from shore, where there is deep water, and no need of a pilot to conduct the ship.

Oil.—There exist two species of oil in vegetables, agreeing in the common properties of unctuosity and inflammability, but essentially different in many of their chemical qualities and relations. The one, from being capable of being volatilized without decomposition, is named volatile oil; the other is denominated fixed oil. The character of the latter must be first examined.

Fixed oils are generally contained in the seeds and fruits of those vegetables of which they are the products, and are formed principally at the period of maturity. They are extracted by pressure, whence they are named expressed oils, or in some cases by decoction with water. They are frequently impregnated with the mucilaginous or extractive matter of the vegetable, whence they acquire colour, odour, and taste; and if heat has been employed to favour their extraction by expression they acquire acrimonious qualities, and suffer even a change in some of their chemical properties. The purest oils are those expressed from the fruit of the olive or the seeds of the almond; others less pure are extracted from linseed, hempseed, and the seeds of other plants.

Fixed oils are usually fluid, but of a thick consistence, and they congeal at a moderate temperature: some are even naturally concrete; when fluid they are transparent, colourless, or of a yellow or green tinge, inodorous, and insipid; they are lighter than water; they are incapable of combining with water, and are very sparingly soluble in alcohol in the cold, with the exception of castor oil, which is abundantly dissolved by rectified alcohol, and of linseed oil, which is dissolved, though more sparingly; boiling alcohol dissolves it, and also the others in sensible quantity.

Expressed oils cannot be volatilized by heat unchanged. At temperatures below 600° of Fahrenheit they remain fixed; nearly at that temperature they are converted into vapour, but the oil thus condensed is altered in its properties; it has lost its mildness and has become more limpid and volatile, a portion of carbon being likewise deposited. Transmitted through an ignited tube, oil is converted into carbonic acid and carburetted hydrogen, with a small portion of acid liquor and a residuum of charcoal.

Exposed to a warm atmosphere, expressed oils gradually acquire a sharp taste and smell and become thick. This change, named rancidity, is owing to absorption of oxygen; hence it takes place sooner when the oil is exposed to oxygen gas, and a large quantity of the gas is frequently absorbed. Drying oils, as those expressed with the aid of heat are named, do not become rancid, but, by absorbing oxygen, are partially converted into a resinous kind of matter. By these drying oils the absorption of oxygen is under favourable circumstances so rapid as to give rise to spontaneous combustion.

At the temperature of ignition, at which it is converted into vapour, oil burns in atmospheric air, a large quantity of light and heat being extricated by its combustion. When the access of the air to the vapour of the oil is not complete it burns with a black smoke, and a quantity of carbonaceous matter which has escaped the combustion is deposited. Hence the utility of a slender wick, which draws up the oil by capillary attraction, and, when kindled, produces sufficient heat to convert it into vapour. In a hollow

cylindrical wick, as in the argand lamp, through which an internal circulation of air is established, the supply of air is more abundant and the whole of the oil is consumed; the illumination therefore is greater, though there is some diminution of it in consequence of the light from the internal surface having to pass through the flame.

Expressed oil is oxidated by a number of the acids. Sulphuric acid soon renders it black, the oxygen of the acid attracting part of the hydrogen of the oil and causing the deposition of charcoal; and if heat is applied a large portion of sulphurous acid is disengaged, and even sulphur is evolved. Nitric acid renders the oil thick and white; if heat is applied the action is more rapid and a yellow colour is communicated, the oil being rendered concrete. The drying oils are even inflamed. Muriatic acid exerts little sensible action; oxymuriatic acid thickens the oil and renders it white.

Expressed oil combines with the alkalies, and when the combination is perfect it forms soap. If one part of oil be mixed with half its weight of a strong solution of pure potash or soda, a thick white mass is formed, which can be diffused in water, forming a milky-like mixture. If the oil and the alkaline solution be boiled gently together, a more intimate combination is effected, and, on cooling, a solid compound separates from the liquor. The soap thus prepared differs according to the purity of the ingredients. Common soap is made of animal oil, or fat, or the coarser vegetable oils, with resin; the finer soaps are prepared from olive or almond oil. Potash forms a soap which always remains soft; soda forms one that is more solid and firm. Hence either a solution of carbonate of soda, from which the carbonic acid has been abstracted by lime, is employed in the preparation; or, if a solution of potash rendered caustic by the same operation be used, which is the common method in the preparation of the coarser soaps, there is added towards the end of the boiling a quantity of sea-salt, the soda of which, being in part evolved, has the same effect. The cleansing property of soap depends on its alkali; and, although the detergent power of this is weakened by the combination with the oil, advantage is gained from its softness and smoothness, and from the alkali in the state of combination acting less as a solvent on the cloth.

Soap is soluble in water, the solution being opaque, from the intermixture of particles of uncombined oil. It is also soluble in alcohol, forming a transparent solution. It is decomposed by all the acids and by the greater number of the earthy and metallic salts, the acid combining with the alkali and separating the oil. Hence spring water often decomposes it from the sulphate of lime it contains. The oil separated by these decompositions is soluble in alcohol, a proof that, by its combination with the alkali, it has undergone some chemical change. Soap decomposed by heat affords water, empyreumatic oil, and ammonia.

Ammonia forms with expressed oil a less intimate combination than the fixed oils do, as heat cannot be employed to favour the combination. The addition of a small quantity of it is employed in pharmacy to suspend oil in water. By adding an ammoniacal salt to a solution of soap an ammoniacal soap is obtained by double affinity. It is less soluble in water than common soap, and suffers decomposition from exposure to the air.

The combinations of expressed oil, with the earths and metallic oxides, may be obtained by adding their salts to a solution of soap, when a double decomposition takes place. These compounds have a saponaceous quality, but are in general less soluble in water than the alkaline soaps.

Expressed oil, when boiled on sulphur, combines with it, and forms a compound of a brown colour, an extremely fœtid smell, and an acrid taste. It likewise dissolves phosphorus with the aid of heat, forming a liquid which becomes luminous when exposed to the air.

Expressed oil, promotes the oxidation of some of the metals, as copper or mercury, by the action of the air. It combines with a number of the metallic oxides. Boiled with oxide of lead, it forms a compound of a firm consistence, which is named in pharmacy common plaster.

A mutual action is exerted between expressed oils and several of the other vegetable principles, as gum or resin. Triturated with mucilage, it forms a milky mixture,—a mode of suspending oil in water which is sometimes employed in pharmacy. It melts easily with resin.

Expressed oils, besides their use in pharmacy and medicine, form the basis of paints, being triturated with oxide of lead and the colouring matter. Combined with resins and turpentine, they form varnishes; and printing-ink is a composition of them with lamp black. For some of these uses the drying oils are employed.

Volatile or essential oil is contained in the flowers, fruits, leaves, wood, or bark of many vegetables, generally in inconsiderable quantity, the proportion varying, however, according to the age and vigour of the plant. The oil sometimes exists in distinct vesicles, and may therefore be obtained by expression. But the usual method to procure an essential oil is to subject the vegetable matter containing it to distillation with water.

Essential oils are odorous, sapid, and generally pungent, the taste and smell of the oils obtained from different vegetables being very different; the odour is always that of the plant from which they are procured. They are generally lighter than water, but some have a greater specific gravity. They are usually fluid, and remain so even at a low temperature; but some congeal even at a very moderate degree of cold, and others are naturally concrete. They are volatilized by a very moderate heat. By a strong heat suddenly applied, they are partially decomposed.

Essential oils are soluble in water in minute proportions. The water acquires the taste and flavour of the oil. This impregnation is commonly obtained by distillation, the distilled waters of pharmacy being thus formed. They are much more soluble in alcohol; some of them unite with the alcohol in every proportion, others in limited quantities; and there are even some which are sparingly dissolved. By distilling ardent spirit from vegetables containing much essential oil, distilled spirits are formed.

Exposed to atmospheric air, these oils lose their smell, are thickened, and become concrete, frequently depositing at the same time crystals of an acid nature. These changes are owing to the absorption of oxygen. The acid is similar to the benzoic, and the thickened oil approaches in its properties to resin.

When heated in contact with atmospheric air, they are more easily inflamed than the expressed oils, and

burn with a brighter flame, probably from their greater volatility; the products of the combustion are water and carbonic acid, and the water is in larger quantity than from the combustion of the fixed oils. Hence they differ from the fixed oils in containing a larger proportion of hydrogen, to which probably their greater volatility and inflammability are owing.

The essential oils are oxidated by the acids. Sulphuric acid renders them black, producing at the same time a considerable elevation of temperature, and frequently a violent effervescence, from the disengagement of sulphurous and carbonic acid gases. Nitrous acid communicates oxygen with such rapidity as frequently to inflame the oil. By a more slow action it forms prussic, malic, and oxalic acids, and converts the remaining oil into a kind of resinous substance. In some cases the acids combine with essential oils, and the acid properties are neutralized without decomposition.

With the alkalies these oils combine with difficulty, and the combination can be effected only by long trituration: the compound is slightly saponaceous. Liquid ammonia distilled with the oil combines with it but sparingly.

Sulphur dissolves with the aid of heat in any of the essential oils; the solution has an offensive smell. Phosphorus is also soluble in them; and some of these solutions (that, for example, in oil of cloves), are highly luminous.

These oils unite with mucilage or sugar; and by the medium of ether they may be suspended in water. They dissolve resin, camphor, and other vegetable principles.

In general they are used as perfumes, or in the practice of medicine. Some of them enter into the composition of varnishes.

Several chemists have been of opinion that herbs and flowers, moderately dried, yield a greater quantity of volatile oil than if they were distilled when fresh. It is, however, highly improbable that the quantity of volatile oil can be increased by drying; on the contrary, part of it must be dissipated and lost. But drying may sometimes be useful in other ways, either by diminishing the bulk of the subject to be distilled, or by causing it to part with its oil more easily; and aromatic waters distilled from the dry herb are more fragrant than from the fresh. But the directions sometimes given to dry the herb used in the distillation of volatile oils would be extremely inconvenient, as large quantities of the oils of lavender, peppermint, spearmint, and pennyroyal, are annually distilled in this country from the fresh herb; and the oils of aniseed, camomile, caraway, juniper, origanum, rosemary, and pimento, are usually imported.

The choice of proper instruments is of great consequence for the performance of this process to advantage. There are some oils which pass freely over the swan neck of the head of the common still: others, less volatile, cannot easily be made to rise so high. For obtaining these last, a large low head, having a rim or hollow canal round it, seems best: in this canal, the oil is detained in its first ascent, and is thence conveyed at once into the receiver, the advantages of which are sufficiently obvious.

We cannot separate the volatile oil from aromatic substances by distilling them alone, because the proportion of these oils is so small that they could not be collected; and, besides, it would be impossible to regulate the heat so as to be sufficient and yet not to burn the subject and destroy the product. Hence it is necessary to distil them with a proportion of water, which answers extremely well, as the oils are all more volatile in water, and soluble in it only to a certain extent.

With regard to the proportion of water to be employed, if whole plants moderately dried are used, or the shavings of woods, as much of either may be put into the vessel as, lightly pressed, will occupy half its cavity; and as much water may be added as will fill two-thirds of it. When fresh and juicy herbs are to be distilled, thrice their weight of water will be fully sufficient; but dry ones require a much larger quantity. In general there should be so much water, that, after all intended to be distilled has come over, there may be liquor enough left to prevent the matter from burning to the still. The water and ingredients altogether should never take up more than three-fourths of the still; there should be liquor enough to prevent any danger of empyreuma, but not so much as to be in danger of boiling over into the receiver.

The subject of distillation should be macerated in the water until it be perfectly penetrated by it. To promote this effect, woods should be thinly shaved across the grain or sawn, roots cut transversely into thin slices, barks reduced into coarse powder, and seeds slightly bruised. Very compact and tenacious substances require the maceration to be continued a week or two or longer; for those of a softer and looser texture two or three days are sufficient; while some tender herbs and flowers not only stand in no need of maceration, but are even injured by it. The fermentation which was formerly prescribed in some instances is always hurtful.

The fire ought to be quickly raised and kept up during the whole process; but to such a degree only that the oil may freely distil; otherwise the oil will be exposed to an unnecessary heat, a circumstance which ought as much as possible to be avoided. Fire communicates to all these oils a disagreeable impregnation, as is evident from their being much less grateful when newly distilled than after they have stood for some time in a cool place; and the longer the heat is continued the greater alteration it produces in them.

The greater number of oils require for their distillation the heat of water strongly boiling; but there are many also which rise with a heat considerably less; such as those of lemon and citron peel, of the flowers of lavender and rosemary, and of almost all the more odoriferous kinds of flowers. We have already observed that these flowers have their fragrance much injured or even destroyed by beating and bruising them; it is impaired also by immersion in water in the ordinary process, and the more so in proportion to the continuance the of immersion and the heat; hence oils distilled in the common manner prove much less agreeable in smell than the subjects themselves. For the distillation of substances of this class another method has been contrived: instead of being immersed in water, they are exposed only to its vapour. A proper quantity of water being put into the bottom of the still, the odoriferous herbs or flowers are laid lightly in a basket, of such a size that it may enter into the still and rest against its sides just above the water. The head being then fitted on, and the water made to boil, the steam, percolating through the subject, im-

bibes the oil without impairing its fragrance, and carries it over into the receiver. Oils thus obtained possess the odour of the subject in an exquisite degree, and have nothing of the disagreeable scent perceivable in those distilled by boiling them in water in the common manner.

Plants differ so much according to the soil and season of which they are the produce, and likewise according to their own ages, that it is impossible to fix the quantity of water to be drawn from a certain weight of them to any invariable standard. The distillation may always be continued as long as the liquor runs well flavoured off the plant, but no longer.

The mixture of water and oil which comes over may either be separated immediately by means of a separatory, or after it has been put into large narrow-necked bottles and placed in a cool place, that the portion of oil which is not dissolved in the water may rise to the top or sink to the bottom according to its specific gravity. It is then to be separated either by a separatory or by the use of a small glass syringe; or by means of a filter of paper; or, lastly, by means of a woollen thread, one end of which is immersed in the oil, and the other lower end in a phial: the oil will thus pass over into the phial by capillary attraction, and the thread is to be squeezed dry.

The water employed in the distillation of volatile oils always imbibes some portion of the oil, as is evident from the smell, taste, and colour which it acquires. It cannot, however, retain above a certain quantity; and hence such as has been already used, and therefore almost saturated, may be advantageously employed instead of common water in a second, or any future distillation of the same subject.

After the distillation of one oil particular care should be had to clean the worm perfectly before it be employed in the distillation of a different substance. Some oils, those of wormwood and aniseed, for instance, adhere to it so tenaciously as not to be melted out by heat, or washed off by water; the best way of removing these is to run a little spirit of wine through it.

Volatile oils, after they are distilled, should be suffered to stand for some days in vessels loosely covered with paper, till they have lost their disagreeable odour and become limpid: they should then be placed in small bottles, which are to be kept quite full and closely stopped, in a cool place. With these precautions they will retain their virtues in perfection for many years.

Most of the oils mentioned above are prepared by our chemists in this country, and are easily procurable in a tolerable degree of perfection; but the oils from the more expensive spices, though still introduced among the preparations in the foreign pharmacopœias, are, when employed among us, usually imported from abroad.

These are frequently so much adulterated that it is not easy to meet with such as are at all fit for use: nor are these adulterations easily discoverable. The grosser abuses indeed may be readily detected. Thus, if the oil be mixed with alcohol, it will turn milky on the addition of water; if with expressed oils, alcohol will dissolve the volatile, and leave the other behind; if with oil of turpentine, on dipping a piece of paper in the mixture, and drying it with a gentle heat, the turpentine will be betrayed by its smell. But the more subtile artists have contrived other methods of sophistication, which elude all trials of this kind.

Some have looked upon the specific gravity of oils as a certain criterion of their genuineness. This, however, is not to be absolutely depended on; for the genuine oils, obtained from the same subjects, often differ in gravity as much as those drawn from different ones. Cinnamon and cloves, whose oils usually sink in water, yield, if slowly and carefully distilled, oils of great fragrancy, which are specifically lighter than the aqueous fluid employed in their distillation; whilst on the other hand the last runnings of some of the lighter oils prove sometimes so ponderous as to sink in water.

The external use of oil as a medicine is of very high antiquity. It was a part of the complicated system of bathing, as employed by the ancients, either as a remedy or for the preservation of health. Bathing was of peculiar importance, since they were unacquainted with linen; and their woollen garments were not very regularly or very delicately cleaned. The peculiar advantages of oily applications, independent of the friction employed, except in giving softness and flexibility to the limbs, are not easily ascertained. After exercise they were undoubtedly refreshing, and prevented stiffness; but as preservatives they seem to have been chiefly useful in preventing the too copious perspiration. When we compare all the directions for anointing, we can see no other point in which they meet; and this, in a climate so warm, after violent exercise, and the relaxation of the warm bath, must have been an object of importance. The use of oil as an external remedy was introduced by Prodicus, more probably Herodicus, the inventor of gymnastics; and in fevers it seems to be directed to the purposes mentioned. We have not the works of this ancient author, but find copious directions for its use in Pliny. It still seemed an appendage to the bath; for, in slow fever, the oil was used in cold water; in the cold fits, united with warm substances. In general it was supposed to strengthen and fortify the body against the access of cold.

Independent of its subsidiary aid to the balneum, it was used by the ancients, in many diseases, applied externally, and often rubbed along the spine; in palsies, in lethargy, in tetanus, in dropsy, and in ephidrosis. In hydrophobia the patients were thrown into the cold bath, and then into oil; in melancholia, into a bath of water and oil. It was supposed to allay irritation, and we still retain its use in burns, in bites of insects, in prurigo, &c.; but the ancients employed it to allay pain after severe operations, to soften the exuberant callus of bones, to remove the pain attending luxations or wounds. St. Luke, whom we may quote as an intelligent physician, describes the good Samaritan as pouring oil and wine into the wounds of him who fell among thieves (ch. x. 34).

When luxury increased this salutary custom was, as usual, abused, and the oil was combined with the most costly perfumes. The simplicity of ancient manners consigned without a blush the fatigued body of the traveller to the hands of a female; but this custom was afterwards extended, and the bath became the scene of wantonness and lust. In the progress of empire, of science, and the arts, eastward, the use of oil might have been carried into that

luxurious region, unless the same necessity which suggested it in Greece introduced it also into Hindostan; though the cotton dress would in a great degree render the use of the bath less necessary.

In the east the use of oil, however, seems of considerable antiquity; and, besides the more obvious effects of giving sleekness to the skin and flexibility to the limbs, it is supposed to assist the strength, increase the secretion of fat and other fluids, as well as to prolong life. The Hindoos use oil to cure fevers, epilepsy, mania, dropsy, worms, and cutaneous diseases; to relieve pains from bruises, and the colic; to prevent bad effects from the bites of mad animals and of serpents.

Modern practice continues the application of oil to allay irritation, particularly the pains felt in old fractures or wounds on the change of weather, as advised by Rosenstein; and in irritations of the genital organs, as recommended by Hufeland.

Oil was used externally by the ancients in low fevers, and the practice continued in Egypt to the time of Prosper Alpinus. On this foundation it may have been recommended in the plague, in which it has been said to be of essential use. Its advantages, however, arise not from the oil, but from the friction; for, unless continued so as to excite perspiration, it is of little utility. In dropsies also the oil seems only to assist the friction, by preventing the excoriation which might otherwise soon occur. In tetanus, if ever useful, it is also perhaps in consequence of the friction and the perspiration excited by means of the friction.

In the bites of insects it seems to relieve pain, but in those of serpents Fontana found it inefficacious; nor are the experiments of Mr. Baldwin on its effects in the bites of scorpions, or rats, unexceptionable. In hydrophobia it has been recommended on the authority of an ancient Greek manuscript; and, though we have received accounts of cases in which it seemed to relieve the spasms, it has not been found to cure the disease.

That oil may be useful in securing a person from contagion appears from evidence apparently more decisive. From very different sources we find that oil porters, oil sellers, tallow-chandlers, and tanners, are usually exempt from the plague and the worst epidemics.

Volatile oils, medicinally considered, agree in the general qualities of pungency and heat; in particular virtues they differ as much as the subjects from which they are obtained, the oil being the direct principle in which the virtues, or at least a considerable part of the virtues, of the several subjects reside. Thus the carminative virtue of the warm seeds, the dieretic of juniper berries, the emmenagogue of savine, the nervine of rosemary, the stomachic of mint, the cordial of aromatics, &c. are supposed to be concentrated in their oils.

There is another remarkable difference in volatile oils, the foundation of which is less obvious—that of the degree of their pungency and heat. These are by no means in proportion, as might be expected, to those of the subject they were drawn from. The oil of cinnamon, for instance, is excessively pungent and fiery; in its undiluted state it is almost caustic; whereas cloves, a spice which, in substance, is far more pungent than the other, yields an oil which is much less so. This difference seems to depend partly upon the quantity of oil afforded, cinnamon yielding much less than cloves, and consequently having its active matter concentrated into a smaller volume, partly upon a difference in the nature of the active parts themselves; for though volatile oils contain always the specific odour and flavour of their subjects, whether grateful or ungrateful, they do not always contain the whole pungency: this resides frequently in a more fixed matter, and does not rise with the oil. After the distillation of cloves, pepper, and some other spices, a part of their pungency is found to remain behind; a simple tincture of them in alcohol is even more pungent than their pure essential oils.

The more grateful oils are frequently made use of for reconciling to the stomach medicines of themselves disgustful. It has been customary to employ them as correctors for the resinous purgatives; a use to which they do not seem to be well adapted. All the service they can here be of is to make the resin sit more easily at first on the stomach; far from abating the irritating quality upon which the violence of its operations depends, these pungent oils superadd a fresh stimulus.

Volatile oils are never given alone, on account of their extreme heat and pungency; which in some is so great that a single drop let fall upon the tongue produces a gangrenous eschar. They are readily imbibed by a piece of dry sugar, and in this form may be conveniently exhibited. Ground with eight or ten times their weight of sugar, they become soluble in aqueous liquors, and thus may be diluted to any assigned degree. Mucilages also render them miscible with water into a uniform milky liquor. They dissolve likewise in alcohol; the more fragrant in an equal weight, and almost all of them in less than four times their own weight. These solutions may be either taken on sugar, or mixed with syrups, or the like. On mixing them with water, the liquor grows milky, and the oil separates.

The more pungent oils are employed externally against paralytic complaints, numbness, pains, and aches, cold tumours, and in other cases where particular parts require to be heated or stimulated. The toothache is sometimes relieved by a drop of these almost caustic oils, received on cotton, and cautiously introduced into the hollow tooth.

Oil of Vitriol. The old and erroneous name for Sulphuric Acid, which see.

Olefiant Gas, was discovered at Haarlem, in 1796, by the associated Dutch chemists, and received its present name from its property of giving rise to a substance resembling oil, when mingled with chlorine (*oleum fio*). It is sometimes called *bi-carbureted*, or *per-carbureted hydrogen*. It is prepared by mixing in a capacious retort, six measures of strong alcohol with sixteen of concentrated sulphuric acid, or one measure of common alcohol and three of ordinary oil of vitriol or weak sulphuric acid, and heating the mixture over an argand lamp. The acid soon acts upon the alcohol; effervescence ensues, and olefiant gas passes over. At the commencement of the process, the olefiant gas is mixed with a little ether; but in a short time the solution becomes dark, the formation of ether declines, and the odour of sulphurous acid begins to be perceptible; and towards the close of the operation, though olefiant gas is still the chief product, sulphurous acid is freely disengaged, some carbonic acid is formed, and charcoal in large quantities deposited. The olefiant gas is collected

over water or mercury. The greater part of the ether condenses spontaneously; and, the sulphurous and carbonic acids may be separated by washing the gas with lime-water or potash. The olefiant gas, in this process, is derived solely from the alcohol; and its production is owing to the strong affinity of sulphuric acid for water. Alcohol is composed of carbon, hydrogen and oxygen; and from the proportion of its elements it is inferred to be a compound of eight parts, or one equivalent of oxygen gas united with one equivalent, or nine parts of water. It is only necessary, therefore, to obtain olefiant gas, to deprive alcohol of the water which is essential to its constitution; and this is effected by sulphuric acid.

Olefiant gas is a colourless, elastic fluid, which has no taste, and scarcely any odour when pure. It extinguishes flame, is unable to support the respiration of animals, and is set on fire when a lighted candle is presented to it, burning slowly, with a dense white light. With a proper quantity of oxygen gas, it forms a mixture which may be kindled by flame or the electric spark, and which explodes with great violence. On conducting this experiment with care, it is found that, for each measure of olefiant gas, precisely three of oxygen are required, when the mixture wholly disappears, giving rise to a deposition of water and two measures of carbonic acid. Olefiant gas, by weight, consists of

Carbon, ...	25.418
Hydrogen, ...	4.236

When olefiant gas is mingled with chlorine in the proportion of one measure of the former to two of the latter, they form a mixture which takes fire on the approach of flame, and which burns rapidly, with the formation of muriatic acid gas, and deposition of a large quantity of charcoal. But if the gases are allowed to remain at rest after being mixed together, a very different action ensues. The chlorine, instead of decomposing the olefiant gas, enters into direct combination with it, and a yellow liquid, like oil, is generated. This substance is sometimes called *chloric ether*; but the term *hydro-carburet of chlorine*, as indicative of its composition, is more appropriate. To obtain it pure, and in a dry state, it should be well washed with water, and then distilled from chloride of calcium. As thus purified, it is a colourless, volatile liquid, of a peculiar sweetish taste, and ethereal odour. Specific gravity, 1.2201. It boils at 152° Fahr., and may be distilled without change. Its composition is

Chlorine, . . .	2.5	36 one proportion;
Olefiant gas, . .	0.9722	14 one proportion.
	3.4722	50

From an observation made by professor Silliman, that the chloric ether is readily soluble in alcohol, imparting to it its peculiar sweet taste, and forming with it a grateful diffusive stimulant. Mr. Guthrie, an American chemist, was led to attempt the manufacture of this etherized spirit in a more economical way, in which he fully succeeded. The following is his process :—Into a clean copper still, put three pounds of chloride of lime and two gallons of alcohol, of specific gravity .844, and distil. Watch the process, and when the product ceases to come highly sweet and aromatic, remove and cork it up closely in glass vessels. The remainder of the spirit should be distilled off for a new operation. The quantity of ethereal spirit afforded is one gallon. So far as the effects of this new stimulant have been tried, it is found to be singularly grateful, both to the palate and stomach, producing promptly a lively flow of animal spirits, and leaving, after its operation, little of that depression consequent to the use of ardent spirit.

Olefiant gas unites with iodine, by exposing it to the vapour of iodine in the direct rays of the sun. The *hydro-carburet* of *iodine* thus formed is a solid, white, crystalline body, which has a sweet taste and aromatic odour, It consists of

Iodine, ...	124, or one proportion;
Olefiant gas	14, or one proportion.

A *hydro-carburet* of *bromine* is also formed by adding one part of hydro-carburet of iodine to two parts of bromine, contained in a glass tube. Instantaneous re-action ensues, attended with disengagement of caloric and a hissing noise; and two compounds, the bromuret of iodine and a liquid hydro-carburet of bromine, are generated. The latter, after being washed with a solution of potash, is colourless, heavier than water, very volatile, of a penetrating ethereal odour, and an exceedingly sweet taste, which it imparts to water. This compound is also formed by letting a drop of bromia fall into a flask full of olefiant gas.

Oleic Acid.—When potash and hog's lard are saponified, one portion of the alkali separates in the form of a pearly-looking solid, while the fluid fat remains in solution, combined with the potash. When the alkali is separated by tartaric acid, the oily principle of fat is obtained, which is purified by saponifying it again and again, recovering two or three times, by which means the whole of the margarine is separated. As this oil has the property of saturating bases, and forming neutral compounds, it is called an acid. It is an oily fluid, without taste and smell; specific gravity 0.914. 100 of the oleic acid saturate 16.58 of potash, 10.11 of soda, 7.52 of magnesia, 14.83 of zinc, and 13.93 of peroxide of copper.

Olives. This fruit is in its natural state bitter, acid, and exceedingly disagreeable; though its taste is much improved when pickled, as we receive it from abroad, particularly the smaller kind, or Lucca olives. Those of Florence are esteemed excellent; but on account of the abundance of oil they contain, they are not adapted to delicate stomachs, and are pernicious, especially when eaten as a dessert, after a heavy dinner. Though pickled olives are grateful to the stomach, and are supposed to promote appetite and digestion, the ripe ones are more eaten among the Greeks, forming a considerable part of their food, especially in Lent. There are three kinds of olives frequently sold, different in size and quality; namely, those of Verona, those of Spain, and those of the south of France.

Olla Podrida; a favourite dish of the Spaniards, consisting of several kinds of meat cut up and stewed together. The same name is also given to a vase of odoriferous flowers and herbs. It is often used, metaphorically, to denote a medley.

Omnium; a term in use among stock-brokers and speculators in the funds, to express the whole of the articles which the subscribers to a loan receive from government. Thus, if the subscribers, according to their agreement with government, are to have, for every hundred pounds advanced, a certain sum in

three per cent. consols, a further sum in four per cents., and a proportion of the long annuities, the blank receipts which they receive for making the instalments on the several articles, are, when disposed of independently of each other, as the three per cent. consols only, called *scrip* (a contraction of *subscriptions*); when the receipts are sold together as originally received, they are usually called *omnium*. As the omnium of every loan is the subject of extensive speculations, it generally is liable to considerable variations with respect to its current price, sometimes selling at a high premium, at other times at a discount, according to the circumstances which take place between the agreement for the loan and the day fixed for paying the last instalment.

Opera. The opera is a musical drama. The music makes an essential part of it; and in this it is distinguished from other dramas accompanied by music. Song and music may be said to be the poetry of the opera, and, though the opera remains a drama, and never ought to lose this character, yet, as music is lyrical, the opera must be principally directed to the expression of feelings and passions. Comparatively little display of character and action can be expected from it. An opera, like every work of art, must bear the stamp of unity: one character must prevail through the whole, as the soleman and grave in Mozart's Magic Flute (though there are *naïf* passages interspersed in it), or the glowing, vivid colouring of Figaro, or the heroic elevation of Gluck's *Alceste*. It is further necessary to give individuality of character by means of the music, and the lyrical monologues (airs, *cavatine*, *ariosos*) and dialogues (*duettos*, *terzette*, &c.) must alternate in pleasing variety. But our limits do not allow us to give a description of the various parts requisite to these exquisite productions.

According as the serious or the comic character prevails in the opera, it is termed *opera seria* or *opera buffa*. There is also a style—*mezzo stilo*—between both, the limits of which it is, of course, impossible to define. *Grand opera* is the name given to that kind which is confined to music and song. The *recitativo* is an essential part of this. By *operetta* is understood a short musical drama of a light character. The Italians have a species of musical dramas called *intermezzo*. The French *vaudeville* belongs to this species of compositions, but not the German melodrama, in which music, indeed, is introduced either by itself, or in connection with the dialogue, but no singing takes place.

Origin of the Italian Opera.—About the year 1594, three young noblemen of Florence, who were attached to each other by a similarity of tastes and pursuits, and a love of poetry and music, conceived the idea of reviving the chanted declamation of the Greek tragedy: they induced the poet Rinuccini to write a drama on the story of Daphne, which was set to music by Peri, the most celebrated musician of the age, assisted by count Glacomo Corsi, who, though only an amateur, was also, for the period, a good musician: the piece, like the Mask of Comus, was privately represented in the palace of Corsi. The interlocutors, or singers, were the author and his friends; and the orchestra of his first opera consisted but of four instruments, viz. a harpischord, a harp, a *viol di gamba*, and lute. There was no attempt at airs; and the *recitative*—if such it could be called—was merely a kind of measured intonation, which would appear to us insufferably languid and monotonous; yet it caused, at the time, an extraordinary sensation, and was frequently repeated. Four years afterwards, the first public opera, entitled *Euridice*, written by the same poet, and set by the same musician, was represented at the theatre of Florence, in honour of the marriage of Mary de' Medici with Henry the Fourth of France. On this occasion, the introduction of Anacreontic stanzas, set to music, and a chorus at the end of each act, were the first imperfect indications of the airs and choruses of the modern opera. Monteverde, a Milanese musician, improved the recitative, by giving it more flow and expression; he set the opera of Ariadne, by Rinuccini, for the court of Mantua; and in the opera of Glasone, set by Cavili and Cicoguini, for the Venetians (1649), occur the first *airs* connected in sentiment and spirit with the dialogue. According to another account of the origin of the opera, John Sulpitious, about 1486, exhibited short dramas, accompanied with music, in the market-place at Rome, and also before the pope and some cardinals.

The commencement of the *opera seria* at Rome reminds us of the waggon of Thespis and his lees-besmeared company of strollers. The first performance of this kind, consisting of scenes in recitative and airs, was exhibited in a cart during the carnival of 1606, by the musician Quagliata and four or five of his friends. The first regular serious opera performed at Naples was in 1615: it was entitled *Amor non ha Legge*. During the next half century, the opera not only did not improve, but it degenerated: it became in Italy what it was in France during the last century—a grand spectacle addressed to the eye, in which the poetry and music were the last things considered, while the scenery, méchanical illusions, and pantomime, were on the most splendid scale. As Goldoni said long afterwards of the grand opera at Paris, *C'était le paradis des yeux et l'enfer des oreilles.*

The first *opera buffa* is said to have been represented at Venice in 1624, where also the first stage for operas was erected (in 1637). In 1646, the opera was transplanted to France by Cardinal Mazarin. In Germany, carnival plays, in which the performance consisted of singing, existed even in the times of Hans Sachs, who died in 1567. Opitz and others imitated the Italian pieces; but the first German original opera is said to have been Adam and Eve, played at Hamburgh, in 1678. Some consider The Devil let loose the first comic opera in Germany. In Sweden, the first Swedish original opera was performed in 1774. The Italian opera was introduced into England in the seventeenth century. Handel then effected a revolution here, which, however, did not exert a permanent influence on the English opera. The Italian opera did not penetrate into Spain. until the second half of the eighteenth century. The Italians draw the line between the *opera seria* and *opera buffa* much more distinctly than the Germans, so that the Italian *opera seria* appears almost insipid to a German; the *buffa*, on the contrary, is quite grotesque and quite national, and produces a lively effect when played by Italians. The compositions of Rosini are now considered as master-pieces in the modern Italian school: and Weber, that of Germany.

Ophthalmia; an inflammation of the mucous membrane which covers the globe of the eye and of the correspondent surface of the eyelids. It differs very much in its exciting causes. Residence in damp or sandy countries, exposure to the sun, and sudden

changes of weather, are among the most usual causes. Its characteristic marks are pain and redness. Ophthalmia is either *acute* or *chronic*; the one arising from an excess of stimulus and re-action of the living solid, the other connected with debility which is generally limited to the vessels of the parts affected, but sometimes extends to the whole system.

The presence of acute ophthalmia, in a mild degree, may be inferred from the suddenness of its occurrence, the mildness of its attack, and the *absence* of any *previous* disease, local or constitutional, such as erysipelas, syphilis, scrofula, rheumatism, or gout. If inflammation came on suddenly a sensation is felt that suggests the idea of sand being between the lid and the eye-ball, a profuse discharge of tears; if these symptoms be increased by exposure of the eye to the rays of light, solar or artificial; if there be heat and redness of the eye itself, the nature of the case is evident, and it demands the immediate application of leeches, which, in young children, should be employed with great caution, and in small numbers (one to each lid); in adults, from two to eight, or ten, may be applied, according to the severity of the symptoms: it will be well to apply two or three on the upper lid of the affected organ, and four to the lower lid; some should also be applied to the temple of the affected side. After the application of the leeches, apply a blister behind one or both ears. A brisk purgative (if the patient be strong), containing calomel and rhubarb, should be immediately given, and be repeated in twenty-four hours. A mixture of one ounce of Epsom salts, two drachms of nitre, and one ounce of antimonial wine, with a pint of cinnamon water, should be prepared, and the patient, if an adult, should take, according to the vigour of his constitution, from one tablespoonful to one wine glassful, every three, or four, or five hours. If a young person, of course the dose and frequency of taking must be diminished and regulated according to circumstances. The diet should be mild, and without meat and fermented liquors. The eyelids and part of the forehead should be kept constantly covered with lint dipped in goulard-water. These measures will generally abate the acute inflammation in twenty-four or thirty-six hours; after which time the treatment may be moderated, and the mixture taken less frequently. When the pain is much diminished, the heat and swelling less, and the eye is more tolerant of light, the cold lotion may be omitted, and a green shade substituted; the eye often bathed with cold spring water; and once or twice a day the following lotion to be used by means of a glass eye-cup. Sulphate of zinc, five grains; rose-water, four ounces: after using this for several days, the strength of this lotion may be doubled.

When the acute ophthalmia changes into the chronic one, attended with local weakness, it is highly important, in the treatment, to substitute for topical emollient, relaxing applications, such as partake of an astringent, corroborant quality. That chronic ophthalmia may depend upon a morbid irritability of the eye is evinced, not only from its resisting topical astringents and corroborants, to which the disease from simple relaxation and weakness yields, but from its being exasperated by them, and even by cold water. The patient complains of a sense of weight in the upper eyelid, and restraint in opening it; the conjunctiva has a yellowish cast, and when exposed to the damp cold air, or a brilliant light, or when a patient studies by candle-light, its vessels become filled with blood. If in combination with such symptoms, the habit of body be weak and irritable; subject to spasms; hypochondriasis, &c., then it is manifest, that the chronic ophthalmia is connected with a general impairment of the nervous system.

When the chronic ophthalmia depends upon preternatural irritability, the internal exhibition of bark with valerian is proper; animal food of easy digestion; gelatinous and farinaceous broths; wine in moderation; gentle exercise; living in salubrious and mild situations; are all severally productive of benefit. Externally, the applications should be of the sedative and corroborant kind; such as aromatic spirituous vapours applied to the eye through a funnel, for half an hour, three or four times a day; and the eyebrows and eyelids may also be rubbed with a liniment of camphor. Patients, both during the treatment and after the cure, must refrain from straining the eye, and, immediately the least uneasiness is felt, must desist from exercising it. When they write, or read, it should constantly be in a steady uniform light, and too little, as well as too much, aggravate the disease. Having once begun to use spectacles, they should never study, or survey minute objects, without them.

Opium; the inspissated juice of a species of poppy, a native originally of the East, but naturalized throughout the greatest part of Europe. The capsules contain a prodigious number of seeds. It is found in most gardens as an ornamental plant, and is, besides, cultivated extensively in many parts of Europe, but only for the sake of the oil which is obtained from the seeds. It is from the East, from the different parts of the Turkish empire, and from Hindoostan, that the opium of commerce is chiefly procured.

In many provinces of Asia they sow the white poppy (for this is the variety from which the true opium is procured) as we sow wheat. As soon as the heads appear, a slight incision is made in them, and some drops of a milky fluid exude, which are suffered to dry, and then collected. Tournefort tells us, that the greatest quantity of opium is made by bruising and pressing the heads; but Kæmpfer and Belon, though they speak of three kinds of opium, describe each as produced by incision and exudation only. In Persia, the opium is collected in summer, when the heads are nearly ripe; and these are wounded on one side by a knife, which makes five incisions at once. The next morning the inspissated juice is collected with a spatula. The operation is then repeated on the other side of the heads, but the first tears, styled *gobaar*, are preferred: these are whitish, or of a light yellow, but become brown in the sun, or when too much dried. The second tears are darker, and less efficacious; those of the third operation, black and inefficacious.

When the opium is collected, it is beat up with a little water or honey, till it has the consistency of pitch. It is then rolled into cylinders, and, in this state, offered for sale. If small quantities are wanted, they are cut off with scissars. Sometimes the honey is in so large a proportion as to prevent its drying, and to soften its bitterness. The most remarkable preparation of opium in the East, is uniting it with nutmeg, cardamoms, canella, and mace. It is called *philonia*, and is the philonum of the Persians, sup-

posed to strengthen the heart and the brain. Others add only saffron and ambergris; and almost every one varies the additions according to his fancy. A celebrated liquor, called *Cocomar*, is mentioned by Kæmpfer, which is an infusion or a decoction of the leaves, sometimes of the heads, adding various ingredients to please the palate. Another preparation to produce a temporary intoxication is called an electuary, and often employed in the East.

Olivier, in his travels into Asia, saw the plantations of poppies on a large scale, chiefly in the vicinity of a village called Affiom Kara-Hissar (the black castle of opium). The poppy is sown in autumn, transplanted in spring, and the harvest is collected about July.

The preparation of opium in Britain has long been a desideratum. Premiums have been offered by the Society of Arts, and more recently by the Caledonian Horticultural Society. Specimens of British opium have been produced, and proved to be in no degree inferior to the best foreign opium: but it has not yet been ascertained whether this valuable drug can be cultivated on the large scale with profit to the grower. The earliest experiments were conducted according to the eastern mode. But to this mode of cultivation the temperature, winds, and rain of this climate, have hitherto been justly considered as great obstacles. Of these the temperature may be held as the least objectionable; for the large white poppy, from which foreign opium is obtained, comes to maturity in our climate. But it is further objected that the high winds beat down the plants, and the rains wash off the opium, before it can be collected, when the eastern mode of gathering it is practised. It has therefore been proposed to cultivate the garden poppy of this country, because it is not so liable to be damaged by wind as the large white poppy.

It is our present object to describe a method by which these obstacles have been completely removed, and to demonstrate, from the result of experiment, that opium, superior in quality to the best Turkey opium, can be procured in Britain in sufficient quantity, not only for home consumption, but also for exportation.

As the method of gathering opium about to be described differs materially from any other previously in use, it may be proper to observe that Mr. Ball, who obtained a premium of fifty guineas from the Society of Arts, collected his opium according to the Bengal method, which is accurately described by Mr. Kerr, who was an ocular witness, and by Mr. W. Davis, whose accounts agree with that given by Kæmpferius respecting the mode of collecting opium in Persia. The seeds, according to Mr. Kerr, are sown in quadrangular areas, the intervals of which are formed into aqueducts for conveying water into each area. The plants are allowed to grow six or eight inches from each other, and are plentifully supplied with water till they are six or eight inches high, when a nutrition compost of dung, ashes, and nitrous earth, is laid over the areas. A little before the flowers appear, they are again well watered, till the capsules are half grown, when the watering is stopped, and they begin to collect the opium. This they effect by making, at sunset, two longitudinal incisions from below upwards, without penetrating the cavity, with an instrument that has two points as fine and as sharp as a lancet. The incisions are repeated every evening, until each capsule has received six or eight wounds, and they are then allowed to ripen their seeds. The juice which exudes is collected in the morning, and being inspissated to a proper consistence, by working it in an earthen pot in the sun's heat, it is formed into cakes for sale. In this manner Mr. Ball collected four ounces of opium from one fall and twenty-eight square yards of ground, which is at the rate of 22 lbs. 8 oz. per acre.

It is probable that Mr. Thomas Jones, who was a candidate for the premium offered by the Society of Arts, was misled by the speculations of Mr. Ball. Mr. Jones collected only 21lbs. 7 oz. of opium from five acres and upwards of poppies, and obtained the premium of fifty guineas for the largest specimen. He collected his opium according to the Bengal method; but some of his poppies, he says, became stunted, and others were entirely destroyed by remarkably dry weather, which continued six weeks from the beginning of May. This may be considered as the reason why he obtained so little from five acres. In another place he says that the largest quantity which his man, seven children, and himself, were able to procure in one morning, from five to nine o'clock, was one pound and a half. This happened when the dew was remarkably great, and succeeded one of the warmest days of the summer. And, as he admits in another place that the opium (which appeared upon the heads in a soft ash-coloured substance), when first collected, is, from its union with the dew, much too soft to be formed into a proper consistence, making a proper allowance for the evaporation of its watery part, it may be concluded that he gathered only in one morning, after a warm day, in the same ratio that they gather opium in the East Indies. They have no rain in India during the season of gathering opium, and Mr. Kerr says that there one acre of poppies yields 60 lbs. of opium.

Dr. Howison, who was some time inspector of opium in Bengal, gave an account of the result of his experiments for making opium in this country. Although he was not the first who collected the milky juice of the poppy in a fluid state, it is supposed he is the first who, in this country, has given the preference to that mode. Dr. Alston collected the milky juice in the fluid state according to Dioscorides, and also in the Persian way described by Kæmpferius, from several varieties of the poppy. He also collected the true tear, as he calls it, by cutting off the star of several heads, bending them down, and suffering the milk to drop into a tea-cup; yet he says that he collected most by the Persian way.

The instrument used by Dr. Howison for wounding the poppy-heads consisted of a brass ring, mad to fit the middle finger of the operator, in which is fixed a wheel set with lancets, which, when put in motion by drawing the hand along the poppy head, makes with great expedition whatever number of perforations are wanted, each giving out its distinct drop of milk, by which a great surface is affor ed, both for support and evaporation, and to prevent the flowing milk from running upon the ground, *the unavoidable consequence of the method formerly in use.* And for gathering the opium he employed a ti flask, flattened at the mouth about half an inch, with which he *scraped* off the opium. By means of these instruments, Dr. Howison obtained a cake of opium that weighed 8½ oz., and which was collected from a field of poppies measuring about five falls, which is at the rate of 17 lbs. weight of opium per acre.

Dr. Howison's puncturing instrument and collecting flask may certainly be considered as a material improvement upon the Hindoo instruments, and he found that they answered his purpose to a certain extent in gathering opium from the garden poppy. But, when the unevenness upon the surface of the capsules of the white poppy is considered, it will be found impossible to adapt the mouth of the flask so as to collect the whole of the juice without materially injuring the capsule, and much of the juice would still remain in the interstices of the ridges, which are for the most part found upon the capsules of the white poppy. Besides, the juice very soon acquires a ropiness, and adheres to the mouth of the flask, which must interrupt the gathering, and there is a chance of the juice being spilt by having the flask suspended to the body of the gatherer.

Dr. Howison has stated several objections to the cultivation of the large white poppy in this country, and has given the preference to the double red garden poppy and its varieties. He says that the white poppy, from its large head and very considerable height, is of all others the most liable to be hurt by winds; and unless they be cultivated in a sheltered situation, few will be found standing when the season for gathering the opium arrives. But, independent of this, he says that it never arrives at such perfection in this climate as to yield milk of proper consistence for making good opium, and that the few that do come to afford milk continue in that state only for a day, and any attempt to bleed them a little sooner or later would be without success.

Mr. Kerr, however, informs us that the large white poppy grows in Britain, without care, to be a much statelier plant than it does in India with the utmost art; and Dr. Alston, after commenting upon the controversy whether opium is obtained from the white poppy or from the black, concludes that as a medicine it is of no consequence whether it be taken from the one or from the other. Dr. Crump also observes that the white variety is to be preferred, as affording opium in greater quantity than any of the rest; and there can be no doubt that this poppy yields the largest and most juicy heads.

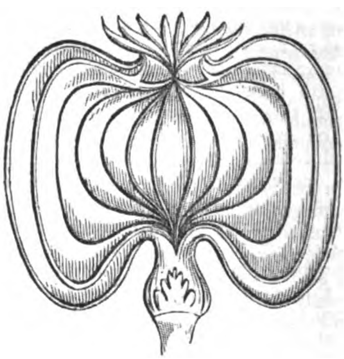
Dr. Howison has stated that 200,000 lbs. of opium are made annually in Bengal; and that, notwithstanding all the care that is taken in collecting it, one-third of the crop is lost: but there is reason to believe that the waste is much greater than he supposes; for, in whatever way the incisions are made, the milky juice instantly flows in a wasteful stream, and, by running upon the ground or upon the leaves, one-third of the crop at least must be lost before the gathering commences in the morning. "In this climate, "he remarks," where the serenest day is often followed by a night of deluging rains, the adoption of the Bengal method would be worse than trusting our fortune to the chance of a lottery."

Although Dr. Howison was convinced that the juice of the poppy undergoes no change in its properties by exposure to the air, further than acquiring a greater consistence from the evaporation of its watery part, he states in another place that in Bengal, where there is no rain during the opium gathering season, the custom of allowing the milk to thicken, by remaining for some time on the capsule, is highly judicious; while, in another part of his account, he admits that that custom is the only reason why they lose one-third of their crop.

Supposing that if 200,000 lbs. of opium give the East India Company 100,000*l.* sterling annually, by Dr. Howison's account they thus lose more than 30,000*l.* But, were the loss to amount only to half that sum, sufficient importance, it is to be supposed, would be attached to the means by which such a saving could be effected.

Mr. Kerr states that there are about 600,000 lbs. of opium annually exported from the Ganges, independent of what is consumed in the interior. He also states that it is frequently mixed with cow-dung, the extract obtained by boiling the plants, and other additions, which are kept secret. It is, indeed, frequently so much adulterated that considerable quantities are burnt at Calcutta by order of the Government.

Mr. Young, in a valuable paper on the preparation of opium, thus describes his own experiments. To render his process intelligible it may, however, be advisable to give a section of the capsule, showing the relative situations of the seeds and external rind, from whence the narcotic principle is obtained:—



"In the summer of 1817, I cultivated a small field of poppies, containing about 20,000 plants of the papaver somniferum of Linnæus, out of which I selected two beds, measuring one fall and fourteen square yards, for the purpose of ascertaining what quantity of opium it would produce. I collected the opium from that part selected for the experiment myself, while the rest of the crop was gathered by the people I employed. I collected as much of the milky juice as was equal to one drachm of solid opium in the space of an hour; but, as my professional avocations prevented me from regularly superintending the people at work, they did not gather so much as I expected. I ascertained, however, that they could gather at the rate of one drachm in the hour.

"I had my poppies sown in three different ways. The first, broad-cast upon beds three feet wide, with an alley between, and thinned out to the distance of four and five inches when the plants were about two inches high above the ground. The second on beds three feet wide, in rows, six rows to a bed, and six inches between the plants. The third, on the spaces between rows of asparagus, two rows of poppies on each space, eight inches between each row, and six inches between the plants; two feet four inches between each double row of poppies occupied by the asparagus.

"The first produced only one capsule, the second two, and the third three capsules. Having ascer-

tained that the white poppy, when cultivated upon the wide drill plan that I have adopted, not only gives out more capsules, but much larger ones than when cultivated in the broad-cast way, or close rows; it is evident there must be a great saving of labour, for it will take as much time to gather the juice from a small head as it would do to collect three times the quantity from a large head.

"The plants between the asparagus rows, having more room to grow, had not only more capsules, but they were much larger than those sown broad-cast or in beds in close rows; and as early potatoes, cultivated in a piece of ground adjoining my crop, were sold for a high price before my plants began to flower, I proposed the following year to have, by this mode of culture, the same quantity of opium with a crop of early potatoes, as I obtained from an equal measurement of ground where there was nothing but poppies. Accordingly, in 1818, I selected a piece of ground in the highest state of cultivation, well manured with horse-dung, in which I planted early potatoes, in rows four feet wide. Furrows were first drawn; in these furrows the dung was laid; then the sets were dropped on the dung, about nine inches asunder, and covered by the hoe. The potatoes were planted the first week of February, and the poppies were sown about the middle of April, on the middle space between the potato rows, two rows of poppies on each space, and twelve inches between the rows. When the poppy plants were about two inches above the ground, they were at first thinned out by the hoe, and afterwards by the fingers, to the distance of eight inches between the plants.

"In this manner I raised a crop of early potatoes equal to 36 bolls per acre. Although the potatoes will be ready for immediate use before the gathering of opium commences, the whole crop will not be entirely ripe for lifting till after the opium is collected. The early potato gives out but a small stem, but where the soil is rich some of them may spread in the areas, yet they can be easily pushed over to one side, so as to allow the opium gatherers to walk along the areas without trampling upon them.

"The distance between the poppy plants being wider than last year, upon an average they produced four full-grown capsules each, and some of them produced seven or eight capsules; and I gathered this season at the rate of two drachms of solid opium in one hour, while, by the same method of gathering, I could not collect more than one drachm in the same time last year.

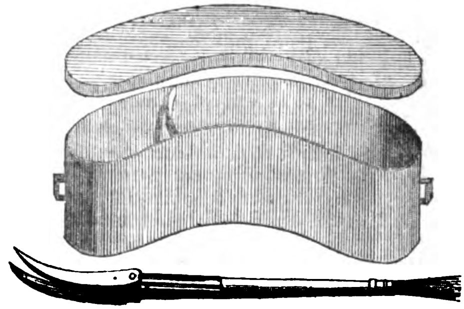
"Supposing one acre had been cultivated in the same manner as that piece of ground on which my experiment was made, the produce in that case would have been equal to 57 lbs., 9 oz. 4 drs., and 48 grs. of solid opium, which is just twice as much as I collected the year before. But the season of 1818 being so much more favourable than the preceding year will in a great measure account for the success of this experiment. Therefore the quantity of opium that may be collected depends greatly upon the season; yet the comparative view of the result of the experiment made in 1817, although the season was extremely unfavourable, is sufficient to prove that my method of extracting and gathering opium has a decided advantage over any other that has been recommended.

"As my poppies were sown about the middle of April, they were ready for bleeding about the middle of July.

"For making the incisions, I use a double-bladed convex-edged knife, having all the blade covered with sealing-wax, except so much of the cutting edge as is sufficient for wounding the external rind of the capsule, without penetrating its cavity, and with which I make one or more double incisions, according to the size of the head, at first longitudinally, and afterwards obliquely upwards from the stalk. This operation commences about a week after the flowers fall, when the capsules discovér to the pressure a proper degree of hardness.

"The instrument I used consisted of two convex-edged scalpels, the blades of which were covered with sealing-wax, except about one-sixteenth part of an inch of the edge, and, being wound round the handles with waxed thread, the two were fastened together with other thread twisted round them, and thus held at the distance of about half an inch between each blade."

We have preferred giving a description of Mr. Young's instrument in his own words, as they occur in the paper, but it may be proper to observe that the form he really recommends is shown in the engraving beneath. There is also a representation of the tin flask, with a bridge to remove the opium from the brush which is attached to the opposite end of the knife.



"When the capsule is sufficiently scarified in the manner described, I then cut off, with a sharp scalpel, the capitellum or star, with a thin slice of the external rind round it, and by this last incision I obtained more juice than from a scarification upon the side of the head.

"It is my method of gathering the milky juice of the poppy in the fluid state that differs materially from any other that has been used, and it is on that account that I have been more successful than any other that has tried the experiment.

"In my communication to Dr. Duncan, relative to lactucarium or lettuce-opium, published in the second edition of his *Observations on Pulmonary Consumption*, I proposed to gather the opium by means of a sponge. But, when I began to collect opium in that way, I soon found that it would not do; for, although the sponge removes the juice more effectually than the flask proposed by Dr. Howison, it cannot be again entirely expressed, because the sponge decomposes or separates the component principles of the milky juice, and the resinous part adheres to the sponge and soon clogs its pores. I therefore adopted the use of a small common hair brush used by painters, and known to the trade by the name of a sash-tool, which answers the purpose most completely, and with which I gathered the

milky juice, even though some of the plants were laid by wind and rain, as well as if they had been standing erect. I used a camel-hair brush, but found the same objection to it as to the sponge. The common sash-tool, rounded a little at the point, without being ground, is that which I prefer.

"For the sake of experiment, I exposed myself one morning to a shower of rain for half an hour, while making the incisions and gathering the opium, and succeeded as well as when there was no rain.

"When the brush is sufficiently charged with juice, I scrape it off upon the edge of the tin flask, fastened to the breast of the gatherer, and capable of holding more than a day's gathering.

"The gatherers follow the bleeders immediately. One bleeder will occupy two gatherers, and if he be very expert he may keep three gatherers constantly employed. When I performed both operations myself, I held the knife between the thumb, fore and middle fingers, and the brush between the ring and little fingers of the right hand, while I held the poppy by the stalk with the left hand.

"The juice is afterwards formed into cakes or balls by spontaneous evaporation in shallow earthen dishes, placed in a close room, stirring it occasionally during the evaporation of its watery part, to be afterwards kept in bladders.

"The operation for gathering cannot be repeated with advantage oftener than three times a week upon the same capsules; for no more juice will flow from one wound than what may be collected immediately, and a certain time must elapse before the plant forms more juice. But it is evident a number of hands may be kept constantly employed upon a large field, till the plants cease to give out juice.

"One acre will keep twelve gatherers and six cutters constantly employed for thirty days. That number can only gather a third part of an acre in one day, and by the time they have gone through the crop, the capsules at that place where they began to gather will be ready for the operation being repeated; so that, when the milky juice ceases to flow, five operations, as already described, will have been made upon each capsule.

"Supposing twelve gatherers to work ten hours in the day, and that each gathers two ounces and a half, or as much of the juice as will make that quantity of solid opium, in thirty days they will gather fifty-six pounds of opium from one acre.

"One acre of poppies, cultivated according to my method, will yield 1000 lbs. of seed, and this quantity of seed will give by expression 375 lbs. of oil."

Although the produce of such a crop has not yet been clearly ascertained upon a large scale, the following may be taken as the estimate of one acre, from what has actually been produced in Mr. Young's experiment.

Estimated value of the produce of one acre.

56 lbs. opium, at 36*s*.	£100	16	0
36 bolls early potatoes, at 24*s*. . .	43	4	0
250 lbs. of oil, cold drawn, at 1*s*. 6*d*. .	18	15	0
125 lbs. ditto warm, at 6*d*. . . .	3	2	6
500 oil-cakes, at 18*s*. per 100 . .	4	10	0
	£170	7	6
Expenses,	60	0	0
Total of profit,	£110	7	6

Or it may be taken this way.

56 lbs. opium, at 17*s*. 6*d*. . . .	£49	0	0
36 bolls of potatoes, at 24*s*. . .	43	4	0
250 lbs. of oil, cold drawn, at 1*s*. 6*d*. .	18	15	0
125 lbs. ditto warm, at 6*d*. . .	3	2	6
500 oil-cakes, at 18*s*. per 100 . .	4	10	0
	£118	11	6
Expenses,	60	0	0
Profit,	£58	11	6

A few facts illustrative of the chemical and medicinal properties of opium must conclude our article. Opium contains acidulous meconate of morphia, extractive matter, mucilage, fecula, resin, fixed oil, caoutchouc, a vegeto-animal substance, debris of vegetable fibres, occasionally a little sand, and small white pebbles, together with the white crystalline salt of opium, now known under the name of *narcotine*. If we treat opium first with abundance of ether, a tincture of a deep yellow shade is obtained, from which there gradually falls a powder, insoluble in water, alcohol, and ether, and, when distilled, it affords a considerable quantity of ammonia. The ethereous tincture, freed from this yellowish powder, yields, on evaporation, crystals impregnated with a viscid oil, among which small masses, of more consistence, are seen to float. These are caoutchouc, which may be separated from the oil by a fine tube. The oily liquid is to be decanted, in order to insulate the crystals, which are then treated with boiling alcohol. On cooling, this affords the narcotine, slightly impregnated with caoutchouc. From this a new solution frees them completely. Hence, by this process, are eliminated four different products: 1. a fixed oil; 2. caoutchouc; 3. a vegeto-animal substance; 4. narcotine. The opium, after being thus exhausted by ether, when dissolved in water, affords solutions equally acid as ordinary opium, and which comport themselves with magnesia or ammonia as if no ether had been applied to it. (See MORPHIA.) It is obvious, therefore, that the two crystalline bodies, narcotine and morphia, exist in opium quite independent of each other.

The external and internal effects of opium appear to be various in different constitutions, and in the same at different times. By some, when applied to the tongue, the nose, the eye, or any part deprived of skin, it has been said to stimulate and to induce in the eye in particular a slight degree of redness. But, if this effect do take place, it is at the utmost extremely inconsiderable, particularly when compared with the effect of a variety of other articles applied to the same organ; and there can be no doubt that in a very short time the sensibility of the part to which it is applied, even when there has not taken place the slightest mark of preceding stimulus or inflammation, is very considerably diminished. Some allege that when applied to the skin it allays pain and spasm, procures sleep, and produces all the other salutary or dangerous effects which result from its internal use; while others allege that thus applied it has little or no effect whatever.

It sometimes allays the pain from a carious tooth, by deadening the sensibility of the part, which is sufficient to prove that this is occasionally useful as a local remedy.

Opium, when taken into the stomach to such an

extent as to have any sensible effect, gives rise to a pleasant serenity of mind, in general proceeding to a certain degree of languor and drowsiness. The action of the sanguiferous system is diminished, the pulse becoming for the most part softer, fuller, and slower than it was before. There often takes place a swelling of the subcutaneous veins, and sweating; both probably the consequence of a diminution of resistance at the surface, from a diminution of muscular action; and accordingly opium diminishes those discharges which depend on muscular action, as is particularly exemplified in its effects on the digestive organs. Opium taken into the stomach in a larger dose gives rise to confusion of the head and vertigo. The power of all stimulating causes, of making impressions on the body, is diminished; and, even at times and in situtions when a person would naturally be awake, sleep is irresistibly induced. In still larger doses, it acts in the same manner as the narcotic poisons, giving rise not only to vertigo, headache, tremors, and delirium, but to convulsions also; and these terminate in a state of stupor, from which the person cannot be roused. This stupor is accompanied with slowness of the pulse, and with stertor in breathing, and the scene is terminated in death, attended with the same appearances as take place in apoplexy.

From these effects of opium in a state of health, it is not wonderful that recourse should have been had to it in disease, as mitigating pain, inducing sleep, allaying inordinate action, and diminishing morbid sensibility. That these effects do result from it is confirmed by the daily experience of every observer: and as answering one or other of these intentions, most, if not all, of the good consequences derived from it in actual practice are to be explained. If, therefore, by a sedative medicine, we mean an article capable of allaying, assuaging, mitigating, and composing, no substance can have a better title to the appellation of sedative than opium.

With regard to the dose, one grain is generally sufficient: maniacal persons, and those who labour under violent spasms, require oftentimes two, three, or more grains; but it is more advisable to repeat the dose at proper intervals than to enlarge it. By frequent use, much greater quantities may be borne: the Turks, who habituate themselves to opium as a succedaneum for spirituous liquors, are said to take commonly a drachm at a time.

Dr. Hancock has published a paper in a medical journal tending to show the importance of cold water affusion in cases of poisoning with opium. Dr. Hancock commences by observing that "the superior effects of general applications (or those acting through the medium of the whole dermoid system) over the use of inward remedies are exemplified in the decisive results of cold affusion in the high state of fevers, and in cases of over-doses of opium. When the torpor, congestion of brain, and insensibility, have occurred from an excessive dose of opium, when medicines cannot be swallowed (and where, if they could, they would be useless), it is surprising to see how the patient is roused and restored to sense and muscular motion, by dashing the naked body with cold water.

"This brings to mind an interesting and instructive case, which occurred in my practice four years ago, and called forth a combination of the two potent remedies under consideration. It was a case of lock-jaw, in a black man, named Dan, at Plantation Coffee Grove, Essequibo. The disease was violent; and very large doses of opium and camphor were administered, till at length, during my absence, the administration of these remedies was carried to such an extent as not only to remove all tetanic symptoms, but also to produce the most deadly insensibility and apoplectic stupor. He was so far exhausted that the cold affusion produced but a transient effect, although it roused him for a moment from the deepest lethargy. He was then rubbed over smartly with pepper, salt, and lime-juice, which caused no signs of sensation. Again, however, dashing the body with cold water, it had more effect; by repeating the friction, and the cold affusion alternately, he was successively more excited till able to swallow an emetic, which brought up much opium and camphor. He regained his senses, had no recurrence of the spasms, and has since been tolerably healthy."

It is much to be lamented that the directions we meet with in books, for counteracting the results of excessive doses of opium, refer in general only to the methods of removing opium from the stomach, whilst no efficient means are proposed for counteracting the deleterious effects of the poison already absorbed into the system. The stomach-pump is certainly an important instrument in those cases where the torpor and the insensibility which ensue prevent vomiting, but in such cases, unless speedily resorted to, it will seldom prove effectual, although the stomach be completely emptied, instances of which are of frequent occurrence.

It may here be observed that the same means have proved equally effectual in restoring persons in the most advanced state of inebriation from excessive drinking of spirituous liquors; and any person suffering in a morning from the effects of inordinate potations may prove the efficacy of this remedy by causing a pailful of cold water to be dashed over his head and naked body. There can be but little doubt that the same remedy might prove equally successful against the effects of all other narcotic poisons, as well as opium.

END OF VOL. I.
